The third voyage from Kamtschatka in 1762, and the most fortunate and most remarkable of the whole, was that of the Andrean and Natalia, which was fitted out by Terenty Tsebaeffskoi and Company, under the command of Stephen Glottof, an experienced and skilful seaman of Yarensk. This vessel sailed on the 1st October, with a crew of thirty-eight Russians and eight Kamtschadals. Having wintered at Copper Island, they set sail from thence on the 26th July 1763, and steered for the Fox Islands. In consequence of storms and contrary winds, they were thirty days on the voyage to Umnak, where they arrived on the 24th August, and, without dropping anchor, sailed farther in quest of new islands, of which they passed eight contiguous to each other, and separated by straits from 20 to 100 versts broad. Glottof, however, did not land until he reached the most eastward of these islands, called by the inhabitants Kadyak. Here, and in the neighbouring islands, they passed the winter, and collected a considerable quantity of furs; but as the conduct of the natives, at first decidedly hostile, was always suspicious, Glottof did not think it prudent to prolong his stay; and accordingly, having taken on board all the peltry and stores, he left Kadyak on the 24th May 1764, and sailed for Umnak, where he arrived on the 3d July. He remained here two years, sending out hunting parties through the islands of Umnak and Unalashka, and commenced his voyage homewards in the month of July 1766. In the month of August he arrived safe in Kamtschatka river with a rich cargo.

Voyage of Stephen Glottof, in the Andrean and Natalia.

Soloviof, to whose voyage we have already alluded, sailed from Kamtschatka on the 25th of Au-

Voyage of Soloviof in 1764.

* This was the fourth vessel which sailed in 1762; but, as the whole crew were massacred by the natives, we have no distinct account of the voyage.

Aleutian Islands.

gust 1764, in a ship called the Holy Apostles Peter and Paul, fitted out by Jacob Ulednikof and Company, merchants of Irkutsk. This vessel reached Unalashka on the 17th September, where Soloviof passed two winters; and having succeeded, notwithstanding the continual hostility of the natives, in collecting a considerable cargo of peltry, he returned to Kamtschatka in the month of July 1766.

Having thus traced an outline of the gradual progress of early discovery in this archipelago, it seems unnecessary to proceed with an enumeration of the subsequent voyages performed by private individuals. These were undertaken merely for commercial purposes; the accounts brought home by the adventurers were generally imperfect and incorrect; and rather tended to excite than to gratify the curiosity of those who might be desirous of obtaining more accurate and more ample information. We shall, therefore, now turn to the conduct of those expeditions, which were fitted out by the State for the express purpose of discovery.

Expedition of Capt. Krenitzin and Lieut. Levashef. 1768.

In the year 1768, Captain Krenitzin and Lieutenant Levashef sailed from the mouth of the Kamtschatka river, by order of the Empress Catharine, to examine the chain of Aleutian Islands. This commission they accordingly executed very carefully, having surveyed the whole of this archipelago, from Behring's Island to the promontory of Alaska; and, after spending the winter among the Fox Islands, they returned to Kamtschatka in the autumn of 1769.

Capt. Cook's last Voyage. 1778.

But our great navigator, Captain Cook, communicated more accurate scientific information respecting these islands, as well as the coasts of the two continents, than all the previous voyages of the Russian discoverers had afforded. During his third and last voyage, in the year 1778, he surveyed the eastern portion of this archipelago, accurately determined the positions of some of the most remarkable islands, and corrected many errors of former navigators.

Expedition under Capt. Billings. 1785.

In the year 1785, a fresh expedition was set on foot by the Russian government, the command of which was entrusted to Captain Billings, an English naval officer in the Russian service, who had accompanied Captain Cook in his last celebrated voyage to the Pacific Ocean. This expedition appears to have been suggested by Mr Coxe, who was at that time at St Petersburgh, and whose *Account of the Russian Discoveries between Asia and America*, had already attracted the attention of the Russian government. During this voyage, which was not completed until the year 1796, Captains Billings and Sarytschef explored the whole chain of the Aleutian islands, particularly that part of it which had been visited by Captain Cook, and some parts of the adjacent western coast of America. Ample details of the conduct of this expedition have been published in the narratives of Martin Sauer, who officiated as secretary to Captain Billings, and of Admiral Sarytschef.

Expedition from Cronstadt, to the north-west coast of America.

Some years after the termination of the expedition under Captain Billings, the attention of the Russian American Company was turned towards the best means of supplying their settlements on the north-west coast of America with provisions and stores of all kinds; and it was resolved to try whether the conveyance by sea would not answer the purpose better, than the long and tedious journey by land to Ochotsk. With the view of ascertaining the practicability of the project, Captain Krusenstern, an experienced Russian naval officer, who had served for a long period in the British Navy, suggested the plan of an expedition from Cronstadt, round Cape Horn, to the Aleutian Islands and the north-west coast of America. This plan was approved of by Count Romanzof, the Minister of Commerce, and Admiral Mordwinof, Minister of the Marine, and obtained the sanction of his Imperial Majesty. Two vessels, called by the Russians the Nadeshda and the Neva, were accordingly purchased in London for the voyage. The command of the expedition was intrusted to Captain Krusenstern, the original author of the plan; and Captain Lisiansky was appointed to the Neva. These two vessels accordingly sailed in company from Cronstadt, in the month of August 1803, and, after a short stay at Falmouth, proceeded to the Brazils; from whence they sailed round Cape Horn to the Sandwich Islands. Here they separated; the Nadeshda being ordered on a distinct mission to Japan and China; while Captain Lisiansky, in the Neva, proceeded to Kadyak and the American settlements. Of this voyage, very full and interesting accounts have been lately published by Captains Krusenstern and Lisiansky, and by Dr Langsdorff, who accompanied the expedition in the quality of physician.

Voyage of Captains Krusenstern and Lisiansky, 1803.

Enumeration and Description of the Aleutian Islands.

From the ample sources of information, to which we have alluded in the foregoing narrative, we shall now proceed to exhibit an enumeration and general description of the islands composing this singular chain, which appears to be a prolongation of either continent. We shall begin with the more westerly part of the chain, consisting of those islands which lie nearest to Kamtschatka, and proceed eastwards to the American promontory. The first is Commodore's or Behring's Island, situate (according to Cook's reckoning), in 55° of latitude, and 6° of longitude from the harbour of Petropaulowska in the bay of Awatska. It is from 70 to 80 versts long, and stretches from north-west to south-east. Ten leagues from the south-east point of this island, in the direction of east by south, or east-south-east, lies Mednoi Ostroff, or Copper Island, so called from large masses of native copper being found upon the beach. To the south-east of Copper Island lie three small islands, Attak, or Attoo, Semitshi, and Agattoo, called by the Russians *Plishnie Ostrova*, or the nearest Aleutian Islands. Of these Attak is the largest; it is nearly of the same shape as Behring's Island, but rather more extensive, stretching from west to east to the length of 18 leagues. These islands are situate between 54° and 55° of north latitude. Attak has two harbours, one of which lies on the southern coast. From the eastern extremity of the Aleutian Islands, properly so called, another group runs south-eastward, continuing the chain as far at the western extremity of the Fox Islands. These are called the Andreanofskie Islands; but we have less accurate information respecting this central part of

Aleutian Islands.

the chain, than regarding the eastern and western groups. They are said to lie within the 52d and 54th degree of north latitude, to be of inconsiderable extent or importance, and, therefore, seldom visited by recent navigators. The most remarkable are, Takavangha, which has in its centre, near the northern coast, a burning mountain; Kanaghi, or Kanaga, likewise with a high smoking mountain; Ayag, which has a number of good bays and anchoring-places; and Tshetchina, on which a high white mountain overtops the rest, which apparently is an extinct volcano, as there are still hot springs on this island. Atshak, or Atchka, and Amlac, are also usually reckoned among the number of the Andrenovian isles. The former greatly resembles Copper Island, and is provided with a commodious harbour.

By far the most important and best explored portion of this archipelago is the most easterly group, called by the Russians *Lyssie Ostrova*, or the Fox Islands. Of these islands the most considerable are, Umnak, Unalashka, or Oonalashka, and Unimak; the last of which is separated by a narrow strait from the promontory of Alaska. Beyond these, to the north-east, lies the large island of Kadyak, or Kodiak, which is generally included among the group called Schumagin's Islands.

The whole of the islands composing this chain are bare and mountainous; their coasts are rocky and surrounded by breakers, which renders the navigation of those seas exceedingly dangerous. The land rises immediately from the coasts to steep bald mountains, gradually ascending higher behind each other, and assuming the appearance of chains of mountains, with a direction lengthwise of the island. Springs take their rise at the bottom of the mountains, and either flow in broad and rapid streams into the neighbouring sea, or, collecting in the rocky vales and glens, form ample lakes, which send off their superfluous waters, by natural canals, into the adjacent bays. These islands bear evident marks of volcanic formation; and several of them have still active volcanoes, which continually emit smoke, and sometimes flames. No traces of metals have been discovered on these islands; but carneoles and sardonyxes are brought from thence. Their soil is said to be similar to that of Kamtschatka; and affords the same kinds of edible wild berries and roots; excepting some few vegetables which seem to be of foreign origin. No wood of any considerable growth has been perceived upon any of these islands, except a very small quantity on Unalashka. The land animals are bears, wolves, river-otters, river-beavers, and ermines. The sea-otter, so valuable on account of its skin, is frequently caught; but the number of these animals, it is believed, is much diminished of late. On the Fox Islands they have a great variety of foxes, black, grey, red, and brown. The sea abounds with all sorts of seals, dolphins, and whales; sea-lions and porpoises are rare, and sea-cows not at all to be seen. Salmon are caught in great abundance and variety; and halibut of an immense size are frequently taken. The winter upon these islands is tolerably mild, but the summer is equally short and unpleasant. The inhabitants are pretty numerous, and tributary to Russia, from whence vessels are sent out, and establishments formed upon these islands, on account of the very profitable chace of sea-otters and foxes.

Island of Unalashka.

Unalashka, one of the largest of the Fox Islands, was visited by Captain Cook during his last voyage, and seems to merit particular notice. This island stretches from north-east to south-west, and is from 70 to 80 versts in length, but of very unequal breadth. On the north and north-east side there are many bays and creeks, in some of which are very secure harbours for vessels. A part of the south-west shore consists of very high, steep, inaccessible cliffs; and another part has remained hitherto wholly unexplored. The whole island consists of a mass of rocks, covered only with a very thin coat of earth; the hills are of very unequal height, and are intersected by irregular vallies, the soil of which is commonly argillaceous, or an earth which appears washed down from the hills. In the lower vallies there is great abundance of grass, which would furnish very good food for cattle; indeed Captain Cook was of opinion that cattle might subsist at Unalashka all the year round, without being housed; and the soil, in many places, appeared capable of producing grain, roots, and vegetables. But the Russian traders, and the natives, seem satisfied with what nature brings forth. No wood grows on this and the neighbouring islands; only low bushes and shrubs of dwarf-birch, willow, and alder. For all the timber used for the purposes of building, &c. they are indebted to the sea, which wafts it to their shores from the adjacent continent of America. The inhabitants are rather low of stature, but plump and well shaped; with short necks, swarthy chubby faces, black eyes, small beards, and long, straight, black hair, which the men wear loose behind, and cut before, but the women tie up in a bunch. With regard to their character, Captain Cook describes them as, to all appearance, the most inoffensive people he ever met with, and perfect patterns of honesty. But, according to the accounts of the first discoverers, this does not seem to have been their original disposition; and recent travellers have observed, that although generally kind-hearted and peaceable, yet, when roused to anger, they become exceedingly malevolent, and indifferent to all danger, even to death itself.

Character of the Natives.

Dress.

The clothing of the men and women is nearly the same, and consists of a sort of frock or shirt, called *parka*, fastened round the neck with a broad stiff collar, and descending below the knee. These garments are made of the skins of seals, prepared in a manner peculiar to themselves, and sewed together very ingeniously. Though simple in their form, they are ornamented in a variety of ways; with glass beads; beaks of sea parrots; long white goat's hair, brought from Siberia, or small red feathers. Over the frock, the men sometimes bear a *kamleika*, or rain-garment. This is made of gut, which is water-proof; and has a hood to it, which draws over the head, and is tied under the chin. When on shore, the men wear boots, made of seal's skin; and they all have a kind of oval snouted cap, made of wood, with a rim to admit the head. These caps are dyed with green and other

Aleutian Islands.

colours, and are very fancifully ornamented with ivory figures, carved from the teeth of the sea-cow, with glass or amber beads, and with the bristles from the beard of the sea-lion. They make use of no paint; tatooing was formerly very much in use among them, particularly among the women; but their intercourse with the Russians has rather brought this practice into disrepute. Both men and women, particularly the latter, bore the under lip, and insert pieces of bone or other ornaments; but this practice has also decreased of late. The women, for the most part, go barefooted; they wear bracelets of glass beads just above the wrist and ankle-joints, and are very fond of rings upon their fingers.

Food.

The principal food of these islanders consists of fish, sea-animals, birds, roots and berries. They dry large quantities of fish in summer, which they lay up in small huts for winter use; and roots and berries are also preserved for the same time of scarcity. Among the fish, the most common and most abundant are several sorts of salmon, cod, herrings, and halibut. The last is the most esteemed, and is sometimes caught of an enormous size. The fat of the whale is also a favourite species of food; when it grows old and rancid, it serves to light and warm their houses. They eat almost every thing raw; but of late, they have learnt some simple modes of cookery from the Russians. Vegetable food does not appear to be held in much esteem by the Unalashkans. That sweet plant, the Siberian parsnip, (*Heracleum Sibericum)*, is but little eaten, any more than the bulb of the *Saranna*, or Kamtschadale lily. Berries of an eatable quality abound; such as bramble-berries, cran-berries, hurtle-berries, heath-berries, and several others. Of late, the Russians have begun to plant potatoes, which succeed extremely well, and are much liked by the people.

Habitations.

The habitations of the Unalashkans are holes dug in the earth, covered with a wooden roof, over which they throw grass and earth; so that a village has the appearance of an European church-yard full of graves. The entrance into these huts is from the roof; some of the largest, however, which are inhabited by the Russians, have a low door in the side. The light is also admitted by the roof, through an opening or window covered over with seal's entrails, or dried fish-skin. Several divisions are made within, by means of seal-skins or straw-mats, which separate the apartments of the different families that occupy the habitation.

Household-Furniture.

Their household-furniture consists of bowls, spoons, buckets, piggins or cans, matted baskets, and perhaps a Russian kettle or pot. The knife and the hatchet, or rather a small flat piece of iron, made like an adze, by fitting it into a crooked wooden handle, are the only iron tools found amongst them. Yet all their instruments and utensils are made with the greatest neatness, and the most exact symmetry.

Needle-work and Embroidery.

The needles, with which they sew their clothes and embroider, are made of the wing-bone of the gull, with a very nice cut round the thicker end, instead of an eye, to which they tie the thread so skilfully, that it follows the needle without any obstruction. Their thread is made of the sinews of the seal, the fibres of which they split to the thickness which each sort of work requires. All sewing is performed by the women; they are the tailors, shoemakers, and boat-builders, or boat-covers. At their leisure hours, particularly in long winter evenings, they make fine mats, little baskets, and pocket-books of straw, that are both beautiful and strong. Indeed, Captain Cook observes, there is a neatness and perfection in most of their work, that shows they neither want ingenuity nor perseverance.

Use of Fire and Modes of producing it.

Their houses have no fire-place, but are heated, as well as lighted, by lamps. These are made of a flat stone, hollowed on one side like a plate; in the hollow part they put the oil, mixed with a little dry grass, which serves the purpose of a wick. They produce fire both by collision and by attrition; the former by striking two stones one against another, one of them being previously rubbed with brimstone. The latter method is with two pieces of wood; one of which is a pointed stick, and the other a flat piece. The pointed end of the stick they press upon the other, whirling it nimbly round as a drill; thus producing fire in a few minutes.

Occupations.

The principal occupations of the Aleutians, are fishing and hunting, and preparing the implements necessary for both. Their *baidars, baidarkas*, or boats, resemble the canoes of other savages. They consist of a skeleton of wood, over which is stretched a leather covering made of seals' skins. The boats of the Unalashkans are much superior in point of beauty to those of any of the other islands; some of them appear so transparent that one might trace the formation of the inside, and the manner in which the rower sits. In their form, they are long and narrow, and commonly hold only one person; sometimes they are made to hold two, and very rarely three; each person sitting in a round hole just fitted to the size of the body. The whole canoe is so extremely light, even when sodden with water, that it may be carried with ease in one hand. They are impelled by means of double paddles, seven or eight feet long, which are managed with great dexterity. Experienced navigators will sometimes venture out a considerable way to sea in these boats, even in very stormy weather.

Darts used in Hunting.

The darts, or javelins, with which they kill their game, are formed with the same neatness as their other instruments, and adapted with the greatest judgment to the different objects of the chace. For land animals, a single barbed point; for birds, three points of light bone, spread, and barbed; for seals, &c. they use a false point, inserted in a socket at the end of the dart, which parts on the least effort of the animal to dive, remaining in its body. A string of considerable length is fastened to this barbed point, and twisted round the wooden part of the javelin. This serves as a float to direct them to the seal, which, having the stick to drag after it, soon tires, and becomes an easy prey.

Curious method of throwing them.

These darts are not shot from a bow, but slung from a small plank, about 18 inches long and two inches broad. In order that the weapon may be held the faster, they have a sort of handle at the lower end, and an opening through which the fore-finger is thrust. At the other end is a small channel, into which the javelin fits with a little knob, which serves to retain it When the javelin is to be thrown, the plank is held horizontally, and the aim being taken, the weapon is directed by the middle finger and thumb. This is done

Aleutian Islands. with so much dexterity, and the motion given to it is so powerful and so rapid, that the object aimed at is rarely missed; even whales are killed without any other weapon.

Amusements. Their favourite amusement appears to be dancing; in which, however, they do not seem to exhibit any particular exertion of strength, or expression of elegance; the only motion being a sort of hop, the performer scarcely moving from the place he first takes up. Their music is exceedingly rude, consisting of a small drum or tambour, and a rattle made of the bladder of a sea-dog, filled with peas or small pebbles. Mechanical skill. In their leisure hours, they amuse themselves with making these little drums and rattles, which are frequently ornamented with a good deal of ingenuity and elegance; and with cutting out from the teeth of the sea-cow, small figures of men, fish, sea-otters, and other objects, in a manner that appears very extraordinary, considering that the sea-cow's teeth are much harder than ivory, and that they have no proper tools to work with.

Religion. The religion of these Islanders, like that of most uncivilized nations, consists in superstitious observances, and a belief in charms. Many of them have been baptized, and are nominally professors of the Greek faith; of which, however, they understand nothing more than Marriages. making the sign of the cross. They have no marriage ceremony; every man may have as many wives as he can conveniently maintain; if his means decrease, he sends first one, then another back to their parents; and these women become perfectly at liberty to look out for other husbands. Sometimes the same woman lives with two husbands; and it is not uncommon for men to sell or exchange wives. Boys, if they happen to be very handsome, are often brought up entirely in the manner of girls; instructed in the arts of female blandishment; and used as concubines. This shocking, unnatural, and immoral practice, has prevailed here even from the remotest times. Burials. Such men are known under the name of *schopans*. The bodies of the dead, especially of the men, were formerly interred in places set apart for the purpose, and with particular ceremonies. Their best javelins and clothes, with a portion of train-oil and other articles of food, were laid with them in the grave; and sometimes even slaves of both sexes were slaughtered upon the occasion. These customs are now, however, entirely laid aside.

Population and Government. The population of Unalashka, and the neighbouring islands, appears to have been formerly considerable, amounting to several thousands. In 1790, Sarytcheff reckoned it at 1300. According to the most recent accounts, it does not appear to amount to more than 300. This rapid depopulation is ascribed partly to the practice of sending the best hunters from hence to a distance, to chace the large sea-otters, few of whom ever return again to their families; and partly to the state of oppression under which the natives live, and the change which has taken place in their modes of living. Captain Cook seems to consider the natives of these Islands as originally of the same extraction with the Greenlanders and Esquimaux. When first discovered by the Russians, they were under the government of *Toigons*, or chiefs, who, however, possessed little superior distinction or dignity, and had no revenue. At present they are all subject to the government of the Russian settlers.

Russian settlements, Throughout the whole of the Aleutian Islands, on the island of Kadyak, and the western coast of America, the Russians have formed settlements for the purpose of hunting, and collecting furs; with which they carry on a lucrative commerce, particularly with the Chinese. The most valuable fur is that of the sea-otter; an animal which has now become rare on these islands, in consequence of the extreme eagerness with which they have been hunted and killed. Besides the sea-otter, there are numbers of foxes, especially on the Fox Islands. The black foxes found on these islands are not so valuable as those of Siberia. The Arctic, or ice fox, called also the rock fox, and the blue fox, from the natural colour of the fur, which is of a blueish grey, is very common. and commerce. From the first discovery of these islands by Behring and Tscherikoff, in 1741, the fur-trade was carried on for a long period entirely by private adventurers; and appears to have been productive of great abuses. The natives were frequently treated in the most cruel and barbarous manner; and the keenness displayed by these rapacious hunters, threatened to extirpate the race of animals upon which the trade depended. Convinced of the extreme necessity of putting a stop to this destructive plan of proceeding, Schelikoff, an intelligent Russian merchant, took considerable pains to unite the different partakers of this trade into a company, in order that it might be conducted with prudence and precaution, upon some plan that might prove advantageous to all parties. Establishment of the Russian American Company. In 1785, he succeeded in joining company with the Golikoffs. They increased their capital, and fitted out several ships, which the enterprizing Schelikoff commanded in person. Factories, protected by forts, were established in almost all the Aleutian islands, as far eastward as Kadyak; and, during several years, they continued this lucrative trade in conjunction, by which they acquired considerable wealth. The success of this connection induced several merchants to unite like Schelikoff and the Golikoffs; and, in this manner, was laid the foundation of the present *Russian American Company*. The irregular manner, however, in which the trade was still carried on, and the cruelty which was frequently exercised by the Russian merchants towards the natives of the islands, drew upon them great and well-founded censure; insomuch, that the Emperor Paul determined to put an end to the company and the trade at the same time. This determination would have infallibly been carried into effect, but for the interference of M. Von Resanoff, who had married Schelikoff's daughter, and was personally interested in the successful continuance of the American Company. In consequence of his active interposition, the new established company was formally confirmed, in 1799, with considerable privileges. On the accession of the present Emperor, his Majesty interested himself very much in behalf of the company, of which he became a member, and thus induced many of the nobility to follow his example; and by means of the active superintendence of the minister, Count Romanzoff, and the Commer-

Aleutian Islands || Alfarabius.

cial Counsellor Benedict Cramer, this branch of the Russian commerce has undergone several advantageous changes. But, according to the accounts of recent observers, many abuses still exist which loudly call for correction. The miserable situation of the *Promüschleniks*, or fur-collectors, themselves the slaves of the company's agents, and exercising, in their turn, the most oppressive tyranny over the wretched Aleutians, has been represented by several eye-witnesses in the most deplorable colours. It is to be hoped, that these representations may attract the serious attention of the Russian Government; and that the information which the late voyages have brought to light, with regard to the evils connected with the present system of management, may lead to the adoption of measures, tending at once to the better regulation of the trade, and to the amelioration of the condition of those remote settlements.

Present state of the trade and Settlements.

They who are desirous of obtaining more ample information on the subject of this article, may consult the following works: Müller's *Samlung Russischer Geschichte;* particularly the third volume. *Neue Nachrichten von denen neuentdeckten Insuln in der See zwischen Asia und America, &c. verfasset von J. L. S.*—Hamburgh and Leipsic, 1776. Coxe's *Account of the Russian Discoveries.* Tooke's *View of the Russian Empire.* The *Voyages* and *Travels* of Billings; Sarytcheff; Cooke; Meares; Dixon; Vancouver; La Peyrouse; Mackenzie; Krusenstern; Lisiansky; and Dr Langsdorff. (H.)

ALFARABIUS, a celebrated Eastern philosopher of the tenth century, was born, in what year is not known, at Farab, a city of Asia Minor, now called Othrar. He studied for sometime at Bagdad, then the chief seat of learning; and afterwards travelled, in order to form an acquaintance with the learned of other countries.

A great revolution of sentiment in regard to letters, had taken place, in the preceding century, among the followers of Mahomet. The Commanders of the Faithful had become the patrons and cultivators, instead of the scourgers and contemners, of science and literature. Knowledge found her only sanctuary under the successors of those rulers who had sought to extinguish every ray of intellectual light, by means of the destruction of the libraries of Alexandria. Instead of proscribing every book as useless but the Koran, some of these rulers carried their zeal in the cause of learning so far, as to make the acquisition of Greek manuscripts an object of negotiation, in their treaties with the Emperors of Constantinople. Under the Caliphs of the house of Abbas, men of learning were raised to a degree of favour and consequence, which has never been enjoyed by that class, under the sovereigns of any other country, in any age of the world. The munificence which shone forth with so much lustre in the supreme depositaries of power, was widely emulated among the inferior rulers and governors; and "this emulation," to use the words of Gibbon, "diffused the taste and the rewards of science, from Samarcand and Bochara, to Fez and Cordova." Every little court had its circle of men of letters, who were always admitted to the society of the Prince, and for the most part liberally supported by his bounty. Thus, when Alfarabius, after he had finished his travels, came to settle at Damas, he was received with open arms by its sovereign, who bestowed upon him a pension, which he continued to enjoy till his death, in the year 950.

Alfarabius || Alfergan.

But to gain the notice of princes, or to acquire wealth, formed none of the aims of this philosopher. He is said to have led a very retired and ascetic life, rather contemning than seeking after the good things of the world. "He constantly slept, even during winter, upon straw; his countenance was always sorrowful, and he found no consolation in any thing but philosophy." (Enfield's *Hist. of Philosophy*, B. v. c. 1.) His works were numerous, and very various in their subjects; his speculations seem, indeed, from the list of his writings, to have embraced the whole circle of the sciences. He is particularly deserving of notice, as having been perhaps the first compiler of an *Encyclopædia.* Such is the title of one of his works, of which there is a copy in manuscript, in the library of the Escurial. It contains, according to the brief notice of it given in Casiri's valuable account of the Arabic Manuscripts in that collection, a clear and comprehensive definition and compendium of all the Arts and Sciences; and it appears to have been regarded in the East as the most valuable of Alfarabius's compositions. It would have been agreeable to the lovers of literary history to have possessed some more detailed view of the extent, plan, and contents of an Encyclopædia, written by an Arabian, so many centuries before any work of that description was thought of in Europe.

Next to this in estimation appears to have been his treatise on *Music;* in which he is said to have applied the principles of physics to correct the errors of musical theorists, and to regulate the construction of musical instruments. (*Biog. Universelle*, Tom. I.) Casiri gives a complete list of his writings; but it is too long to be copied in this place. (See *Bibl. Arabico-Hispana Escurialensis*, Tom. I.) Some of his pieces were published, in the Latin tongue, at Paris, in 1638, under the title of *Opuscula Varia* Alfarabii.

ALFERGAN, or ALFRAGAN, an Arabian astronomer, who lived under the reign of the Caliph Almamon, and who, on account of his skill in calculation, was surnamed the *Calculator*. He wrote an *Introduction to Astronomy*, which contains little that is original, being chiefly compiled from the *Almagest* of Ptolemy. He was also the author of a treatise on *Dials*, and of an account of the construction and use of the *Astrolabe*. These two pieces still remain in manuscript; but there have been three different Latin translations published of his astronomical work. The first, by Joannes Hispalensis, was published at Ferrara in 1493. This translation was afterwards reprinted at Nuremberg in 1537, with a preface by Melanchton. The second was the work of John Christman, and was published at Frankfort in 1590. The third, and the most esteemed of these translations, was by Golius, Professor of Mathematics and Oriental Languages at Leyden. It was published at Amsterdam in 1669, accompanied with the Arabic text, and with notes by Golius, which are extremely curious. But these notes extend no farther than the ninth chapter, as the author did not live to complete

this part of his undertaking. The work itself contains thirty chapters, all of which are very short.

ALFIERI (VICTOR), chiefly celebrated as the author who raised the Italian tragic drama from its previous state of degradation, was born on the 17th January 1749, at the town of Asti in Piedmont. He lost his father in early infancy; but he continued to reside with his mother, who married a second time, till his tenth year, when he was placed at the academy of Turin. After he had passed a twelvemonth at the academy, he went on a short visit to a relation who dwelt at Coni, and during his stay there, he made his first poetical attempt in a sonnet chiefly borrowed from lines in Ariosto and Metastasio, the only poets he had at that time read. When thirteen years of age he was induced to commence the study of civil and canonical law; but the attempt only served to disgust him with every species of application, and to increase his relish for the perusal of French romances.

By the death of his uncle, who had hitherto taken some charge of his education and conduct, he was left, at the age of fourteen, to enjoy without controul his vast paternal inheritance, augmented by the recent accession of his uncle's fortune. He now began to attend the riding-school, where he acquired that rage for horses, and equestrian exercise, which continued to be one of his strongest passions till the close of his existence.

After some time spent in alternate fits of extravagant dissipation, and ill-directed study, he was seized with a desire of travelling; and having obtained permission from the king, he departed, in 1766, under the care of an English preceptor. Restless and unquiet, he posted with the utmost rapidity through the towns of Italy; and his improvement was such as was to be expected from his mode of travelling and his previous habits. Dissatisfied with himself, he felt as little relish for spectacles or entertainments as for literature; and was as little amused by the gaiety of a carnival at Naples, as he was impressed by the remains of antiquity at Rome, or the exhibitions of modern art at Florence and Bologna. This indifference and insensibility did not, however, arise from defect of talent or the natural powers of taste, but from the want of some serious passion, or some ennobling or praiseworthy pursuit. Hoping to find in foreign countries some relief from the tedium and *ennui* with which he was oppressed, and being anxious to become acquainted with the French Theatre, he proceeded to Paris; but his feelings were only those of disgust or indifference for the dramas which he saw represented in that capital. He seems, indeed, to have been completely dissatisfied with every thing he witnessed in France, and contracted a dislike to its people, which his intercourse in future years rather contributed to augment than diminish. In Holland he became deeply enamoured of a married lady, who returned his attachment, but who was soon obliged to accompany her husband to Switzerland. Alfieri, whose feelings were of the most impetuous description, was in despair at this separation, and returned to his own country in the utmost anguish and despondency of mind. While under this depression of spirits, he was induced to seek alleviation from works of literature; and the perusal of Plutarch's Lives, which he read with profound emotion, inspired him with an enthusiastic passion for freedom and independence. Under the influence of this rage for liberty he recommenced his travels; and his only gratification, in the absence of freedom among the Continental States, appears to have been derived from contemplating the wild and sterile regions of the north of Sweden; where gloomy forests, lakes, and precipices, conspired to excite those sublime and melancholy ideas which were congenial to his disposition. Human manners and human institutions he seems invariably to have surveyed with an eye of passion or prejudice, instead of viewing them with the calmness of a philosopher, who meditates how they may be rectified, or what lessons may be drawn from them. In every country his soul felt as if confined by the bonds of society; he everywhere panted for something more free in governments, more elevated in sentiment, more devoted in love, and more perfect in friendship. In search of this ideal world, he posted through various countries, more with the rapidity of a courier, than of one who travels for amusement or instruction. During a journey to London, he engaged in an intrigue with a married lady of high rank; and having been detected, the publicity of a rencounter with the injured husband, and of a divorce, which followed, united to the knowledge he now acquired of the infamous character of the woman, to whom he was ardently attached, rendered it expedient and desirable for him to quit England. He then visited Spain and Portugal, where he became acquainted with the Abbé Caluso, who remained through life the most attached and estimable friend he ever possessed. In 1772, Alfieri returned to Turin, where he again became enamoured of a lady, whom he loved with his usual ardour, and who seems to have been as undeserving of a sincere attachment as those he had hitherto adored. In the course of a long attendance on his mistress, during a malady with which she was afflicted, he one day wrote a dialogue, or scene of a drama, which he left at this lady's house. About a year after, on a difference taking place between them, this piece was returned to him. Having then retouched and extended it to five acts, it was performed at Turin in 1775, under the title of *Cleopatra*, whose amours had always been a favourite subject with Italian dramatists.

From this moment, Alfieri was seized with an immeasurable thirst of theatrical fame, and the remainder of his life was devoted to its attainment. His two first tragedies, *Filippo* and *Polinice*, were originally written in French prose; and when he came to versify them in Italian, he found that, from his Lombard origin, and long intercourse with foreigners, he expressed himself with feebleness and inaccuracy. Accordingly, with the view of improving his Italian style, he went to Tuscany, and, during an alternate residence at Florence and Sienna, he completed his *Filippo* and *Polinice*, and conceived the plan of various other dramas. While thus employed, he became acquainted with the Countess Albany, who then resided with her husband at Florence. For her he formed an attachment, which, if less violent

Alfieri.

than his former loves, appears to have been more permanent. With this motive to remain at Florence, he could not endure the chains by which his vast possessions bound him to Piedmont. He therefore resigned his whole property to his sister, the Countess Cumiana, reserving an annuity, which scarcely amounted to a half of his original revenues. At this period, the Countess Albany, urged by the ill treatment she received from her husband, sought refuge in Rome, where she at length received permission from the Pope to live apart from her tormentor. Alfieri followed the Countess to that capital, where he completed fourteen tragedies, four of which were now for the first time printed at Sienna.

At length, however, it was thought proper, that, by leaving Rome, he should remove the aspersions which had been thrown on the object of his affections. During the year 1783, he therefore travelled through different states of Italy, and published six additional tragedies. The interests of his love and literary glory had not diminished his rage for horses, which seems to have been at least the third passion of his soul. He went to England solely for the purpose of purchasing a number of these animals, which he brought with him to Italy. On his return, he learned that the Countess Albany had gone to Colmar in Alsace, where he joined her, and resided with her under the same roof during the rest of his life. They chiefly passed their time between Alsace and Paris; but at length took up their abode entirely in that metropolis. While here, Alfieri made arrangements with Didot for an edition of his tragedies; but was soon after forced to quit Paris by the storms of the Revolution. He recrossed the Alps with the Countess, and finally settled at Florence. The ten last years of his life, which he spent in that city, seem to have been the happiest of his existence. During that long period, his tranquillity was only interrupted by the entrance of the Revolutionary armies into Florence in 1799. Though an enemy of kings, the aristocratic feelings of Alfieri rendered him also a decided foe to the principles and leaders of the French Revolution; and he rejected, with the utmost contempt, those advances which were made with a view to bring him over to their cause. The concluding years of his life were laudably employed in the study of Greek literature, and in perfecting a series of comedies. His assiduous labour on this object, which he pursued with his characteristic impetuosity, exhausted his strength, and brought on a malady, for which he would not adopt the prescriptions of his physicians, but obstinately persisted in employing remedies of his own. Under this regimen his disorder rapidly increased, and at length terminated his life on the 8th October 1803, in the fifty-fifth year of his age.

The character of Alfieri may be best appreciated from the portrait which he has drawn of himself in his own *Memoirs of his Life*. He was evidently of an irritable, impetuous, and almost ungovernable temper. Pride, which seems to have been a ruling sentiment, may account for many apparent inconsistencies of his character. While it made him abhor kings, because superior to himself, it led him to detest those republicans who, by too near an approach, contaminated aristocratic dignity; and it induced him, while yet undistinguished himself, and panting for literary fame, to decline a proffered introduction to Metastasio and Rousseau. But as all his bad qualities were greatly softened by the cultivation of literature, it may be presumed, that a better education, and an earlier employment of his faculties, would have rendered him a much more perfect character. His application to study gradually tranquillized his temper, and softened his manners; leaving him, at the same time, in perfect possession of those good qualities which he had inherited from nature;—a warm and disinterested attachment to his family and friends, united to a generosity, vigour, and elevation of character, which rendered him not unworthy to embody in his dramas the actions and sentiments of Grecian heroes.

To these dramas Alfieri is chiefly indebted for the high reputation to which he has attained. Before his time, the Italian language, so harmonious in the *Sonnets* of Petrarch, and so energetic in the *Commedia* of Dante, had been invariably languid and prosaic in dramatic dialogue. The pedantic and inanimate tragedies of the sixteenth century were followed, during the iron age of Italian literature, by dramas, of which extravagance in the sentiments, and improbability in the action, were the chief characteristics. The prodigious success of the *Merope* of Maffei, which appeared in the commencement of the last century, may be attributed more to a comparison with such productions, than to intrinsic merit. In this degradation of tragic taste, the appearance of the tragedies of Alfieri was, perhaps, the most important literary event that had occurred in Italy during the eighteenth century. On these tragedies it is difficult to pronounce a judgment, as the taste and system of the author underwent considerable change and modification during the intervals which elapsed between the three periods of their publication. An excessive harshness of style, an asperity of sentiment, and total want of poetical ornament, are the characteristics of his four first tragedies, *Filippo*, *Polinice*, *Antigone*, and *Virginia*. These faults were, in some measure, corrected in the six tragedies which he gave to the world some years after; and in those which he published along with *Saul*, the drama which enjoyed the greatest success of all his productions;—a popularity, which may be partly attributed to the severe and unadorned manner of Alfieri being well adapted to the patriarchal simplicity of the age in which the scene of the tragedy is placed. But though there be a considerable difference in his dramas, there are certain observations applicable to them all. None of the plots are of his own invention. They are founded either on mythological fable or history; most of them had been previously treated by the Greek dramatists, or by Seneca. *Rosmunda*, the only one which could be supposed of his own contrivance, and which is certainly the least happy effusion of his genius, is partly founded on the eighteenth novel of the third part of Bandello, and partly on Prevost's *Mémoires d'un Homme de Qualité*. But whatever subjects he chooses, his dramas are always formed on the Grecian model, and breathe a freedom and independence worthy an Athenian poet. Indeed, his *Agis* and *Bruto* may rather be considered oratorical declamations and dialogues on liberty than tragedies. The unities of time and place are not so scru-

pulously observed in his, as in the ancient dramas; but he has rigidly adhered to a unity of action and interest. He occupies his scene with one great action, and one ruling passion, and removes from it every accessary event or feeling. In this excessive zeal for the observance of unity, he seems to have forgotten, that its charm consists in producing a common relation between multiplied feelings; and not in the bare exhibition of one, divested of those various accompaniments which give harmony to the whole. Consistently with that austere and simple manner which he considered the chief excellence of dramatic composition, he excluded from his scene all *coups de théâtre*, all philosophical reflections, and that highly ornamented versification, which had been so assiduously cultivated by his predecessors. In his anxiety, however, to avoid all superfluous ornament, he has stripped his dramas of the embellishments of imagination; and for the harmony and flow of poetical language, he has substituted, even in his best performances, a style, which, though correct and pure, is generally harsh, elaborate, and abrupt;—often strained into unnatural energy, or condensed into factitious conciseness. The chief excellence of Alfieri consists in powerful delineation of dramatic character. In his Philip II. he has represented, almost with the masterly touches of Tacitus, the sombre character, the dark mysterious counsels, the *suspensa semper et obscura verba* of the modern Tiberius. In *Polinice* the characters of the rival brothers are beautifully contrasted; in *Maria Stuarda*, that unfortunate Queen is represented unsuspicious, impatient of contradiction, and violent in her attachments. In *Mirrha*, the character of *Cynaras* is perfect as a father and king, and *Cenchris* is a model of the virtues of a wife and mother. In the representation of that species of mental alienation where the judgment has perished, but traces of character still remain, he is peculiarly happy. The insanity of Saul is skilfully managed; and the horrid joy of Orestes in killing Egisthus rises finely and naturally to madness, in finding that, at the same time, he had inadvertently slain his mother.

Whatever may be the merits or defects of Alfieri, he may be considered as the founder of a new school in the Italian drama. His country hailed him as her sole tragic poet, and his successors in the same path of literature have regarded his bold, austere, and rapid manner, as the genuine model of tragic composition.

Besides his tragedies, Alfieri published during his life many sonnets, five odes on American independence, and the poem of *Etruria*, founded on the assassination of Alexander I. Duke of Florence. Of his prose works, the most distinguished for animation and eloquence is the *Panegyric on Trajan*, composed in a transport of indignation at the supposed feebleness of Pliny's eulogium. The two books, entitled *La Tiranide* and the *Essays on Literature and Government*, are remarkable for elegance and vigour of style, but are too evidently imitations of the manner of Machiavel. His *Antigallican*, which was written at the same time with his *Defence of Louis XVI.*, comprehends a historical and satirical view of the French revolution. The posthumous works of Alfieri consist of satires, six political comedies, and the *Memoirs of his Life*;—a work which will always be read with interest, in spite of the cold and languid gravity with which he delineates the most interesting adventures and the strongest passions of his agitated life. See *Mem. de Vitt. Alfieri.—Sismondi de la Litt. du Midi de l'Europe.*—Walker's *Memoir on Italian Tragedy.—Giorn. de Pisa.* Tom. LVIII. (M.)

ALHAZEN, an Arabian author of the eleventh century, who is better entitled to the appellation of philosopher, than most of those of his countrymen by whom it has been obtained. The place of his birth was Bassorah; the year, uncertain; but his death took place at Cairo in 1038. There was another author of the same name, who translated the *Almagest* of Ptolemy; but that writer lived during the reign of the Caliph Almamon. In some accounts of Alhazen, we find it said, that he lived in Spain; but it appears from Casiri, (*Bibl. Arabico-Hispana Escurialensis*), that, after he left his native city, Egypt was his place of residence. It also appears, that he was invited to that country by one of the Fatemite Caliphs; and that the reason was, some boasts which he had made of being able to obviate the evils attendant upon the overflowing, as well as the decrease of the waters of the Nile. He surveyed the country with a view to this project, to aid which, every thing that he asked was liberally furnished by the Caliph; but finding that his imagination had seduced him into a wild and impracticable scheme, he feigned madness, thereby to avoid the punishment which he dreaded; and he continued to play this humiliating part till the Caliph's death relieved him from his apprehensions.

But whatever figure he may have made as a projector, there can be no doubt that he was a skilful geometrician; and that his name deserves a conspicuous place among the improvers of the science of optics. He was not a mere compiler from the ancients, or commentator upon their works; he followed the bent of his own genius; and, striking into the right path of experiment and observation, his inquiries were productive of a real accession to the stock of knowledge, in regard to some of the most interesting phenomena of nature. He refuted the error of the ancient philosophers, that vision was produced by rays emitted from the eye. He gave the first sensible explanation of the cause of the apparent increase of the sun and moon when seen near the horizon; showing that this is occasioned by their being then supposed, owing to the number of intermediate objects, to be at a greater distance from the spectator. He was the first who applied the laws of refraction, to show how the heavenly bodies are sometimes seen as if above the horizon when still below it; and who, in the same way, explained the cause of the morning and evening twilight;—of that beneficent provision of nature, by which the glories of day are made gradually to approach, and gradually to withdraw. These dioptrical discoveries of the Arabian philosopher have furnished M. Bailly with one of the many fine passages which embellish his celebrated work on the History of Astronomy. (*Astron. Moderne*, L. vi. sect. 20.)

As a writer, Alhazen is censurable for unmeaning prolixity, and scholastic subtlety. It appears, from

Casiri, that his works were numerous; but only two of them have been published, namely, his Treatise on *Optics*, and that on the *Twilight*. They were both published in Latin, in 1572, by Frederic Risner, under the title of *Opticæ Thesaurus*.

ALIMENTS. See Food in the Encyclopædia, and Dietetics in this Supplement.

ALKALIMETER, a name given to a small instrument, invented by M. Descroizilles, for ascertaining the value of the alkalis in commerce. There is an account of it in the 60th volume of the *Annales de Chimie*, which is translated in the 28th volume of Tilloch's *Philosophical Magazine*.

ALLAN (David), a Scotch historical painter of considerable celebrity, was born at Alloa, on the 13th February 1744. At a very early age he showed such marks of genius as attracted the notice of some gentlemen living in the neighbourhood. In a remote part of the country, and deprived of the ordinary means of indulging his propensity to drawing, he betook himself, when a boy, to such implements and materials as he could readily procure; and the mechanical skill and taste which, in particular, he displayed in using his knife, have been mentioned as remarkable for his years. Mr Stewart, then Collector of the Customs at Alloa, having mentioned these proofs of natural talent to Mr Fowlis the Painter, who sometime before had instituted an Academy in Glasgow, for painting and engraving, invited young Allan to study under his care. Here he remained about seven years, studying the elementary principles of his art; and by the proficiency which he attained, justified the opinion of his talents, which had procured him admission to that ill-fated seminary. But, although, the public taste for the fine arts, which then existed in Scotland, was so feeble as to leave his preceptor without that support which his liberal and spirited efforts justly claimed, Allan, on leaving the academy, had the good fortune to gain the patronage of individuals, whose generosity enabled him to prosecute his views, and to improve his taste, by studying the works of art abroad. At the joint expence of several persons of fortune, particularly Lord Cathcart and Mr Abercrombie of Tullibody, he was enabled to go to Italy; and at Rome he devoted himself with great zeal to his profession. Here he remained for no less a period than sixteen years, during which time, his subsistence chiefly depended on the copies which he made from the most celebrated pictures of the ancient masters; but one original work which he then painted, does the highest credit to his talents, namely, his composition representing the *Origin of Painting*. On this picture, indeed, the fame of Mr Allan, as a historical painter, chiefly rests; and its merit was rewarded, by his receiving the gold medal given by the Academy of St Luke, in the year 1773, for the best specimen of historical composition. There is an excellent engraving of this piece by Cunego.

On his return to his native country, he took up his residence in Edinburgh, where he was appointed master of the Academy established by the Trustees for Manufactures in Scotland. There he executed a great variety of works, of various degrees of merit; but perhaps none such as might have been expected from the author of the *Origin of Painting*. Those, indeed, by which he is most known, are of a cast altogether different, being remarkable for the comic humour which they display. The *Scotch wedding*; the *Highland dance*; the *Repentance-stool*, with his *Illustrations of the Gentle Shepherd*, are all of this class, and so generally known, as to need no description. Four pictures representing the Carnival, are said to have been very successful. Of his graver compositions, the *Prodigal Son*, in possession of Lord Cathcart, and his *Hercules and Omphale*, in the possession of Mr Erskine of Mar, are regarded as works of great merit.

As an artist, Mr Allan possessed much facility of invention; with a keen discernment of those evanescent circumstances in the outward form, which mark the different shades of passion and affection in the mind. With the talent of artfully arranging the various parts of a crowded and bustling scene,—such as appears in some of his comic productions, he possessed that feeling for simplicity, which gives to his graver compositions, a classical and antique air of elegance. In his drawing he often was hasty and incorrect. He executed a great variety of etchings and drawings in water colour, which are valuable, on account of their excellent humour, and the great knowledge of national character which they express. Many of the original plates and drawings are now in the possession of Mr George Thomson, to whose kindness and friendship their author was much indebted. We do not know that Allan left any pupil who has followed his particular line in painting. Mr H. W. Williams received from him the rudiments of art, but his genius has directed him to a different course, which has conducted him to merited eminence as a landscape painter.

Mr Allan is remembered and spoken of as an excellent private character. He died at Edinburgh on the 6th of August 1796, in the 53d year of his age. (N.)

ALUM, a salt very much employed by Dyers and other artists, in their different processes. It has a white colour, an astringent and acid taste, and crystallizes in regular octahedrons. Its specific gravity is 1.731, according to a mean of the experiments of Fahrenheit, Wallerius, Watson, and Hassenfratz. Water at the temperature of 60° dissolves about one fifteenth of its weight of alum; while boiling water dissolves about three-fourths of its weight. When alum is exposed to a dry atmosphere, it effloresces slightly. When heated, it speedily becomes liquid. If the heat be continued, its water is driven off, and it loses about 44 *per cent.* of its weight. What remains, is a vitreous looking substance, known by the name of *burnt alum*. When alum is exposed to a strong red heat, it gives off a quantity of oxygen gas, as Dr Milner first ascertained. The same fact was afterwards pointed out by Gay-Lussac.

Alum is one of those substances which chemists have distinguished by the name of triple salts. It is composed of sulphuric acid, potash, alumina and water. That it contained sulphuric acid as a constituent, was known even to the Alchemists. Pott and Margraaf demonstrated, that alumina was another constituent. Mr Pott, in his *Lithogeognosia*, showed

Alum. that the earth of alum, or the precipitate obtained when an alkali is poured into a solution of alum, is quite different from lime and chalk, with which it had been confounded by Stahl. Margraaf went much farther. He not only showed that alumina is one of the constituents of alum; but that this earth possesses peculiar properties, is different from every other substance, and is one of the ingredients in common clay. (*Experiences faites sur la terre d'alun.* Margraaf's *Opusc.* II. 111.) Margraaf showed likewise, by many experiments, that crystals of alum cannot be obtained by dissolving alumina in sulphuric acid, and evaporating the solutions. The crystals formed are always soft, and quite different in their appearance from alum crystals. But, when a solution of potash or ammonia is dropt into this liquid, it immediately deposites perfect crystals of alum. (*Sur la regeneration de l'alun.* Margraaf's *Opusc.* II. 86.) He mentions likewise, that manufacturers of alum, in general, were unable to procure the salt without a similar addition; and that at first, it had been customary to add a quantity of putrid urine, and that afterwards a solution of carbonate of potash was substituted in its place. But subsequent chemists do not seem to have paid much attention to these important observations of Margraaf; they still continued, without any rigid examination, to consider alum as a sulphate of alumina.

Bergman indeed had observed, that the addition of potash or ammonia made the alum crystallize; but that the same effect was not produced by the addition of soda or of lime, (*De confectione aluminis.* Bergman's *Opusc.* I. 225.) He had observed likewise, that sulphate of potash is frequently found in alum. He decomposed the solution of alum by means of ammonia, evaporated the filtered liquid to dryness, and exposed the residue to a red heat. A quantity of sulphate of potash often remained behind in the crucible, (*Ibid*, p. 326.) He drew, as a conclusion from these facts, that sulphate of potash readily combines with sulphate of alumina. Yet, it is obvious from the whole of his dissertation, that he had no conception that alum is a triple salt. He ascribed the difficulty of crystallization, to the excess of sulphuric acid present. He thought that the only use of the potash was to saturate this excess; and advises manufacturers to substitute clay instead of potash, as a method which would not only saturate the excess of acid, but increase the quantity of alum. This very bad advice was not, we presume, followed by any alum makers. If they tried it, they would soon be convinced of its injurious consequences. Instead of alum, they would have obtained an insoluble tasteless powder, well known by the name of *alum saturated with its earth.*

After Klaproth had discovered the existence of potash as an ingredient in *leucite* and *lepidolite*, it occurred to Vauquelin, that it was probably an ingredient likewise in many other minerals. He recollected that alum crystals often make their appearance during the analysis of stony bodies; and, considering that alum cannot be obtained in crystals without the addition of potash, he began to suspect that this alkali constituted an essential ingredient in the salt. A set of experiments undertaken on purpose to elucidate this important point, soon satisfied him that his conjecture was well founded. Accordingly, in the year 1797, he published a dissertation, demonstrating that alum is a triple salt, composed of sulphuric acid, alumina and potash. (*Annales de Chimie*, XXII. 258.) Soon after, Chaptal published the analysis of four different kinds of alum, namely, Roman alum, Levant alum, British alum, and alum manufactured by himself. This analysis led to the same result as that of Vauquelin. (*Ann. de Chim.* XXII. 280.) Alum.

Since that time, alum has been admitted by chemists to be a triple salt; and various analyses of it have been made to determine its constituents. Vauquelin, (*Ann. de Chim.* L. 167), Thenard and Roard, (*Ibid. Tom.* LIX. 72), Curaudon, (*Journal de Physique*, LXVII. 1.) and Berzelius, (*Ann. de Chim.* LXXXII. 258.) successively published the results of their experiments. They differ but little from each other. We shall therefore satisfy ourselves with giving the analysis of Berzelius, which is the latest, and in all probability the most accurate. His result was as follows:

| | |
|---|---|
| Sulphuric acid - - | 34.23 |
| Alumina - - - - | 10.86 |
| Potash - - - - - | 9.81 |
| Water - - - - | 45.00 |
| Loss - - - - - | 0.10 |
| | 100.00 |

Or

| | |
|---|---|
| Sulphate of alumina - | 36.85 |
| Sulphate of potash - | 18.15 |
| Water - - - - - | 45.00 |
| | 100.00 |

Now, as we shall show in a subsequent article, (See Atomic *philosophy*), an integrant particle of sulphuric acid weighs 5, an integrant particle of alumina 2.136, and an integrant particle of potash 6. We shall show likewise in the same article, that sulphate of potash is composed of one integrant particle of sulphuric acid, united with one integrant particle of potash; and sulphate of alumina of one integrant particle of sulphuric acid, united to one integrant particle of alumina; therefore, the relative weight of an integrant particle of each of these salts, is as follows:

| | |
|---|---|
| Sulphate of potash - | 11.000 |
| Sulphate of alumina - - | 7.136 |

But the quantities of each of these salts in alum, according to the preceding analysis, are as the numbers 18.15 : 36.85. Now, the ratio 18.15 : 36.85, is very nearly the same as 11 : 7.136 × 5. Hence it follows, that alum contains 1 integrant particle of sulphate of potash, and 5 integrant particles of sulphate of alumina. An integrant particle of water, as will be shown likewise in the article Atomic *philosophy*, weighs 1.132. Now, one integrant particle of sulphate of potash, × 5 integrant particles of sulphate of alumina, weigh 46.680. But alum con-

tains 45 *per cent.* of water. To find how many integrant particles of water these amount to, we have this proportion; 56 : 45 : : 46.680 : 38.213. Now, 38.213, is very nearly the weight of 34 integrant particles of water. For $1.132 \times 34 = 38.488$. Hence, it follows, that alum is a compound of

| | | |
|---|---|---|
| Sulphate of potash | - | 1 integrant particle. |
| Sulphate of alumina | - | 5 |
| Water | - - - - | 34 |
| | Total | 40 |

Making altogether no fewer than 40 integrant particles united together. It is not easy to see how these 40 particles, by their symmetrical union with each other, can form a tetrahedron, which Hauy conceives to be the primitive form of the integrant particle of alum. The octahedron is a much more probable primitive form. It might be conceived to be formed by the six integrant particles of sulphate of potash, and sulphate of alumina, and the thirty four particles of water, which are probably much smaller, may fill up the intervals between them. The objection to this supposition is, that in that case the atom of sulphate of potash cannot be surrounded by the atoms of sulphate of alumina, as one would naturally expect, from their mutual affinity for each other. The most probable supposition of the arrangement of the integrant particles of alum is, that the atom of sulphate of potash occupies the centre; that it is surrounded at equal distances by the five atoms of sulphate of alumina, each surrounded by seven atoms of water. But, we do not readily see how such an arrangement would either form a tetrahedron or octahedron. This symmetrical arrangement of the different integrant particles that compose a crystal, deserves to be studied with care, because it is probable, that it will throw light on the nature of *affinity*, and the way in which atoms combine together.

The word *alumen*, which we translate *alum*, occurs in Pliny's Natural History. In the 15th chapter of his 35th book, he gives us a detailed description of it. By comparing this with the account of στυπτηρια given by Dioscorides in the 123d chapter of his 5th book, it becomes quite obvious, that he alludes to the same substance. Hence it follows, that στυπτηρια is the Greek name for *alumen*. Pliny informs us, that alumen was found naturally in the earth. He calls it *salsugoterræ*. Different substances he informs us, were distinguished by the name of alumen; but they were all characterized by a certain degree of astringency, and were all employed in dyeing and in medicine. The light-coloured alumen was useful in brilliant dyes; the dark-coloured only in dyeing black, or very dark colours. One species of alumen was a liquid, which was apt to be adulterated; but, when pure, it had the property of striking a black with the juice of the pomegranate. This property seems to characterize a solution of sulphate of iron in water. It is quite obvious, that a solution of our alum would possess no such property. Pliny says, that there is another kind of alum which the Greeks call *schistos*. It forms in white threads upon the surface of certain stones. From the name, *schistos*, and the mode of formation, there can be little doubt, that this species was the salt which forms spontaneously on certain slaty minerals,—as alum slate and bituminous shale, and which consists chiefly of sulphate of iron and sulphate of alumina. Possibly in certain places the sulphate of iron may have been nearly wanting; and then the salt would be white, and would answer, as Pliny says it did, for dyeing bright colours. Several other species of alumen are described by Pliny, but we are unable to make out to what minerals he alludes.

The alumen of the ancients, then, was not the same with the alum of the moderns. It was most commonly a sulphate of iron, sometimes probably a sulphate of alumina, and usually a mixture of the two. But the ancients were unacquainted with our alum. They were acquainted with sulphate of iron in a crystallized state, and distinguished it by the names of *misy*, *sory*, *chalcanthum*, (*Plinii*, xxxiv. 12.) As alum or green vitriol were applied to a variety of purposes in common, and as both are distinguished by a sweetish and astringent taste, writers, even after the discovery of alum, do not seem to have discriminated the two salts accurately from each other. In the writings of the Alchemists we find the words *misy*, *sory*, *chalcanthum*, applied to the alum as well as sulphate of iron, and the name *atramentum sutorium*, which ought to belong (one would suppose) exclusively to green vitriol, applied indifferently to both.

When our alum was discovered is entirely unknown. Beckman devoted a good deal of time to trace the history of this salt, and published a curious dissertation on the subject. But his attempts to trace its origin were unsuccessful. The manufacture of it was discovered in the East; but at what time or place is totally unknown. It would appear, that, about four or five hundred years ago, there was a manufactory of it at Edessa in Syria, at that time called Rocca. Hence, it is supposed, the origin of the term *Rock alum*, commonly employed in Europe; though there are others that pretend that the term originated at Civita Vecchia, where alum is made from a yellow mineral in the state of a hard rock.

Different alum works existed in the neighbourhood of Constantinople. About the time of the fall of the Grecian empire, the art of making alum was transported into Italy, at that period the richest and most manufacturing country in Europe. Bartholomew Pernix, a Genoese merchant, discovered alum ore in the island of Ischia, about the year 1459. Nearly at the same time, John di Castro, who was well acquainted with the alum works in the neighbourhood of Constantinople, suspected that a mineral fit for yielding alum existed at Tolfa, because it was covered with the same trees that grew on the alum mineral near Constantinople. His conjecture was verified by trials, and the celebrated manufactory at Tolfa established. Another was begun in the neighbourhood of Genoa, and the manufactory flourished in different parts of Italy. To this country it was confined for the greatest part of a century. Various manufactories of it were established in Germany, by the year 1544. In the time of Agricola, there was a manufactory of it at Commoton in Bohemia. About the same time,

 an alum work was established near Carthagena in Spain, at Alcmaron.

England possessed no alum works till the reign of Charles I. Thomas Chaloner, Esq., son of Dr Chaloner, who had been tutor to Charles, while hunting on a common in Yorkshire, took notice of the soil and herbage, and tasted the water. He found them similar to what he had seen in Germany, where alum works were established. In consequence of this, he got a patent from Charles for an alum work. This manufactory was worth two thousand a-year, or perhaps more. But some of the Courtiers thinking this too much for him; prevailed with the King, notwithstanding the patent, to grant a moiety of it to another person. This was the reason why Mr Chaloner was such a partizan of the Parliament, and such an enemy of the King, that, at the end of the civil war, he was one of those who sat in judgment upon his Majesty and condemned him.* Since that time, various alum works have been established in different parts of England and Wales. But none at present exist, except the Whitby works, originally established by Mr Chaloner, and two works at the Hurlet and Campsie, both in the neighbourhood of Glasgow.

Several alum works likewise exist in Sweden, particularly in West Gothland. There is one for example at Hænsæter, near the borders of the Wene lake, on the west side of the mountain called Kinnekulle. But, for a description of the Swedish works, we refer to Bergman's *Opuscula*, Vol. I. p. 284, or the English translation, Vol. I. p. 342. We do not know if any alum works exist in Poland or Russia; but, as the greatest part of these extensive countries consists of alluvial soil to a great depth, it is probable, that little alum ore will be found in them.

Various minerals are employed in the manufacture of alum; but by far the most important of them are the following three: *alum stone, alum slate, bituminous shale.*

Alum stone is the mineral which occurs at Tolfa, near Rome, from which the celebrated Roman alum is made. Werner also possesses specimens of the same mineral from Hungary. At Tolfa, it is said to constitute a hill. Its colour is greyish white, sometimes yellowish grey, and sometimes, as Gay Lussac informs us (*Ann. de Chim.* LV. 267.) reddish from the peroxide of iron. It is massive and rather hard. It has no lustre. It is translucent on the edges. Fractures uneven, approaching to the fine earthy. Fragments blunt edged. Does not adhere to the tongue. It is rather heavy; but its specific gravity is not accurately known. This mineral, according to the analysis of Klaproth (Gehlen's *Neue Allgemeine Journal der Chemie*, VI. 35.) is composed of the following constituents:

| | |
|---|---|
| Silica - - - - | 56.5 |
| Alumina - - - | 19.0 |
| Sulphuric Acid - | 16.5 |
| Potash - - - - | 4.0 |
| Water - - - - | 3.0 |
| Loss - - - - | 1.0 |
| | 100.0 |

Vauquelin likewise analyzed this mineral, and found the same constituents, though in different proportions. We have no analysis of the varieties of alum stone which contain peroxide of iron. Thus it appears, that alum stone contains all the ingredients of alum ready formed.

Alum slate is a much more abundant mineral than alum stone. It is said to alternate with primitive clay slate. It occurs abundantly along with transition slate; and there can be little doubt that it occurs likewise in the flœtz formations. In West Gothland in Sweden, it constitutes a part of different hills; as Kinnekulle, Hunneberg, and Halleberg; in all of which it appears to alternate with flœtz trap rocks. It occurs likewise abundantly in Whitby in Yorkshire. We have never ourselves been upon the spot; but, from the general structure of Yorkshire, and the neighbouring counties, indeed of the whole east coast of England, there can be very little doubt that, in this position, it is also a flœtz rock.

Alum slate, as the name implies, is a slaty rock, though sometimes it occurs in balls. The colour is blueish-black, with a strong shade of grey. Fracture straight slaty. Fragments tabular. Its internal lustre is glimmering. It retains its colour in the streak; but acquires more lustre. Soft. Not particularly brittle. When exposed to the air it effloresces, and acquires an aluminous taste.

This mineral has never been accurately analyzed. But there can be no doubt that it contains silica, alumina, iron, sulphur, charcoal, and often likewise potash. Probably this was the mineral upon which the *alumen scissile* of the ancients was found.

Bituminous shale, the *brandschiefer* of the Germans, is a slaty mineral, which almost constantly accompanies beds of coal; and, accordingly, is very common in Great Britain. Its colour is brownish-black. Its fracture is thin slaty. Fragments tabular. Internal lustre glimmering; but the colour is not altered. Very soft. Rather sectile. Feels rather greasy. Easily frangible. When heated, it burns with a pale flame and sulphureous odour, and becomes white. It has never been accurately analyzed; but it is probably nothing more than slate clay, which occurs so abundantly in the independent coal formation, impregnated with the matter of coal. Its other principal constituents must be silica, alumina, and iron pyrites.

Slate clay itself, at least not sufficiently impregnated with coaly matter to deserve the name of bituminous shale, is frequently employed in the making of alum. This is the case in the neighbourhood of Glasgow.

Four different processes are employed by the alum manufacturers, according to the nature of the mineral from which the alum is to be extracted.

* *Letters written by Eminent Persons, in the Seventeenth and Eighteenth Centuries; and Lives of Eminent Men*, by John Aubrey, Esq.; Vol. II. p. 281.

The process employed at Tolfa is the simplest of all. If the Tolfa stone be kept constantly moistened with water for about two months, it falls to powder of itself, and yields alum by elixiviation. But this is not the process employed by the manufacturers. The alum stone is broken into small pieces, and piled on the top of a perforated dome, in which a wood fire is kindled. The smoke and flame of the wood penetrate through the pieces of alum stone, and a sulphureous odour is disengaged, owing to the decomposition of a portion of the sulphuric acid in the stone. This roasting is twice repeated; the pieces of ore which, the first time, were at the edge of the dome, being the second time put in the middle. The process of roasting this stone requires considerable attention. If the heat be too great, the quality of yielding alum is destroyed. If the heat be too small, the stone does not readily fall to powder. There can be little doubt that the unroasted stone would yield more alum than the roasted; but probably the additional labour requisite in the latter case would more than swallow up the increase of product.

The roasted stone, which has now acquired a reddish colour, is placed in rows between trenches filled with water. This liquid is so frequently sprinkled on it, that the stone is always moist. In two or three days it falls to powder, like slacked quicklime; but the daily watering is continued for a month. The success of this part of the operation is said to depend very much on the weather. When the weather is rainy, the alum is all washed out, and little or nothing left for the manufacturer to extract. In such cases, it is obvious that the alum stone should be covered by a shade from the rain.

When the stone has by this process been reduced to a sufficiently fine powder, it is thrown into a leaden boiler, filled two-thirds with water. During the boiling, the powder is frequently stirred up, and the water that evaporates is replaced. When the boiling has been continued for a sufficient time, the fire is withdrawn, and time allowed for the earthy matter to subside to the bottom. A cock is then opened, which allows the clear liquor to flow out into deep wooden square vessels, so made that they can be easily taken to pieces. Here the alum gradually crystallizes, and attaches itself to the sides and bottom of the vessel. The mother liquid is now drawn off into shallower wooden troughs, where more alum crystals are deposited. The liquid has now a red colour, and is muddy; and the last alum crystals are mixed with this red matter. They are washed clean in the mother liquor, which is finally pumped into a trough, and used in subsequent processes.

The alum obtained at Tolfa is the purest of all. It is known by the name of *Roman alum*, and is in very high estimation. It is always mixed with a little reddish powdery matter, which is easily separated from it. What this red matter is, has not been ascertained; but it is not peroxide of iron. To the eye it has very much the appearance of a vegetable matter. We have some notion that it is added artificially by the sellers of Roman alum. Probably Roman alum at first had a red tinge, in consequence of the red matter in the mother liquor remaining partially attached to it. The goodness of the alum may have given the purchasers a partiality to the red colour, and induced the sellers to add a red powder artificially. We have never had an opportunity ourselves of examining this matter; but have been informed by those that have, that it contains no iron.

It is not improbable that this process would be improved by grinding the Tolfa stone to a fine powder in a mill, without any previous roasting, and then keeping the powder moistened with water for a considerable time. If the residual earth, after the alum is extracted, be boiled with sulphuric acid, the liquid yields alum crystals by evaporation. This is a demonstration that neither the alumina nor the potash is exhausted, and that the sulphuric acid, driven off by the roasting, is so much alum lost to the manufacturer. Indeed, the quantity of sulphuric acid in the alum stone is not sufficient to occupy the whole of the potash in the formation of alum. It would be necessary to add about one-tenth of the weight of the alum stone of sulphuric acid, if it were wanted to employ the whole potash present in the stone. The consequence of this addition (supposing no loss) would be an additional quantity of alum, amounting to rather more than one-fifth of the weight of the alum stone employed.

Alum slate being very different in its composition, requires a different treatment to fit it for yielding alum. If the alum slate contain a notable quantity of lime or magnesia, it does not answer the purposes of the manufacturer so well. Indeed, the proportion of lime present may be conceived to be such, that no alum would be obtained whatever. As alum slate has never been subjected to accurate analysis, we do not know in what proportion these two earths exist in it, or whether they may not, in many cases, be absent altogether. The essential ingredients in alum slate for the alum-makers are alumina and iron pyrites.

The first process is to roast the ore. In Sweden, where the fuel is wood, and consequently expensive, it is customary to use the alum slate itself as fuel for roasting the ore. For this purpose, a small layer of brushwood is covered with pieces of alum slate, and set on fire; and, as the combustion proceeds, new layers of alum slate are added. It is usual to place alternate layers of roasted and unroasted alum slate. The combustion continues for a month or six weeks. At Whitby, coal is employed for roasting the alum slate. Indeed, the alum slate of Whitby is lighter coloured than that of Sweden, and probably would not burn of itself. So great is the quantity of combustible matter in the Swedish alum slate, that it is employed as fuel for burning limestone. Great quantities of limestone are burnt in this manner at Hunneberg, near the south side of the lake Wener. The roasted ore has usually a brown colour. When it is red, the quantity of alum which it yields is considerably diminished.

By this roasting the pyrites is decomposed. The sulphur is converted into sulphuric acid, while the iron is oxydized. In what manner this change is produced it is not easy to say. Indeed, it does not seem certain that pyrites is a constant ingredient in alum slate. We have never been able to detect any, by the eye, in any specimens of Whitby alum slate which we have examined. At Hænsæter in Sweden, no sulphate of iron crystallizes when the liquid is

evaporated; yet, if pyrites had been present, it is difficult to see any reason that should prevent this salt from being formed. Hence it is probable, that, in alum slate, the sulphur is sometimes at least combined with other substances than iron. It must always be in a state of combination; for, if it were in a loose state, it would be driven off by the roasting. This point deserves to be elucidated, by analyzing different varieties of alum slate.

The roasted ore has an astringent taste, owing to the sulphate of iron and sulphate of alumina which it contains. The next process is to lixiviate it with water, in order to dissolve out these salts. For this purpose, it is put into reservoirs made of wood or masonry, with a stop-cock at the bottom to draw off the water. The usual method is to keep the water for twelve hours in contact with ore that has been twice lixiviated; then to draw it off, and allow it to remain for an equal period on ore that has been once lixiviated. Lastly, it is run upon fresh ore, and allowed to remain on it for twelve hours longer. If the specific gravity of the liquid thus treated be 1.25, at the temperature of 55°, it may be considered as saturated with sulphate of alumina and sulphate of iron. But we presume that this specific gravity is not often obtained.

The liquid, thus impregnated with salt, is now boiled down in leaden vessels to the proper consistency for crystallization. In Sweden, the fuel employed for this purpose is alum slate. By this means, a double effect is produced. The liquid is evaporated, and the alum slate is roasted. During the boiling, abundance of oxide of iron falls mixed with gelenite, if lime be one of the constituents of the alum slate. When the liquid is sufficiently concentrated, it is let into a square reservoir, in order to crystallize. Great quantities of sulphate of iron crystals are usually deposited in this vessel. These are collected by drawing the liquid off into another reservoir. When all the sulphate of iron that can be obtained has been separated, a quantity of sulphate of potash, muriate of potash, or putrid urine, is mixed with the liquid. The sulphate of potash is procured from the sulphuric acid-makers, and the muriate of potash from the soap-makers. By this addition, alum is formed in the liquid, and it gradually deposites itself in crystals on the sides of the vessel. These crystals are collected, and dissolved in the smallest quantity of boiling water that will take them up. This solution is poured into large wooden casks. In a fortnight or three weeks the alum crystallizes, and covers the sides and bottom of the cask. The hoops are now taken off, and the staves of the cask removed. A mass of alum crystals, having the shape of the cask, remains. This mass is pierced, the mother liquor allowed to run out, and preserved for a subsequent process. The alum, being now broken in pieces, is fit for sale.

The manufacture of alum from bituminous shale, and slate clay, bears a considerable resemblance to the manufacture from alum slate; but differs in several particulars. There are two works of this kind in the neighbourhood of Glasgow, managed with great skill, and excellent in every respect. We shall give a sketch of the processes followed in these works. The bituminous shale and slate clay employed, are obtained from old coal pits, which are very extensive in the neighbourhood of Glasgow. The air in these coal-pits is moist, and its average temperature about 62°. The shale, having been exposed for many years, has gradually opened in the direction of its slaty fracture, so as to resemble in some respects a half-shut fan, and all the chinks in it are filled with a saline efflorescence in threads. This salt is white, with a shade of green; has a sweetish astringent taste, and consists of a mixture of sulphate of iron and sulphate of alumina. Nothing more is requisite than to lixiviate this shale with water, in order to obtain these salts in a state of solution. The lixiviated ore being left exposed to the weather, forms more salt, which is gradually washed out of it by the rain water, and this water is collected and preserved for use.

The next step in the process, is to boil down the liquid to a sufficient state of concentration. At Campsie, all these boilers are composed of stone, and the heat applied by means of steam. This is a great saving, as leaden vessels are not only much more expensive, but require more frequent renewal. When the liquid is raised to a sufficiently high temperature in the stone reservoir, pounded sulphate of potash, or muriate of potash, as they can be procured, is mixed with it, and there is an agitator in the vessel by which it is continually stirred about. This addition converts the sulphate of alumina into alum. The liquid is now let into another trough, and allowed to remain till it crystallizes. There are two salts contained in solution in this liquid, namely, sulphate of iron and alum; and it is an object of great consequence to separate them completely from each other. The principal secret consists in drawing off the mother liquor at the proper time; for the alum is much less soluble in water than the sulphate of iron, and therefore crystallizes first. The first crystals of alum formed, are very impure. They have a yellow colour, and seem to be partly impregnated with sulphate of iron. They are dissolved in hot water, and the solution poured into troughs, and allowed to crystallize a second time. These second crystals, though much purer, are not quite free from sulphate of iron; but the separation is accomplished by washing them repeatedly with cold water; for sulphate of iron is much more soluble in that liquid than alum. These second crystals are now dissolved in as small a quantity of hot water as possible, and the concentrated liquid poured while hot into large casks, the surface of which is covered with two cross beams. As the liquor cools, a vast number of alum crystals form on the sides and surface. The casks are allowed to remain, till the liquid within is supposed to be nearly of the temperature of the atmosphere. This, in winter, requires eleven days; in summer, fourteen or more. We have seen the liquid in a cask that had stood eleven days in summer, still more than blood-hot. The hoops are then removed, precisely as in the manufacture of alum from alum slate.

There always remains in the boilers a yellowish substance, consisting chiefly of peroxide of iron. This is exposed to a strong heat in a reverberatory furnace, and it becomes red. In this state it is washed, and yields more alum. The red residue is ground

to a fine powder and dried. It then answers all the purposes of Venetian red, as a pigment. By altering the temperature to which this matter is exposed, a yellow ochre is obtained instead of a red.

In France, where alum ores are by no means abundant, alum is manufactured from clay. This method of making the salt, was first put in practice by Chaptal, when Professor of chemistry at Montpellier. His methods have been since gradually improved, and brought to a state of considerable perfection. The first process tried was this: the clay was reduced to a fine powder in a mill, and then mixed with sulphuric acid. After remaining some days, it was exposed for twenty-four hours to a temperature of about 130°. It was then lixiviated, and the liquid mixed with urine or potash. This method being found inconvenient, was abandoned for the following: the clay being well ground, was mixed with half its weight of the saline residue, from a mixture of sulphur and nitre. This residue is little else than sulphate of potash. The mixture was formed into balls about five inches in diameter, which were calcined in a potter's furnace. They were then placed on the floor of a chamber, in which sulphuric acid was made. The acid vapour caused them to swell, and to open on all sides. In about a month, they were sufficiently penetrated with the acid. They were then exposed to the air, under shades, that the saturation might become more complete. Finally, they were lixiviated, and the liquid being evaporated, yielded pure alum.

This process has been considerably improved by Berard, the present proprietor of the Montpellier alum work. Instead of exposing the calcined balls to the fumes of sulphuric acid, he sprinkles them with a quantity of sulphuric acid of the specific gravity 1.367, equal to the weight of the clay employed. But it is obvious, that the proportion must vary with the nature of the clay. The solution takes place with the greatest facility, and crystals of alum are obtained by evaporating the liquid.

Another process was put in practice by Chaptal in the neighbourhood of Paris, and is still followed, or was at least followed some years ago by M. Bouvier. A mixture is made of 100 parts of clay, 50 parts of nitre, and 50 parts of sulphuric acid of the specific gravity 1.367; and this mixture is put into a retort, and distilled. Aquafortis comes over, and the residue in the retort being lixiviated with water, yields abundance of excellent alum.

We may mention another process described by Caraudan, and certainly practicable, and even easy, though we do not believe that it would be attended with profit. He forms 100 parts of clay into a paste with water, holding 5 parts of common salt in solution. This paste is formed into cakes, and calcined in a reverberatory furnace. The calcined mass is reduced to powder, and well mixed with the fourth part of its weight of concentrated sulphuric acid. When the muriatic acid vapours are dissipated, as much water is added as there had been employed of acid, and the mass is kneaded with care. A strong heat is produced; the composition swells; more water is added; and at last a solution of potash, in which the alkali amounts to one fourth of the acid employed. The liquor is now drawn off, and, on cooling, it yields a copious deposite of alum crystals.

In the preceding sketch of the manfacture of alum, no notice has been taken of alum earth as an alum ore, because the writer of this article has never had an opportunity of seeing any manufactory of the salt from this material. We conceive the process to be nearly the same as that followed, when bituminous shale or slate clay is the alum ore. Alum earth seems to be a vegetable substance, or rather to be derived from the vegetable kingdom. It is connected with coal, and may, without impropriety, be considered as a variety of brown coal. There is a manufacture of alum from this substance at Frienwalde, in Germany. Klaproth subjected this variety of alum earth to analysis, and from 1000 parts of it obtained the following constituents:

| | |
|---|---|
| Sulphur - - - - - | 28.5 |
| Charcoal - - - - | 196.5 |
| Alumina - - - - | 160.0 |
| Silica - - - - - - | 400.0 |
| Black oxide of iron - | 64.0 |
| Sulphate of iron - - | 18.0 |
| Gypsum - - - - - | 15.0 |
| Magnesia - - - - | 5.0 |
| Sulphate of potash - - | 15.0 |
| Muriate of potash - - | 5.0 |
| Water - - - - - | 107.5 |
| | 1014.5 |

The excess of one and a half *per cent.* obviously proceeded from the water adhering to the salts. (J.)

AMBOYNA. The reader will find some interesting particulars regarding the history of this celebrated island in the body of the work. Its great importance, as the centre of the *Clove-trade*, renders it necessary that we should here enter into some further details. It is divided into two unequal parts, by two deep bays, which are separated only by a narrow isthmus of one mile across. The bay on the west side extends to about two thirds of the length of the island, and forms a commodious and safe harbour. That on the east side is much smaller, and, as a harbour, very insecure, both on account of its bad anchorage, and of its rocky shores. The largest division is called Hitoo, and the smallest division Leytimoor. Although the larger bay is more commodious for a settlement, it is in the Leytimoor division that the Europeans have chosen to fix their residence; and they have here erected their principal fortification of Victoria, which is an irregular hexagon, with a ditch and covered way on the land side, and a horn-work towards the sea. Being commanded however by two ranges of heights, at the distance of from 700 to 1200 yards, it could make no serious resistance against an invading force. "The town of Amboyna is extremely clean, and both neatly and regularly built. The streets run at right angles, and the houses, on account of the frequency of earthquakes, are seldom above one storey high. From the covert way of the fort to the town, there is an esplanade of nearly 250 yards, terminated by a range of handsome dwelling-houses, with a double row of nutmeg-trees

Amboyna. in front of them. In these houses, the principal inhabitants reside. There are two well built churches in the towns established by the Dutch Government, one for the European, the other for the Malay Christians. All the other public buildings are in the fort, except the stadthouse, which fronts the esplanade, and is a neat building of two stories." *(Asiatic Annual Register for* 1800.)

Amboyna has long been the seat of the supreme government of the Spice Islands; and, under its jurisdiction are comprehended ten other islands; namely Ceram, which is equal in size to all the rest, Ceram Laut, Bouro, Amblaw, Manipa, Kelang, Bonoa, Harackau, Saparoua, and Noossa Laut. The cultivation of the nutmeg has been, for some years past, prohibited in Amboyna; the industry of its inhabitants being chiefly directed to the rearing of the clove-tree. It is only in Amboyna, and the three islands of Harackau, Saparoua, and Noossa Laut, that cloves are now cultivated.

"The clove-tree grows to the height of about forty or fifty feet, its branches spread, and its leaves are long and pointed. In a favourable soil, it begins to bear at fifteen years' growth, is in perfection at twenty, and continues to bear, without any apparent decay, till the age of forty or fifty. Some trees yield thirty pounds of cloves; but the average quantity produced, does not amount to more than six pounds a tree. They grow to the greatest perfection in deep vallies, well sheltered by hills and woods, and in a soil of a rich black mould, quite dry; though they require frequent rains for the greatest part of the year, and very hot weather at the gathering season; which commences generally about the latter end of October, or the beginning of November, and continues until February. In April and May, there is an after-crop, but of a very inferior quality." *(Asiatic Annual Register for* 1800.*)*

The Dutch East India Company appear to have been actuated by the same sordid, narrow, and oppressive views, which have, in a greater or less degree, characterized all the European governments established in the east. Cloves, the great article of produce throughout the island, are rigorously engrossed for the benefit of the Company. And for the convenience of this monopoly, the province, and its dependencies, is divided into several districts, over which residents or governors are appointed, for the purpose of preventing all contraband trade, and to take care also, that the whole produce of the country is strictly delivered up at a fixed price. The Governor has under his immediate management seven great, and twenty-four small districts; and the subordinate residents have committed to them from six to ten districts, with the exception of the resident of Saparoua, who has under his superintendence twenty-four districts. These districts are likewise called regencies; and the officers who govern them are distinguished by the names of Regents, Rajahs, Patties, and Orankaios. Several of these regencies are hereditary, and are enjoyed by the lineal descendents of the Portuguese families who first settled in the island. All the others are appointed by the Governor, although, in this respect, he is obliged to regulate his choice by the ancient customs and prejudices of the people, whose reverence for the ties of consanguinity Amboyna. carries them so far, as to induce them to keep a regular pedigree of their families, which is registered in the secretary's office, and on which the candidate for a vacant regency rests his primary claim. The regents are the vassals of the Company, who not only claim the sovereignty of the island, but the actual property of the soil; the whole of the lands being in their immediate possession, except a few pieces of ground belonging to burghers and private persons, who, under the prohibition of cultivating the clove-tree, are permitted to alienate them. A similar claim has been advanced by the English East India Company to all the lands of Bengal. But the justice of these claims is exceedingly doubtful; for it is certain that, before the English or Dutch visited India, the soil was possessed; and the question is, how the new claimants came to have a better title than the original proprietors? In Amboyna, however, though the Dutch Company claim a paramount right in the soil, they still so far acknowledge the rights of individuals to certain districts, that they do not attempt to deprive them of their property without compensation; especially if their lands produce clove-trees, which, being considered the peculiar inheritance of the planters, are held to be inviolable.

It is only in the districts marked out by the state, that the cultivation of cloves is permitted; and the grounds which are appropriated for this purpose, are portioned out to the inhabitants. These grounds are called *Daty-lands*; a regular register of the produce of them is kept; the clove-trees are numbered once a-year; and their qualities particularly noted. The entire produce of these trees the people are bound, under pain of death, to deliver annually into the Company's stores. Where clove-trees flourish spontaneously without the limits of the lands appointed for their cultivation, an account of them is immediately taken, and inserted in the register; and where young trees shoot up, they are immediately transplanted into *Daty-lands*, unless the number of trees in them is already sufficient.

To enforce the law for cutting down all the clove trees, which, from the spontaneous bounty of nature, may shoot up in different parts of the island, an annual circuit is made by the governor, accompanied by a detachment of troops, and such of the gentlemen of the settlement as he may appoint to accompany him. As this expedition is performed by water, it is escorted by a number of the regents of the districts in their barges, which they are obliged to equip at their own expence. The governor generally sets out in the middle of October, attended by all the residents of those districts under the immediate management of the supreme government. As he proceeds, he calls on the attendance of all the principal people of the district through which he passes. He makes the tour in this manner of his whole dominions, continuing to increase his train of attendants, until, having made the complete circuit of the island, he returns to his capital. His annual cavalcade is much complained of, on account of the numerous exactions to which it gives rise.

In gathering the cloves, each labourer brings the quantity which he gathers to a weigh-house, where the

name of the person, together with the quantity delivered, is regularly noted. But, unless the cloves are thoroughly dried, the full weight is not always admitted. There must be an allowance for wastage, which is entirely at the discretion of the receiving officer, and under this pretence the unprotected inhabitants are exposed to numerous frauds. The price at which cloves are received by the State is 4s. 8d. *per* pound. But this price is merely nominal, in consequence of large deductions being subsequently made on various accounts. Of these the principal is an allowance of 20 *per cent.* on the weight of the cloves, for the benefit of the governor, and the other servants of the Company; besides which, there are other deductions for the regent and chief magistrates of the district, and the labourer's wages are also paid out of the price allowed by the State. The annual produce of cloves is estimated at 600,000 lb., from which a deduction of one-fifth, or twenty *per cent.* amounts to 120,000 lb.; and the tribute thus levied is portioned out among the residents and members of the executive government, according to their respective ranks. The produce of cloves is apt to vary, however, according as the season is favourable or otherwise.

For six years, ending 1791, the average quantity of cloves imported into Holland amounted to 597,617 libs., and were sold for a sum equal to L. 155,129; besides which, considerable quantities are annually sent to various parts of India, Persia, Arabia, and China; the exact amount of which it is impossible to ascertain. When the island was taken possession of by the British in 1796, there were in store 515,940 libs. of cloves. The quantity imported by the English East India Company after the conquest of the island by Britain, was, in the years 1803, 1804, 1805, respectively, 49,441; 127,866; 179,507 libs, which were sold for L. 8,789; L. 19,994; L. 27,912.

The despotism under which this fine island is oppressed, is sufficiently implied in the monopoly of its produce for the state, and in the severe and sanguinary laws which are found necessary to prevent contraband trade. If the government were to deal fairly with its subjects, the temptation to resort to other countries with this produce would be much diminished; and, in proportion to the severity of the laws established against such an intercourse, we may, therefore, fairly estimate the extent of the fraud practised upon the inhabitants by their mercantile despots. Monopoly, besides being in itself an odious abuse, is an impure source from which other abuses naturally spring; and in Amboyna, accordingly, we find that, as the produce of the inhabitants is engrossed by the State at an undervalue, they are upon the same principle forced to purchase at prices proportionally exorbitant, whatever necessaries they may require. A lucrative trade of this nature is carried on by the residents of the respective provinces, as well as by the military officers at the outposts with the peasantry under their authority. They procure from the supply of stores which the Dutch company used to send annually from Batavia, such articles as the natives require, particularly blue cloth, which they oblige them to purchase at a price far above its value; and, in order to furnish them with the means of satisfying their wants, the residents lend them money at usurious interest; so that these people are reduced to the miserable alternative either of submitting to the grossest oppression and fraud, or of remaining destitute of those things which nature and custom unite to render necessary. The accumulated debt in which the peasantry are thus involved, is a never-failing instrument of bondage and oppression; as it places them entirely at the discretion of their task-masters, to whose bounty they are indebted for their miserable subsistence. An order in council was published by the Dutch government, some time before the island was conquered by the British, prohibiting the residents from stopping from the peasantry for debts due to themselves, more than two-thirds of the amount of their spice money. But, while the residents retain the extensive powers with which they are necessarily vested, in order to enforce the system of monopoly, the peasantry must be at their mercy; and in that case, the government being tyrannical in its principle, pretexts will never be wanting for evading the force of particular laws.

The maxims on which this country is governed are well explained in a Code of written regulations drawn up by order of the Dutch Company some years before the island came into the possession of the British. This Code, in place of containing mild and liberal regulations for the general improvement of the community, is filled with all the impolitic restrictions of avarice and despotism; the general tendency of which is, by bending down and oppressing the lower orders of the community, to strike at the root of national prosperity, and, finally, to impoverish and degrade the country. From a view of those regulations, it appears to have been the settled policy of the government of Amboyna for 150 years back, to discourage cultivation,—to check all attempts to establish manufactures,—and, in short, to suppress every improvement which might enable the inhabitants to supply their own wants, and might thus render them independent of the monopolies established by their rulers. In this they have been but too successful; and hence the people are fettered down in a state of the most wretched poverty and dependence,—destitute of the common necessaries of life, in consequence of their progressive advance in price; while, in the meantime, the wages of labour have been forcibly depressed, or rather indeed have been kept back from the labourer by fraud; he being bound to the state for a variety of severe duties and services, for which he receives no remuneration. In consequence of these oppressions, the inhabitants are poor and indolent. Agriculture has made no progress. Not more than one-tenth of the island is under cultivation, and it is therefore dependent on Java for supplies of cattle, and grain. The same causes which have discouraged the cultivation of land and the rearing of cattle, have prevented the improvement of manufactures, or of the mechanic arts; of which the inhabitants are so ignorant, that they do not even manufacture the coarse cloth of which they make their own wearing apparel; but are furnished with it from Java or Ben-

gal, and receive it in retail from the residents and men in office, at such prices as they choose to fix on it.

All the natural productions of this island are in like manner neglected by the policy of its rulers. It formerly produced indigo of the finest quality and colour. But the growth of this valuable commodity was discouraged by the Dutch, chiefly with a view of protecting the indigo trade carried on between the mother country and her colonies in the West Indies; and from a jealousy also, that the natives, by acquiring wealth, might be enabled to assert their independence. Sugar grows to great perfection; but its cultivation is discouraged. Coffee is produced in great plenty in different parts of the island; and, were the culture of it sufficiently attended to, it would be equal in quality to the first Mocha coffee. Wheat might be cultivated to great advantage on the beautiful heights contiguous to the town of Amboyna, the soil and climate being well adapted for it. Of maize there is already a great abundance; and the dry and mountain rice is known here; but they have been but little attended to. The bread-fruit tree grows spontaneously all over the island; but is only made use of by the lowest orders of the people. The cocoa tree also grows here; but the cultivation of it is almost entirely neglected. If the culture of vegetables were sufficiently attended to, this island would produce a great variety of the finest quality. All sorts of roots are produced in abundance, particularly yams and sweet potatoes; and the increased circulation of specie, since the island has been in possession of the English, has induced the farmers to bring ample and regular supplies to the market. There is also great variety of fruits, of the finest quality and flavour. The general appearance of the island is extremely beautiful and picturesque. Mountains everywhere covered with lofty woods in perpetual foliage, and valleys clothed in verdure, interspersed with hamlets, and enriched by cultivation, exhibit the most delightful variety that nature in those tropical regions is capable of producing.

Amboyna was captured by the British in 1796, and restored to the Dutch by the peace of Amiens. It was again taken possession of in 1810, and restored to its former owners by the treaty of Paris concluded in 1814. See *Asiatic Annual Register for* 1800, p. 200; and Mr Milburn's valuable work, entitled *Oriental Commerce*, Vol. II. p. 394. (o.)

# AMERICA.

IN the Encyclopædia, there will be found, in its proper place, a full account of the first discovery of this vast Continent, and of the history, manners and institutions of its native tribes. There, also, will be found, some general views of its physical geography, and of its natural history. In the present article, we propose to exhibit a rapid sketch of the progress which has been made towards its full discovery; confining ourselves, however, chiefly, to those more recent exploratory enterprizes, by which its geography has been in any material degree corrected or illustrated.

*Progress of Discovery on the American Coasts.*

I. The sensation excited throughout Europe by the original discovery of America, gave rise among the maritime states to such a spirit of adventure, that in the course of the two succeeding centuries, the eastern, and a considerable part of the western coast was surveyed with tolerable accuracy. But the spirit of enterprise, satisfied with such vast contributions to the stock of geographical knowledge, appears to have languished for a time; and the expeditions of different navigators, who had successfully explored the north west coast of America, were either but imperfectly remembered, or were discredited as fabulous; while, in the absence of any solid discovery, the attention of mankind was occupied with the theory of a great southern Continent, or with the impracticable scheme of a passage to India through some of the inlets on the American coast.

In pursuance of this last project, different expeditions were undertaken during the early part of the last century; and though they all failed as to their original object, they were nevertheless extremely useful, as they led to an accurate survey of the shores of the different bays and inlets, through which there was any possibility of finding this much desired passage. It was owing to views of this sort, that the shores of Hudson's bay were so completely explored; and it was to the same notion of finding out a north west passage to India, that we are indebted for the knowledge which we possess of Baffin's bay. It was partly also with a view to this object, that Mr Hearne was dispatched, in the year 1770, under the orders of the Hudson's Bay Company, into the interior of the country, for the purpose of penetrating by land to the Northern Ocean. Mr Hearne set out in December from Fort Prince of Wales, situate in north latitude 58° 50′; and, after passing in a north-west course through the various tribes, who, without any fixed habitations, spend their miserable lives roving over the dreary deserts and frozen lakes of this immense tract, first added to the known geography of the Globe by this adventurous traveller, he reached Coppermine river on the 13th of July. This river he pursued to its mouth, which he places in the 72° of latitude, and about 25° west longitude, from the Fort from which he took his departure. It was then the 18th of July; and he states, that he viewed the sea at the river's mouth, which was full of islands and shoals, and that, though the season was so far advanced, the ice was not yet broken up, but only thawed about three quarters of a mile from the coast, and a little way round the islands and shoals. The result of this journey determined the northern limits of the American Continent, and set for ever at rest the notion of any passage through the barrier of eternal ice which surrounds its shores.

It was for the purpose of exploring the north west

coast of America, in search of a passage which might communicate with Hudson's or Baffin's bay, that Captain Cook was dispatched on his third and last voyage, in the year 1776. Having touched at the Cape of Good Hope, and at the various islands situate in the great Southern Ocean, this celebrated navigator did not arrive on the coast of America, till the year 1778. He anchored in Nootka sound on the 29th March; but he was so thwarted by unfavourable winds, that, with the exception of a few projecting headlands and capes, he could obtain no accurate view of the coast, until he reached the latitude of 55° 20′. About the latitude of 58°, he discovered an inlet, called by him Cross Sound; which is the last inlet towards the north, on that great extent of broken coast commencing on the north west shores of the American Continent, with the strait, said to have been discovered by a Greek pilot named De Fuca, and of which the reality was long called in question by subsequent navigators.

From the 58th parallel, Cook made an accurate survey of the coast, having explored Prince William's Sound, and the inlet now distinguished by his own name, until he was satisfied that they could lead to no ulterior navigation. He thence coasted along the peninsula of Alaska, and passing through that archipelago which is known by the name of the Aleutian islands, and which has the appearance of being a prolongation of the two opposite Continents, he entered Beering's bason; and advancing to the straits which divide Asia and America, he ascertained with accuracy the relative limits of these two great divisions of the Globe. Coasting along the American shore, and incessantly struggling with shoals and floating mountains of ice, he advanced into the Arctic ocean, as far as the parallel of 70° 44′, which he reached on the 18th of August. Here his further progress was arrested by a plain of solid ice, which extended from shore to shore; and here, therefore, is the utmost limit of the navigable ocean, betwixt the Continents of America and Asia. It may be remarked, that between Europe and America, the ocean continues navigable to within a few minutes of the 81st parallel, which was the latitude reached by Captain Phipps, in the year 1773, when he attempted to penetrate in this direction towards the east.

It appears, from the researches made by Humboldt in New Mexico, that the north-west coast of America was, at an early period, visited by the Spanish navigators, as far as the 57th degree of north latitude. But the result of these expeditions was studiously concealed by the Spanish government; from an apprehension, that the other nations of Europe would be tempted to form establishments on that coast, and thus to encroach on the exclusive title claimed by Spain to its possession. But when it was found, that, notwithstanding the utmost caution of that power, the maritime states of Europe were proceeding to examine those hitherto unknown shores, various expeditions were fitted out after the year 1774, by the government of Spain for the same purpose. In the course of these expeditions, the Spanish navigators extended their survey from San Carlos de Monterrey, on the coast of California, as far as Cook's Inlet; but their researches, though they determined with great accuracy various insulated points, were very far from affording an exact geographical delineation of the American coast.

Beyond the 58th parallel, the discoveries of Captain Cook are blended with those of the Russians, who, from their vicinity to America, have been enabled in some degree to anticipate the visits of the other European states to the north western part of that continent. To him, however, still belongs the glory of having first ascertained the true bearings of this portion of America; of having determined the limits of the two Continents; and of having at length furnished a key to the interesting problem as to the original population of the New World, formerly the source of so many vain, though ingenious conjectures.

While Captain Cook was engaged in these researches on the north-west coast of America, his sailors availed themselves of the opportunity of entering into an intercourse with the natives; from whom they procured, for European articles of small value, a supply of skins of sea otters and other animals. These being carried to China, were sold at an exorbitant profit; and Captain King, who succeeded Captain Cook in the command of the expedition, was so struck with the favourable opening which appeared to present itself for establishing a lucrative commerce, that his account of the voyage contained the exposition of a plan for a regular trade between the north west coast of America and China. The merchants of Europe, America, and China, tempted by the prospect of enormous profits, were eager to enter into the proposed trade, and the hitherto unknown and uninviting shores of north west America, were now frequented by trading vessels from different quarters of the Globe. In the course of those commercial adventures, various important inlets were discovered in the American coasts, which had unaccountably escaped the researches of the different navigators by whom they had been visited. In consequence of these discoveries, the expectation of finding a north-west passage to India began to revive; and the expeditions of the Greek pilot De Fuca, and of the Spanish Admiral De Fuente, both of which had long been treated as fabulous, were again brought into some degree of repute. With the original accounts of De Fuca's and Fuente's voyages, the most romantic tales had been circulated respecting the extent of coast which they had discovered, and the abundance of gold, pearls, and precious stones to be found in those unknown countries. These embellishments were added, for the purpose, apparently, of amusing the credulity of the age, and of thus attracting a degree of consideration which the mere fact of the discovery of an unknown coast would have hardly secured. But as the tradition, in both cases, was accompanied with such obvious fictions, the reality of the voyages was disbelieved; and, indeed, the whole passed for a mere invention. The reader will find some curious details upon this subject, in the Introduction prefixed by Fleurieu to the account of Marchand's *Voyage round the World.*

Juan de Fuca, a Greek pilot of the island of Cephalonia, is said to have been dispatched, in 1592, by the Viceroy of Mexico, to examine the west coast of America, for an inlet which might lead to a communication with the Atlantic ocean. When he ar-

America. rived between the 47th and 48th parallels, the land extended to the north east, and presented a large opening, into which he entered, and continued sailing in it for twenty days. He frequently went on shore, where he met with the natives in great numbers, who were clothed in the skins of animals; and finally, the account stated that he reached the Atlantic ocean, and that he returned to Acapulco after an absence of two years, warmly soliciting to be rewarded for his pretended discovery.

The account of the voyage of Admiral de Fuente, which was undertaken in 1640, states, that, being on an expedition of discovery on the west coast of North America, he came, after a prosperous voyage, from the 26th to the 53d degree of latitude, where, having found an extremely broken coast, he sailed about 260 leagues in crooked channels, and amongst an extensive collection of islands, which he named the Archipelago of St Lazarus. Here, it is said, his ships boats always sailed a mile a-head, to reconnoitre the passage, which was full of shoals, rocks, and sands. The account, besides, contains various details in regard to an extensive inland navigation by means of lakes and rivers; and it is even asserted, that they met a vessel which had come in this way from Boston on the other side of the Continent; but M. Fleurieu contends, that this piece of fiction must have been a spurious addition to the original narrative, as it is explicitly stated in the concluding part of it, that no passage was found which communicates with the Atlantic ocean. If they had met with a vessel from Boston, this of course was a clear proof of the existence of a communication with that ocean.

Although the accounts of these two voyages have been generally regarded as mere fables, the features of this part of the American shore, as they were gradually discovered by the commercial navigators who visited it, from the year 1787, were found to coincide so remarkably with the previous representations contained in the narratives of De Fuca and Fuente, as to afford a strong presumption that they had actually navigated those coasts. It was ound, wherever the coast was explored, from about the 48th to nearly the 58th parallel, that it was broken by numerous inlets; and that it was in the latitude of 53, as Fuente had described it, a complete archipelago, full of bays, harbours, intricate channels, and islands. In like manner, one of the trading vessels which visited this coast in 1787, commanded by Captain Berkeley, discovered a large inlet or strait between the 47th and 48th parallels, which is the latitude assigned for De Fuca's inlet in the narrative of his voyage. The same strait was observed in the following year by Captain Duncan, who anchored also in several harbours on the east of Queen Charlotte's islands; and surveying all that portion of coast which lies between the 54th and 51st degrees, found one continued cluster of islands, with numerous bays and passages. In 1789, this coast was visited by Captain Meares, who discovered the strait, and, anchoring in it, sent forward his long boat to make observations. The boat, he observes, sailed near thirty leagues up the strait, and at that distance from the sea, it was about fifteen leagues broad, with a clear horizon stretching towards the east. The boat's crew were there attacked by the barbarous natives, who had entered into a scheme for robbing and murdering them. A desperate conflict ensued, in which Captain Meares's crew, having repulsed the attack, were glad to escape without attempting any farther examination of those inhospitable shores. In the course of this voyage, the account contained in the exploded narrative of De Fuca, as to the coast, and the inhabitants, was found to agree, in several minute circumstances, with the observations of Captain Meares. In particular, a great headland or island described by De Fuca, was recognized; as well as a high pinnacle rock, placed, as he stated it, in the entrance of the inlet. The inhabitants were also found clothed in furs and bears skins; and a remarkable custom related by De Fuca, of binding the children's heads between two boards when young, so as to give to them the form of a sugar loaf, was still observed by Captain Meares, to prevail generally among these savages. The latitude assigned to the inlet by De Fuca and Captain Meares, was not exactly the same; but, the difference was such, as may be easily accounted for by the comparatively imperfect instruments in use among the early navigators. In addition to the preceding information, it was stated by Captain Meares, that the American ship the Washington, Captain Gray, had completely explored this strait, and found that it inclosed a large part of the Continent, communicating at both extremities with the Pacific Ocean. In the chart annexed by Captain Meares to his work, the track of the Washington through this interior sea is even marked. It appears, however, that no such voyage was ever made, Captain Gray, though he examined De Fuca's inlet, having returned by the same channel through which he had entered, without finding its termination.

The discovery of a great inlet in this part of the American coast, to which no termination had yet been found, and which had escaped the researches both of Cook and of the Spanish navigators, gave rise to various speculations. Among others, it revived the exploded hope of an existing communication between the Atlantic and Pacific oceans. It was imagined, that this inland sea might be connected with some of the great lakes in the interior of North America; that, if no communication actually existed with Hudson's or Baffin's bay, it might not be found a very arduous task, by calling in art and industry to the aid of nature, to effect this great improvement; and at any rate, that the prospect of such an inland navigation as was now opened by the recent discoveries, must be of vast importance to the future commerce and civilization of the American Continent. To ascertain the precise extent of those discoveries, an expedition was fitted out by the British Government, and placed under the orders of Captain Vancouver, (who had sailed twice round the world with Cook); with instructions to survey the west coast of America, from the 30th degree of north latitude to Cook's river. He was particularly directed to examine all the inlets with which he found the coast indented, for the purpose of discovering whether any navigable communication existed with any of the great lakes in the interior; and with this view, Cook's river was

America.

also recommended to his careful observation, as it was conjectured, that it might take its rise in some of the inland lakes already known to the Canadian traders. Captain Vancouver set out on his voyage in the end of the year 1790, and, after visiting several of the islands in the Pacific Ocean, he arrived on the coast of America in 1792. Having surveyed the coast from Cape Mendocino, he entered De Fuca's inlet in latitude 48° 23′½, and continuing his course almost directly into the Continent, for nearly 100 miles, he observed that the strait turned to the north west and south east. The southerly branch was found to terminate after a winding course of about ninety miles, in lat. 47° 21′ N., long. E. 237° 6′, in low and apparently swampy land. The northerly branch was next surveyed by Captain Vancouver, in all its numerous inlets; and after running in a north west direction, generally parallel with the coast, it was found to terminate at length in the Pacific Ocean, in Queen Charlotte's sound, in N. lat. 51° 45′, long. 232, 1 E.; cutting off from the Continent that large island, since distinguished by the name of Quadra and Vancouver, the two navigators, the one belonging to Spain, the other to Britain, by whom it was first surveyed. The survey of this strait was conducted with singular perseverance through a course of most perilous navigation; occasioned by the numerous islands and sunken rocks, which in many parts interrupt the passage,—by the rapidity of the current from those interruptions,—and, finally, by the great depth of the channel, which frequently affords no anchorage. In many places, the strait is of an unfathomable depth; and where it was only two miles wide, no bottom was found with 110 fathoms of line. Proceeding northwards, Captain Vancouver completed, amid various perils and fatigues, his laborious survey of that great archipelago, which extends along the American coast, to nearly the 59th parallel, and ends with Cross sound. Every bay was diligently explored, and every inlet traced to its termination. Prince William's sound was next examined, and, lastly, Cook's river, or rather inlet. Captain Cook, when he was advancing into this inlet, found the water grow less salt the farther he penetrated, and he thence concluded it to be the outlet of a large river. Captain Vancouver entered the inlet with his vessel as far as it was navigable; and he afterwards advanced with his boats, until he found the eastern banks gradually unite with those on the western side, in N. lat. 61° 29′ E. long. 211° 17′. Thus terminated for ever the long cherished hope of a north west passage to India. Every bay and inlet on the north west coast of America has now been minutely examined; and it has been found, that the Continent, throughout its whole extent, interposes between the Atlantic and Pacific Oceans, and that beyond its northern limits, a frozen sea presents an impenetrable barrier of ice to the enterprises of navigation.

While Captain Vancouver was engaged in his survey of the American coast, an expedition was fitted out nearly about the same time from Acapulco, under the orders of Don Dionisio Galiano, and Don Cayetano Valdes, for the purpose of surveying De Fuca's inlet, which had already been entered and examined to a certain extent by the Spanish navigators. In the course of this voyage, the Spanish and English expeditions met. Their respective commanders made a mutual and unreserved communication of their discoveries; they assisted one another in their operations; and the best understanding possible subsisted between them till their separation. The charts drawn up in the course of these expeditions have been all published without reserve; and they contain a most correct delineation of the American coast, from the 45th degree of latitude to Cape Douglas, in the east of Cook's inlet, which, before this period, was but imperfectly known. The coast from the 58th parallel, having been in some parts visited much about the same time by the English, the Spaniards, and the Russians, the same place has frequently received a name from the navigators of each of these nations. From this circumstance some confusion is apt to arise. We are occasionally perplexed by the synonymous appellations of different navigators; and it is only by a minute comparison of their respective charts that this inconvenience can be obviated.

Progress of Discovery in the Interior of North America.

II. While, in the course of three centuries, from its first discovery, the seaward limits of the North American Continent have been thus accurately surveyed, the progress of discovery in the interior has necessarily been much slower. Although numerous perils, no doubt, beset the navigator of an unknown coast, the ocean still presents a more favourable scene of enterprise than the land. An insulated band of travellers, traversing the deserts of an unknown Continent, are exposed to so many causes of destruction from the climate, from fatigue, famine, or the hostility of barbarous tribes, that enterprises of this nature are more unpromising than maritime expeditions; and they have accordingly been less frequently undertaken. Since the first settlement, however, of the European colonists in America, population and improvement have been regularly advancing; and the European inhabitants, gradually extending themselves over a large tract of the country, have now penetrated, more especially in North America, to a great extent into the interior. The rapid increase of population naturally produces an anxiety to inquire into the state of the unexplored country, and to ascertain how far it is adapted to the purposes of civilized life. With this view, several important journies have of late been undertaken, under the orders of the American government; while, in other parts, individuals have been occasionally prompted by a spirit of adventurous curiosity, or the love of science, to penetrate the unfrequented deserts of the New World. Of these journies, with their geographical results, we shall endeavour to submit a short abstract to our readers.

The ardour with which the fur trade in Canada began to be prosecuted from about the year 1770, naturally induced the rival adventurers who were engaged in it to advance as far as possible into the interior parts of the country; and it is now affirmed, that their journies extend from Montreal, in a north-westerly direction, to the astonishing length of nearly 4000 miles. The superintendents, clerks, interpreters, canoemen, and Indians, by whom this trade is carried on, generally set out, to the number of about two thousand persons, from Montreal, in the beginning

of May, and arrive upon Lake Superior about the middle of June. After transacting their business at this station, the different detachments proceed into the interior, for the purpose of collecting furs from the Indian tribes, in exchange for European goods. In conducting this commerce, they pass along a vast succession of dreary lakes and dangerous rivers, interrupted by rapids and carrying-places, which stretch into the interior as far as Fort Chepewyan, on the banks of the Lake of the Hills. Mr Mackenzie, who belonged to the Canada Fur Company, and who, in the course of his commercial business, had been accustomed to encounter all the hardships of this interior navigation, was encouraged, by the experience and knowledge which he had acquired of the country, to undertake a journey across the Continent, with the hope of reaching the Pacific Ocean. He accordingly set out from Fort Chepewyan, on the Lake of the Hills, and passed down the Peace, or Slave River, to the great Slave Lake; the waters of which he found so much incumbered with ice, in the middle of June, that he was obliged to coast round it till he reached its main inlet, towards the north-west, in lat. 61° N. He embarked on this stream, of which, the course being at first westerly, he naturally conceived that it would lead to the Pacific Ocean. It afterwards turned, however, to the north-west, and finally took a northerly course, carrying him forward with a rapid current, not towards the Pacific, but towards the Frozen Ocean. He was warned of his approach to the sea by the action of the tide in the channel, and on the shores; and he was then in lat. 69° N., west long. 134; about 24 degrees to the westward of the point at which Mr Hearne arrived in 1771.

The result of this expedition sufficiently demonstrated to Mr Mackenzie, that the route to the Pacific must be sought further to the south; and, far from being discouraged by the fatigues and perils which he had encountered in his first journey, he resolved to ascend to the source of the Unijah, or Peace River, in the Rocky Mountains, from which it flows nearly in an easterly direction, joining Slave River, and finally entering Slave Lake from the south. That he might have the whole summer before him, Mr Mackenzie set out from Fort Chepewyan, in the month of October 1792, with the intention of wintering in the remotest establishment of the Company, and of beginning his journey from this advanced station, as early in the spring as the river was navigable. He spent the winter accordingly among a tribe of Chepewyan Indians, and set out upon his adventurous expedition on the 9th May 1793. He arrived, after many difficulties and dangers, at the source of the Unijah, in lat. 54° N. long. 121° W. on the 13th of June. Here he found that he was only a few miles from the Tacoutche or Columbia, which, taking a southerly course, falls into the Pacific, in 46° 10′ N. lat. He embarked on this stream, and experienced great difficulties at first, from rapids and falls; but, as the stream enlarged, the navigation became easier, and he followed the course of this river till the 24th of the month, when he was induced, by the information which he received from the natives, to leave it, and to proceed by land directly across the Continent to the sea. In the course of twelve days, during which he was exposed to a variety of fatigues and dangers, he reached another stream, of which the navigation was more practicable; and having procured a canoe, he arrived on the shores of the Pacific Ocean, about the 22d of July, in lat. 52° 21′ N., long. 128° 2′ W.; immediately to the southward of the islands which Vancouver has distinguished by the name of Princess Royal's Islands. Mr Mackenzie returned by the same route, and arrived safely at the point from which he set out, on the 24th August 1793.

The journies of Mr Mackenzie appear to have been conducted with singular perseverance and intrepidity; and they have thrown considerable light on the geography of North America. The countries, indeed, which he traversed, are inhabited by savage tribes, who possess no peculiarity in their character different from other savages; being chiefly occupied with the mere wants of animal life, and having little attention or curiosity to bestow on any thing else. They are fickle besides, and treacherous, but easily deterred from open violence. It was of importance, however, to determine, at particular points, the northern limits of the American Continent, and to mark the course of the rivers which flow through this dreary country into the Frozen Ocean; and the account of the river since known by the name of Mackenzie's River, is in this view a real accession to geography. It is pleasing also to observe the near approach of the sources of the Unijah, or Peace River (which is connected with that great succession of lakes and rivers, terminating in the St Lawrence), and the Tacoutche, or the Columbia, which flows into the Pacific Ocean. In the present desolate state of this part of the American Continent, the vicinity of the various streams which flow in opposite directions into the Atlantic and Pacific, from that great dividing ridge of mountains which intersects the interior almost to the Frozen Ocean, can be of little moment; but, in a different stage of its progress, when these dreary abodes, at present the haunts of savages or of beasts of prey, are filled with industrious inhabitants, the facilities of inland communication which the country derives from the convenient distribution of its lakes and rivers, must be of vast importance to its future improvement.

The expeditions of discovery into the interior of North America, undertaken by order of the government of the United States, have been productive of much interesting information. These are, first, the journey of Major Pike, with a small detachment of troops, to the source of the Mississipi; second, his journey into the interior of Louisiana, for the purpose of exploring the course of several of its subordinate streams; and, third, the remarkable journey of Captains Lewis and Clarke to the source of the Missouri, and afterwards across the Rocky Mountains to the mouth of the Columbia, which flows into the Pacific Ocean.

The source of the Mississipi, and the country through which it takes its course, were but imperfectly known before they were visited by Major Pike. This enterprising officer left Fort St Louis, near the

America. junction of the Missouri with the Mississipi, on the 9th August 1805, and was nearly nine months in performing his interesting journey; during which, he laid down, with the greatest accuracy, the course of the Mississipi. He examined its banks, and collected information respecting the barbarous tribes who inhabit the adjacent country. The Mississipi, it appears, is divided near its source into two branches, one of which loses itself in Leech Lake, while the other, which may be termed the upper source of the river, takes its rise in Upper Red Cedar Lake, of which the lat. is 47° 42′ 40″ N. From this point, the distance to some of the head waters, which fall into Hudson's bay, is only about two leagues; the waters of the American continent being, in this manner here, as in other places, admirably disposed for interior navigation and commerce. The Mississipi generally flows from N. W. to S. W., and from its source to its mouth, in the Gulf of Mexico, is estimated to run a course of 2000 miles.

The second expedition of Major Pike was undertaken in the years 1806 and 1807; and was directed into the interior of Louisiana, with a view of examining the course of the various rivers which take their rise in the Rocky Mountains, and, running nearly westward, either fall into the Missouri from the south, before its confluence with the Mississipi, or into the Mississipi, after the two rivers are joined. Within this space four capital streams flow into these rivers; namely, the Kanses and the Osage, which join the Missouri, and the Arkansaw and the Red River, which flow into the Mississipi. The course of these rivers was but very imperfectly known until of late years, when they were surveyed by different parties of discovery, sent out by the Spanish or American governments. Several rivers were seen, indeed, to rise in the Rocky Mountains, which, it was nearly certain, must fall into the Missouri or the Mississipi; and as these last rivers were, in like manner, known to receive several large streams, it was naturally conjectured, that they were the same of which the source had been discovered at so vast a distance in the Rocky Mountains. Humboldt, accordingly, concluded that the river which rises to the north-east of the village of Taos, and which receives the Rio Mora from the vicinity of Santa Fe, is the same river which, in Louisiana, is called the Red River; and recent investigations have proved his conjecture to be right. In the course of Major Pike's expedition, in which the whole party had nearly perished from cold and famine, the Osage river was first surveyed, and was found to run a course of 1500 miles before its junction with the Missouri. The party next proceeded by land across the country to the Arkansaw, which they traced to its source; from which this great river, taking its windings into the account, was estimated, before it joins the Mississipi, to run the enormous length of 2173 miles. During the whole of this space, it may be navigated with boats properly constructed for the purpose, except for about 200 miles after it enters into the mountains. It receives, also, several small rivers, which are navigable for upwards of a hundred miles. From the Arkansaw, the exploring party proceeded northwards, and discovered the sources of America. two streams, which they conjectured to be the head waters of the Plate and the Yellow-stone rivers. Great light has been thrown on the geography of this part of the country, by the journey of Lewis and Clarke, and from their researches, Major Pike's conjecture as to the Plate appears to have been right; but he has mistaken a subordinate branch of the Yellow-stone River, called by Lewis and Clarke Beghorn river, for the principal stream. Major Pike returning, and proceeding to the south, struck into another stream, which he supposed to be the Red River. But he was met by a party of Spanish troops, who informed him that it was the Rio del Norte; and, being on the Spanish territory, he was made prisoner with his whole party, and carried into New Mexico.

The course held by Major Pike never brought him near the Red River. This river, however, had been previously examined in 1804, in the lower part of its course, to its confluence with the Mississipi, by Mr Dunbar and Dr Hunter, who were employed for this purpose by the government of the United States; while it had been explored from its source downwards, for about 230 leagues, by a large body of Spanish cavalry, who set out on this expedition from Santa Fe, in 1806. The course of this river, taking in all its irregular windings, cannot, according to recent observation, be estimated at less than 2000 miles. By the researches of these travellers, we have thus obtained a sufficiently accurate view of the course of the various streams which intersect this part of the American Continent; and it will be found, that all these rivers are so disposed, as greatly to facilitate the progress of cultivation and improvement. The countries visited by the exploring party of Major Pike, were inhabited by savage tribes, who subsist almost entirely by hunting; and the abundance of wild animals of every description to be found in those parts, affords ample encouragement to this mode of life. The borders of the Arkansaw he calls the terrestrial paradise of the wandering savage, on account of the immense herds there to be found, of buffalo, elk, and deer. The antelope is also common; and of the carnivorous animals, the wolf and bear are the most remarkable.

While the interior of Louisiana was, in this manner, so successfully examined, and the course of the various tributary rivers, which either flow into the lower Missouri or Mississipi, was so accurately determined; Captains Lewis and Clarke were entrusted by the American government with the still more important task of exploring the main stream of the Missouri, from its confluence with the Mississipi, to its source; and of afterwards proceeding across the Rocky Mountains to the first navigable river they should meet with, which they were to descend until they should arrive at the Pacific Ocean. They set out with an intrepid band of forty-five followers, mostly American soldiers, from the point of junction between the Missouri and Mississipi, in May 1804; and by the beginning of November, they had nearly ascended about half the course

America. of the river, in a direction almost north. They were now in the 47th degree of north latitude, and as the river had begun to be filled with floating. ice, they took up their winter abode in this station. In the meantime, the cold continued to increase, and the thermometer frequently stood at 52 degrees, and fell even as low as 74 degrees below the freezing point; at which time the cold was so intense that the sentinel who kept guard was forced to be relieved every half hour. The air was also filled with icy particles, which were so thick as to render the weather hazy, and to exhibit the appearance of two suns reflecting one another. The latitude to which the party had arrived, which was only 47 degrees north, will not account, even on the American Continent, for this extreme rigour of the climate. It is probably owing, therefore, in some degree, to the elevation of the ground; which, however, as Captains Lewis and Clarke's party were not provided with a barometer, was not ascertained with any precision. But the velocity with which the stream of the Missouri descends, amounting, according to a calculation by the log, generally to five miles per hour, and in some places to nearly double this rate, marks a great declivity of ground; and as the travellers had been gradually ascending from the time they had left the confluence of the two rivers, it is obvious, that, before they had arrived at their winter-quarters, they must have reached a point of the American continent of considerable elevation; and that this, combined with other causes, must have produced the extreme rigour of the climate.

Captains Lewis and Clarke left their wintering ground about the beginning of April, and proceeded in their hazardous enterprise. As they ascended the river, they found their course was mostly west, and afterwards south for a great length. The current was also less rapid, and the navigation more safe and easy, so that they advanced at the rate of about eighteen or twenty miles a-day. The country is described on both sides of the Missouri, after ascending the adjacent hills, as one fertile unbroken plain; extending as far as the eye can reach, without even a solitary tree or shrub, except in moist situations, or in the steep declivities of the hills, which afford shelter from the fires kindled by the savage inhabitants. On the sides of the hills, and even on the banks of the rivers, as well as on the sand-bars, a white substance was found, in considerable quantities, on the surface of the earth, which tasted like a mixture of common salt with Glauber salts. Many of the streams which came from the hills were so strongly impregnated with this substance, that the water had an unpleasant taste, and a purgative effect. The mineral appearances of coal and sulphur, with burnt hill and pumice stone, were also visible; and they found a bituminous water, with the taste of Glauber salts, and a tincture of alum. These appearances continued as they advanced. The salts were so abundant, that, in many places, the ground looked perfectly white. Pumice stones were observed floating down the river, and the coal appeared of a better quality, affording, when burnt, a hot and lasting fire, and emitting very little smoke or flame. Higher up the river, the bed of coal runs in some places six feet thick; and where wood is not plentiful, the abundance of this species of fuel must be of essential importance towards the colonization of the country. The adjacent hills exhibited also, as they advanced, large irregular masses of rocks and stones; some of which, although two hundred feet above the river, seem to have been once subject to its influence, being apparently worn smooth by the agitation of the water. These rocks and stones consist of white and grey granite; a brittle black rock; flint, limestone, freestone; some small specimens of an excellent pebble; and occasionally broken strata of a black-coloured stone, like petrified wood, which makes good whetstones. The country in the neighbourhood abounds with deer, elk, beaver, buffaloes, antelopes, and their followers the wolves, who make great ravages among them. Here also were met the brown and white bear, which were both found to be exceedingly ferocious. With these animals the party had frequent encounters; and though they were all well armed, and expert marksmen, they were often in great danger from this formidable enemy.

Advancing towards the Rocky Mountains, they found the river divided into two branches, and they were much at a loss which to pursue. At length they chose the branch that came from the south; and having ascended for some time, their ears were saluted with a tremendous noise occasioned by the great falls of the Missouri, and which, from the information of the Indians, they knew to be a certain mark that they were on the main stream. Higher up the river, they found it divided into three branches, which they distinguished by the names of the three leading statesmen in America, viz. Jefferson, Gallatin, and Maddison. They ascended the first of these streams, with a view of reaching, by the nearest course across the mountains, some of the smaller branches which join the Columbia, and lead to the Pacific Ocean.

It being necessary to obtain some knowledge of the country through which they were to direct their perilous course, Captain Lewis set out, accompanied by one of the most expert hunters, and two soldiers, along the Jefferson; and having advanced until the river had become so small that they could step across it, they ascended a high ridge towards the west, which forms the dividing ridge between the waters of the Atlantic and Pacific Oceans. Here they began to descend; and they reached a stream of clear water running to the west, which they rightly conjectured must belong to the waters of the Columbia. After various difficulties and uncertainties, they met with an Indian tribe, whom they fortunately persuaded to return with them to their companions at the source of the Missouri. By this tribe they were directed into the proper road across the mountains, which was to the north-west, the course of the Missouri having carried them considerably to the south of the head waters of the Columbia. In travelling this road, they encountered innumerable hardships from famine, occasioned by the scarcity of game, and the great cold in those higher regions, to which they had now penetrated. This part of their journey lasted about seven weeks, from the 18th August to the 7th October; at which period they em-

America.

barked in canoes built by themselves on the river Kooskooske. This river they found to be much embarrassed by a succession of dangerous rapids and shoals. These difficulties, however, they encountered with all the alacrity of men accustomed to danger; and, after a hazardous navigation, they descended into Lewis's river, and, sailing down this stream, they reached the Columbia, about 400 miles from its mouth. They came within sight of the ocean about the 7th November, when they were deluged for a time with almost perpetual rains. At this station they remained for the winter, which, as usually happens on the western coast of America, was extremely mild. As soon as the weather permitted, they set out on their return; and having, with great difficulty, succeeded in crossing the ridge of the Rocky Mountains, they arrived at Fort Lewis, on the Mississipi, on the 23d September; having, in the course of this remarkable journey, travelled over a space of about 9000 miles. The countries bordering on the Missouri they found inhabited by barbarous tribes, who subsist chiefly by the chace, few or none of them looking to agriculture as any resource. On the western side of the Rocky Mountains, the rivers yielded vast quantities of salmon; and such was the abundance of this fish in the Columbia, that they were caught in any quantity with little trouble. Here the inhabitants draw their chief subsistence from the rivers; and in many parts the salmon were seen, after being cured in a particular manner, built up in large stacks, as a provision for future consumption.

The expedition of Captains Lewis and Clarke, whether we consider the singular perseverance, courage, and address, with which it was conducted, or the important information to which it has led, may be undoubtedly regarded as one of the most memorable exploratory enterprises of which any nation has to boast. The chart which they have laid down of the course of the Missouri, with its subordinate streams, has filled up an immense chasm in the geography of North America, which may now be considered as complete in all its great features; namely, the direction of its mountains, and the course of its chief rivers. The researches of future travellers must therefore be limited to the subordinate task of filling up the details of the picture, of which the general outline has been already so boldly and successfully sketched. This, however, must be the work of time. At present, our knowledge of the interior of North America seems to be sufficient for every useful purpose; and it is only when population and improvement have made greater progress, that a more exact survey of the country will be required.

**Progress of Discovery in the Interior of South America.**

III. In South America, although the country may be said to be merely skirted with an exterior border of cultivation and improvement, the interior has been explored with considerable success. The immense rivers, with the innumerable tributary streams, which flow through the country in all directions, afford great facilities for traversing those vast regions; and it is no doubt in a great measure to this inland navigation that we are indebted for the geographical knowledge which we possess, imperfect as it is, of this portion of the American Continent. In Africa, a difference of climate, and a difference also in the configuration of ground, has given rise to a different disposition of its rivers. The Nile holds its solitary course through parched and burning deserts, where no rain ever falls, and where, for more than a thousand miles, not a single stream arises to pour its waters into the main channel. The water, on the contrary, which falls on the American Continent, seeks its way to the ocean through many different channels; and all the great rivers, until they fall into the ocean, are joined, in their course, by a variety of capital streams; all of which, communicating either by means of the main channel, or by its tributary waters, with a vast space of inland country, diffuse throughout the Continent all the advantages of a maritime boundary, and afford facilities for exploring the interior, which could not otherwise exist.

The Spaniards, ever since their first settlement in America, have been chiefly intent on the aggrandizement of their power and influence, and on the extension of their authority as widely as possible among the native tribes. For this purpose, they seem occasionally to have employed persuasion and address, and, at other times, to have had recourse to violence. In the latter case, troops were employed to take possession of a certain district; a particular space was then assigned for the villages of the native inhabitants, to which it was understood they were afterwards to be confined. Here they were gradually subjected to a system of magistracy and police, and they were afterwards reduced under a mild species of servitude, for the benefit of their conquerors. In general, the Indians were forced tamely to submit to this injustice; but, in some cases, they rather chose, after a violent struggle, to retire into the interior; from whence, under the influence of a just resentment against their oppressors, they continued to make incursions into the Spanish territories. The frontier which divides those hostile classes of inhabitants is in this manner the scene of a constant and inveterate war; and the Europeans are only secured against the irruption of the native tribes, by the imposing aspect of a strong military force.

Against this system of conquest the ecclesiastics always remonstrated, with laudable and becoming zeal; and they have uniformly recommended, that the improvement of the native Americans should rather be attempted by policy than by arms. Their humane counsels have so far prevailed, that, in later times, the Spaniards, in their attempts to civilize the native Indians, seem to have trusted almost entirely to conciliation. Missions or settlements have been established in different parts under the authority of ecclesiastics, and a few soldiers have generally accompanied the infant colony, to repel aggression, but not to offer violence. They to whom the administration of these settlements is committed, are directed to gain over the Indians by gentle means to habits of civilization,—to make distributions among them of provisions, iron, or of such implements of industry as may enable them to better their condition,—and gradually to inure them to the restraints, by making them duly sensible of the various advantages, of social life. It is also accounted of great

importance, that they should be converted to the Christian faith at the same time that they are instructed in all useful and necessary arts. How far this system, so full of enlightened humanity, is likely to succeed on any great scale, is a question of some difficulty. Azara, in his instructive account of the Spanish settlements in Paraguay, depreciates the services of the ecclesiastics in that part of the Continent. The Indians are so inveterately attached to their habits of barbarism, that force, he seems to think, is absolutely necessary to bring them under the yoke of civilization. It is seldom, he insists, that the savage has any attention to bestow on futurity. He is generally swayed by present objects; and hence the superior advantages of civilization, though they are continually displayed before him, have no effect in withdrawing him from the habits of his wandering and unsettled life. This is no doubt true; and it proves the difficulty, but certainly not the impossibility, of succeeding in the benevolent task undertaken by the Spanish missionaries. There is a very striking account, in the narrative of Vancouver's voyages, of the state of the Spanish missions on the coast of California; and the fine picture which is there exhibited of the reverence and attachment of the Indian population to their pastor, and of his unbounded ascendancy over them, evinces such a spirit of docility and affection in this simple people, as plainly shews that, under a wise system of management, they are capable of civilization; and that, though the existing generation were to remain in their original barbarism, the rising generation at least might be trained to agriculture, and to those other arts by which life is supplied with its most necessary comforts. We cannot, indeed, readily admit, that injustice is in any case the most perfect instrument of policy, or that there is no other way of guiding and controlling the human mind but by violence and cruelty.

With a view of extending civilization among the native tribes, various expeditions have from time to time been undertaken into the interior by the Spanish missionaries. Of these the latest and most remarkable appear to be, *first*, the voyage of Father Sobriela on the river Guallaga; and, *second*, the voyages of Father Girval on the great river Amazons.

Beyond the easternmost of the three ridges of Andes, which run in a direction nearly north and south, through the province of Peru, immense plains stretch out, to the extent of nearly 8000 square leagues, and so level, that they have been compared to the ocean. They lie between the river Ucayale and the Guallaga, which bound them to the east and west, while to the north they are bounded by the river Amazons. These vast plains, which have been denominated by the missionaries *Pampas del Sacramento*, are shaded with forests of eternal verdure, which form a delicious perspective; they contain also abundance of lakes and rivers, the isles and borders of which are inhabited by tribes greatly diversified in their manners and habits. Rain and thunder are frequent, and for some hours of the day thick fogs always rest on the tall trees. The thickness of the woods prevents the rain from penetrating, and the warmth and moisture give birth to innumerable insects and reptiles. Many of the rarest vegetable products are found in those regions: balsams, oils, gums, resins, incense, cinnamon,—superior in strength to that of Ceylon, but not so valuable, on account of a disagreeable juice which it transudes;—cocoa, cascarilla, and excellent spiceries are abundant. But, notwithstanding its valuable produce, and the inviting aspect of its evergreen forests, the warmth and humidity of the climate render the country so unhealthy, that few among the native tribes are said to live beyond fifty years of age. This vast region was first discovered about the year 1726; and several missions appear to have been established, all of which were, however, afterwards abandoned. As this territory was considered by the Spanish government to be of extreme importance, Father Sobriela was dispatched in 1790 to explore the course of the river Guallaga, its western boundary. This river rises in south latitude 10° 57′, and, after a course of about 400 miles, falls into the Amazons. He set out in July for the city of Guanuco, near the source of the Guallaga, where he spent some time in visiting the Indians; to whom, along with his spiritual doctrines, he gave lessons in agriculture, and the necessary implements of iron, by which those lessons were to be reduced to practice. Having embarked on the Guallaga, he descended the stream, and safely passed several rapids. At the rapid of Aguirre the chains of mountains join on either side, and form the *Ponguillo*;—a term borrowed from the language of Peru, signifying a door; and which is generally applied to those narrow and tremendous outlets where the rivers burst from the mountains. This passage forms a sort of gate, where the traveller passes as it were from one world into another, the whole aspect of nature having undergone a complete change; vast plains clothed with eternal verdure, and extending as far as the eye can reach, now succeeding to the lofty summits of the Andes lost in the clouds, and buried in perpetual snow. After passing the mountains, the Guallaga begins to spread, and rolls its majestic stream along the plain, which is now so large as to be navigable both day and night; while its banks, covered with lofty palms, and trees of every leaf, are enlivened by numerous birds of the richest plumage, and most diversified song. The scene is rendered still more interesting by the prospect of numerous trading canoes sailing up and down the river; while the crews of others are employed in gathering the cocoa-nuts produced in those immense forests, or the honey made by diminutive bees, which lodge their treasure in hollow trunks. The banks of the Guallaga are infested by innumerable swarms of mosquitoes, by which the inhabitants are cruelly tormented; and by that still more formidable animal the cayman or alligator, which grows here to an enormous size, and is seen lurking about in search of its prey. Father Sobriela, having passed the missionary village of Yurimaguas (where he saw the Indian method of catching the tiger or *jaugar*, in a kind of trap formed of stakes), arrived at Laguna, the capital of the province of Maynas, situate in 5° 14′ south latitude, on a lake, which, by a narrow channel, enters the Guallaga from the east. This settlement is not above thirty miles from

the confluence of the Guallaga with the main channel of the Amazons. It is the residence of the President of the missions, who is assisted by a Lieutenant-governor. The number of Christians is 8895, with nineteen Curates, and a Superior of the missions. Great care is taken to train the Indians to industry and to habits of morality; and the benevolent efforts of the ecclesiastics have so far succeeded, that the natives unite, with their ordinary employments of hunting and fishing, the cultivation of little fields of rice and sugar-canes. The villages of this province trade with each other, and with Quito, and Lamas, in salted fish, chocolate, wax, and vegetable candles, being the fruit of a tree, which, when lighted, presents both wax and wick; and the reformation which has been thus brought about in the habits of the native tribes, must be chiefly ascribed to the address, prudence, and indefatigable zeal of the Spanish missionaries, and to the benevolent principles upon which they proceed.

In 1791 the viceroy of Peru received an order to extend and secure the labours of the missionaries; and Father Girval was in consequence instructed to survey the great river Ucayale, which falls into the Amazons from the south, and which may be considered indeed as the main stream, as its course is longer, and as it also contains a larger body of water. In the course of three successive voyages, undertaken in 1791 and 1794, this enterprizing missionary ascended the Ucayale, which he explored to its confluence with the Pachitea. Having two canoes with fourteen Omaguan Indians, robust and dexterous rowers, he made great progress, frequently meeting with fleets of canoes filled with the natives, whom he always contrived either to soothe or to escape. The Guallaga and the Ucayale, which bound on the west and east the immense plains known under the name of *Pampas del Sacramento*, hold a parallel course at the distance of between 300 or 400 miles, until they fall into the Amazons; and it was an object of Father Girval's expedition, to discover whether there existed any navigable streams by which a communication might be opened across the country between these two rivers. After sixteen days navigation, he reached the Manoa, which falls into the Ucayale from the west; and, notwithstanding the rapidity of its stream, he proceeded to ascend it, expecting that it might either conduct him to the Guallaga, or to some of its tributary streams. Being obliged, however, to proceed partly by land, he found the road exceedingly difficult and dangerous on account of the precipices and thick woods; and having discovered a large river, which he supposed to be the Guallaga, but which afterwards proved to be the Manoa, the river he had previously ascended, he returned to the Ucayale; and, embarking on its stream, he arrived on the Amazons, and, ascending this river, he reached the mission of the Maynas on the Guallaga, after an absence of four months.

Father Girval proceeded on his second voyage in 1791. He entered the Ucayale on the 14th November, unaccompanied by any soldier or white person. The natives received him with great cordiality, though he was afraid of encountering the Casibos on the eastern shore, reputed the most ferocious tribe in those regions. But those whom he chiefly met in this part of the river, belonged to the tribe of the Conibos, who are more peaceable and humane, and, who generally, with their rude flutes, make signals of hospitality and peace. They navigate the river in large canoes, from sixteen to twenty yards in length, which they will employ a whole year in hollowing out of a single tree. This they accomplish by means of sharp stones and fire. The canoes of the Paros, another tribe of native Indians, afterwards began to make their appearance; and father Girval proceeded up the river, accompanied by a bark and sixty canoes of friendly savages. Arrived at the river Manoa, he immediately began, in consequence of the orders of the viceroy, to inquire for the beautiful bird called the Carbuncle, which is said to be about half a yard in height, of a most exquisite plumage, while its breast is also finely spotted. He was informed, that it was known to the Piro tribe, who inhabit the upper banks of the Ucayale. The next object of inquiry was, whether any of the tributary streams of the Guallaga and the Ucayale, approached so near each other as to facilitate the communication between the principal streams; and this point, so important to the future civilization of the country, was established by this second journey of father Girval. It was found that, from the Manoa, which enters the Ucayale from the west, the distance to the Chipurana, which enters the Guallaga from the east, is not great. A party of ten men and two women, being accordingly dispatched in this direction, reached the head waters of the Chipurana, after dragging their canoes over the land, which is here a beautiful plain, only one day; and embarking on this stream, they soon entered the Guallaga, which they descended to its junction with the Amazons, after a journey of fifteen days.

In a subsequent voyage, undertaken in the year 1794, father Girval ascended the Ucayale for about 600 miles, to its junction with the Pachitea. He found the river flowing in a gentle current, and abounding with fish, while animals of chace swarmed upon its shores. The savage tribes were generally pacific, and seemed to speak different dialects of the same language. Besides hunting and fishing, they cultivate a few herbs, particularly the *Yuca*, from which they extract an intoxicating drink; they also gather cotton, which serves them for the slight clothing which they wear, and they use axes of copper. They seem to be very dextrous at extracting an active poison from noxious plants; and so great is their confidence in the deadly power which it gives to their arms, that they will awake the fury, and await the attack of the fiercest tiger. They laugh when he prepares to spring, and, aiming at him the fatal shaft, the arrow flies, and he is dead. War is their ruling passion, and they are almost continually engaged in hostility with the neighbouring tribes.

The interior navigable communications which have been disclosed by the journies of those adventurous missionaries, may be of considerable importance to the commerce of South America. The sources of the Rio Guallaga, are not above two or three days' journey from Lima, which may thus open an intercourse, not only with the whole in-

terior of the country, but even with Europe. The productions of Peru may be carried down the great rivers Ucayale or the Guallaga, to the mouth of the Amazons, and from thence to Europe, in the space of five or six weeks; while it would require four months to reach the same point by doubling Cape Horn. But where the waters of an immense Continent, in their course to the sea, pass through the territories of different nations, political arrangements are frequently necessary to secure the advantages of nature. The Amazons, for about one thousand miles of its course, is in the power of the Portuguese; and Portugal has refused to the Spaniards the free navigation of this important river; although the cultivation of those extensive regions, situated on the eastern declivity of the Andes, and the prosperity of their inhabitants, depend, in a great measure, on the possession of this valuable privilege. It is to be hoped, however, that more liberal views will prevail; and that, in the present era of increasing improvement, the Portuguese government will not persist in imposing such a pernicious and useless restriction on the commerce of a great Continent.

The latest, and by far the most interesting journey, which has been undertaken into the interior of America, is that of Baron de Humboldt, a Prussian gentleman; who having, by a long course of study, instructed himself in all those important branches of knowledge, both moral and physical, necessary to form an accomplished traveller, set out, under the impulse of his own ardent genius, and love of science, to explore the wonders which nature has so profusely displayed in the interesting regions of the new world. He was accompanied by M. Bonpland, who, to indefatigable zeal, joined extensive acquisitions in science; and those two travellers arrived, in July 1799, at the port of Cumana, in South America. They employed the remainder of the year in visiting the coasts of Paria, the missions of the Indian Chaymas, the province of New Andalusia (a country liable to the most frightful earthquakes, and of which the climate, though the hottest, is perhaps one of the most salubrious in the world), New Barcelona, Venezuela, and Spanish Guiana. In the beginning of the year 1800, leaving the Caraccas, they went to visit the beautiful vallies of Aragua; and, proceeding southwards from Porto Cabello, they crossed the immense plains of Caloboza, the Apure, and the Orinoco. They next traversed the *Llanos*, a desert similar to those in Africa, wholly without vegetation, and where, by the operation of a vertical sun upon the sand, the horizon everywhere exhibits the well-known illusion of the distant sea. The country is here such an uniform level, that, for a space of 2000 square leagues, the inequality of the ground does not exceed five inches. The heat is excessive; the thermometer, in the shade, rising by the reverberation of the sun's rays, to 110 and 115 degrees of Fahrenheit's scale. The parched earth conceals crocodiles and serpents, which lie in a state of torpor, till they are called into life and activity by the periodical torrents which, for a time, deluge those barren regions. Humboldt and his companion travelled whole days in this pathless expanse, without meeting with a single shrub, or with one solitary dwelling, to refresh the eye. At St Fernando d'Apure, they commenced a most fatiguing navigation of 1000 marine leagues, which they performed in canoes, laying down an accurate chart of the country through which they proceeded. They descended the stream of the Apure, which falls into the Orinoco, at the 7th degree of latitude; and, remounting the last river, they reached the confluence of the Guaviari, after passing the celebrated cataracts of Mapures and Atures. They afterwards ascended several rivers of inferior note; and from the mission of Sarita, they travelled over-land to the sources of the Rio Negro; which Condamine saw at its point of junction with the Amazons, and which he denominates a sea of smooth water. About thirty Indians carried their canoes through lofty forests, to the creek of Pemichin. By this rivulet, they entered the Rio Negro, which they descended to Fort-Charles. From this station, ascending the river Cassiquiari, they reached the Orinoco; and from thence they proceeded to the volcano of Daida, and to the mission of Esmeralda, near the sources of the last mentioned river. These sources they were prevented from reaching by the Guaicas, a pigmy race, of a fair complexion, but exceedingly warlike and ferocious. From the mission of Esmeralda, Humboldt and his companion descended the Orinoco to its mouth; and, in the course of this painful navigation, they were exposed to sufferings of every sort. They were in want both of food and shelter; and, during the night, they were exposed to the periodical rains, which fell in torrents. If they went a-shore to seek shelter or subsistence in the woods, they were tormented by the muskitoes, and by other loathsome insects; if they ventured to bathe their parched limbs in the stream, they were in danger of being devoured by the crocodile; or of being attacked by a small species of voracious crab; and, in addition to all these evils, they were exposed to the unhealthy exhalations of a moist climate under a burning sun.

Having escaped these various dangers, they returned to Cumana, where, after remaining for some months, they set sail for Cuba; and returning from this island to Carthagena, they successively visited the cities of Quito, Santa Fe, Lima, Guayaquil; and, proceeding to the province of New Mexico, they staid in that country for about a year; from whence they returned to France, by the way of North America.

Those illustrious travellers have been since engaged in communicating to the world the result of their inquiries, which are of such extent, that they embrace every object connected either with nature or with society. The works which they have already published abound in the most valuable details, relative to the political institutions of the country, the manners of the people, and the state of the economical arts; while they contain besides much curious information, of great importance to general science. Of these various and interesting details, we shall endeavour to present our readers with an abstract, under the articles to which they more particularly relate; and, in the meantime, it may be added, that the researches of Humboldt have tended to correct many prevailing errors in the geography of America; as he has accurately fixed the position of nearly

three hundred capital points in the Spanish settlements. He has besides ascertained, in the most satisfactory manner, that the river Cassiquiari, which falls into the Orinoco, is also connected, by means of the Rio Negro, with the great river Amazons; and it thus appears, that the more attentively we investigate the geography of the American Continent, we find it the more admirably provided by the number, and still more by the distribution of its rivers, with the means of extensive navigation and commerce.

See Hakluyt's *Collection of Voyages*. Cook's *Voyages*. Vancouver's *Voyage*. Meares's *Voyage*. The learned *Introduction* by Fleurieu to Marchand's *Voyage*. Mackenzie's *Travels in North America*. Pike's *Journey to the Source of the Mississipi*. Lewis and Clarke's *Travels to the Pacific Ocean*. De Pons, *Voyage à la Partie Orientale de la Terre Ferme*. Azara, *Voyage dans l'Amérique Meridionale*. Account of "recent discoveries in South America," in Pinkerton's *Geography*, 3d edition. M. Humboldt has as yet published only part (two volumes) of his *Personal Narrative;* but the reader will find a sketch of his expedition by Dr Kesteloot, annexed to the *Discours sur les progrès des Sciences, ou compte rendu par l'Inst. de France à l'Empereur*, published in Holland in 1809; and there is a similar sketch in the admirable account of his *Tableau Physique des Regions Equatoriales*, in the 16th volume of the *Edinburgh Review*. We have everywhere sought in vain for the Spanish Collection by Estalla, entitled *Viagero Universal*, which extends to 44 vols. 8vo; and which appears, from Mr Pinkerton's references, to contain much valuable geographical information in regard to America. (o.)

---

AMERICA, UNITED STATES OF. A view of the recent history of these Republics, of their statisties, and political relations, shall be given under the head UNITED STATES.

AMES (FISHER), a native of the United States, was born April 9, 1758, at Dedham, a small town about nine miles south of Boston. His father, Dr Nathaniel Ames, who practised as a physician in Bridgewater, died in 1764, leaving his mother with four sons and one daughter. Of these Fisher was the youngest; and though his mother was left in narrow circumstances, she determined to educate him with the utmost care. He accordingly began the study of Latin when he was six years of age, and in July 1770, soon after he was twelve years old, he was admitted to Harvard College; previous to which, he was examined by a gentleman accustomed to teach the languages, who expressed surprise at his uncommon quickness and accuracy. At the university, the singular modesty and mildness of his character, joined to the pleasantness and vivacity of his manners, endeared him both to his companions and to his instructors. He was scrupulous in his attention to his studies, and equally so in the choice of his associates; by which means he soon acquired the character of shining parts, and of unblemished morals.

Among the students who attended this seminary, a society was formed for speculative discussion, and Mr Ames here first displayed his talents for extemporaneous eloquence. But though he was resolved to embrace the profession of the law, several years passed away before he entered on a course of professional study. During this period, he appears to have maintained himself chiefly by teaching a school; and his intervals of leisure were filled up by a diligent perusal of the works of classical writers, both ancient and modern.

He at length commenced his professional career at Dedham, his native place, in the year 1781; and he soon began to be distinguished by his eloquence as a pleader. At this time, however, his attention was attracted to public events, which began to be unusually interesting, and to threaten the rupture which afterwards took place between the colonies and the mother country. Mr Ames espoused the cause of the former, and though he was not of an age at the commencement of the contest to take any active part, he watched its progress with all the anxiety of a genuine patriot. In the course of this eventful struggle, the provisional rulers of America were greatly distressed for the means of paying the troops, and of defraying the other necessary expences of the state; and they were therefore induced to have recourse to the most exceptionable expedients. Among these, the issue of a depreciated paper currency formed a standing resource, and this measure was also accompanied by an arbitrary regulation of prices. Of all these projects Mr Ames was a zealous opposer. At a meeting of a Convention of Delegates assembled at Concord, he pointed out the certain mischiefs which would result from attempts of this nature; expatiating, in strong terms, on the futility and injustice of endeavouring to regulate by force the value of that which must be fixed in the market by the voluntary consent of the buyer and the seller.

In the convention for ratifying the federal constitution in 1788, Mr Ames acted a conspicuous part. He was chosen the same year a member of the House of Representatives, and for eight years he continued a firm supporter of Washington's administration. In the contests occasioned in Europe by the progress of the French revolution, he appears to have been a keen partisan of the powers combined against France; and in the controversy which took place between Britain and America, respecting the privilege of the neutral powers during war, he espoused the cause of the belligerent; pleading warmly for the exercise of the maritime rights of Britain in their fullest extent. In his zealous hostility against France, he advised his countrymen, both in his political speeches and writings, to submit to all the restrictions imposed by this country on the commerce of the neutral powers.

In the year 1796, he retired from public business

in consequence of his declining health; but he still continued a diligent writer of political essays. The purpose of these publications was generally to support the declining cause of the federalists,—to vindicate the policy of Britain,—and to awaken the jealousy of his countrymen against the hostile and ambitious views of France. His health, however, which had been on the decline since the year 1795, was now broken, and though he was chosen president of Harvard college, he was obliged to decline the office. He continued for two years in a state of extreme debility, and on the 4th July 1804 he expired. When intelligence reached Boston of his death, a meeting of the citizens took place to testify their respect for his services and character, and at their request, his remains were brought to the capital for interment.

In America, the literary character of Fisher Ames appears to be held in high estimation; and some of his countrymen have even been absurd enough to compare him to Burke. We perused his essays with a curiosity greatly excited by so ambitious a comparison; but without being able to discover one trait of resemblance to that great master of political philosophy and eloquent composition;—without perceiving any thing much above mediocrity, either in thought or expression;—and with frequent feelings of tedium and disgust, excited by abortive strainings after imagery and eloquence. Having said thus much, we think it but right to add the opinion delivered by perhaps the ablest American writer of the present day, "that Ames, both as an orator and an author, would have reflected lustre on any country; and may be considered as the most perfect model for youthful emulation, which the United States have produced." *American Review*, Vol. I. p. 89.

His works, with an account of his life, were published in an octavo volume, at Boston, in 1809; and the writer to whom we have just alluded pronounces this volume, "not only a treasure of political wisdom, but a literary monument, which every American should contemplate with gratitude and patriotic pride." (o.)

AMMAN (John Conrad), a Physician, and one of the earliest writers on the instruction of the *deaf and dumb*, was born at Schaffhausen, but in what year is uncertain. In 1687, he graduated at Basle; and, his religious principles not permitting him to settle in his native country, he retired to Holland, where he appears to have devoted his time and attention chiefly to the cure of the defects and imperfections of speech. He first called the attention of the public to his method, in a paper which was inserted in the *Philosophical Transactions;* and which appeared in a separate form in the year 1692, under the title, *Surdus Loquens, sive Methodus qua qui surdus natus est loqui possit;* and afterwards, with much additional matter, in 1702 and 1728, under the title, *Dissertatio de Loquela, qua non solum vox humana, et loquendi artificium ex originibus suis eruuntur, sed et traduntur media, quibus ii qui ab incunabulis* SURDI ET MUTI *fuerunt, loquelam adipisci, quique difficulter loquuntur, vitia sua emendari possunt.* In this work, which Haller terms "*vere aureum*," he developes, with great ability, the mechanism of language, and describes the process which he employed in teaching its use to the unfortunate class of persons committed to his care. This consisted principally in exciting the attention of his pupils to the motions of his lips and larynx while he spoke; and then inducing them, by gentle means, to imitate these movements, till he brought them to repeat distinctly letters, syllables, and words. As his method was excellent, we may readily give him credit for the success to which he lays claim. In a long course of practice, he says that he never failed in his endeavours but in two instances; one of which was that of a girl who was an idiot, and the other that of a Jew, from whose father he foresaw that he would not get any thanks for his trouble. The edition of Cælius Aurelianus, which was undertaken by the Wetstens in 1709, and which still ranks as one of the best editions of that author, was superintended by Amman. (E.)

AMMAN (Paul), a Physician and Botanist, was born at Breslau in 1634. In 1662, he received the degree of Doctor of Medicine from the University of Leipsic, and, in 1664, was admitted a member of the Society *Naturæ Curiosorum*, under the name of *Dryander.* Shortly afterwards, he was chosen Extraordinary Professor of Medicine in the above-mentioned University; and, in 1674, he was promoted to the Botanical Chair, which he again, in 1682, exchanged for the Physiological. He died in 1691. Paul Amman seems to have been a man of an acute mind, and extensive learning; but a restless and irritable disposition led him to engage too much in controversy, and to indulge in a degree of raillery in his writings, which the nature of the subjects hardly warranted. By his first work, which was published in 1670, under the title, *Medicina Critica, seu Centuria Casuum in Facultate Lipsiensi resolutorum variis discursibus aucta*, he drew down upon himself the displeasure of the Faculty, who had certainly no cause to rejoice at this exposure of their decisions. In the *Paracænesis ad discentes circa institutionum medicarum emendationem occupata*, which appeared three years afterwards, and in the *Irenicum Numæ Pompilii cum Hippocrate,* which he published in 1689, he showed his independent turn of thinking, by boldly attacking the systems of Galen and Hippocrates, and the abuses to which the implicit adoption of them had given rise. But it is chiefly on his botanical writings that his fame ought to rest. The *Suppellex Botanica, et Manuductio ad Materiam Medicam*, which he committed to the press in 1675, contains a full, but somewhat prolix, catalogue of the plants of the botanic garden of Leipsic and its environs, with their synonyms; followed by a brief introduction to the study of the Materia Medica, which proves an accurate knowledge of the science he was then employed in teaching. His next publication was entitled, *Character Plantarum Naturalis, ab ultimo fine, viz. fructificatione desumptus, et in gratiam philatrorum per canones et exempla digestus;* to the second edition of which, in 1685, he prefixed a dissertation on the true classification of plants. In this work he adopted the arrangement of Morison, endeavouring to show, as the title imports, that the genera of plants were only to

be distinguished by their parts of fructification, and illustrating his method by the description of 1476 different genera and species, in alphabetical order. An enlarged edition of this book was published by Daniel Nebel, in 1700, with the addition of the characters of Tournefort and Hermann. For the complete list of Paul Amman's writings, see Haller, *Bibl. Med.* and Eloy, *Dict. Hist.* (E.)

AMMONIAC, Sal, a saline substance, formerly much used in dyeing, and some other arts. At present, not much of it is employed in this country, most of the sal-ammoniac manufactured in Great Britain being sent to Russia.

Sal-ammoniac is usually in the form of a hard white cake, opaque or only slightly translucent. Its taste is cooling, saline, and rather disagreeable; though it has been occasionally employed as a seasoner of food. Its specific gravity is 1.441, according to the mean of the experiments of Wallerius, Watson, and Kirwan. It requires rather more than three times its weight of cold water to dissolve it. By proper evaporation, the sal-ammoniac may be obtained in crystals. The primitive form of these crystals, according to Hauy, is the octahedron; but most frequently they appear in the state of long four-sided pyramids, or of thin plates, like sword blades. It often assumes the form of plumose crystals, consisting of long hexahedral pyramids attached to a stem. These crystals contain a little water, and therefore dissolve in somewhat less than three times their weight of cold water. A hundred parts of alcohol, of the specific gravity 0.834, dissolve $1\frac{1}{2}$ parts of this salt.

When exposed to a moist atmosphere, it gradually absorbs water and deliquesces, though very slowly. When heated, it sublimes unaltered in a white smoke, having a peculiar smell, very characteristic of sal-ammoniac. If a cold body be presented to this smoke, the sal-ammoniac condenses on it, and forms a white crust. When thus sublimed, it has the property of carrying along with it various bodies, which, when heated by themselves, are perfectly fixed. Thus, if it be mixed with gold leaf, filings of iron, or oxide of copper, these substances rise along with it, and tinge the sal-ammoniac purple, yellow, or red.

If quicklime or potash be triturated with sal-ammoniac, a strong smell of ammonia exhales. If sulphuric acid be poured upon it, vapours of muriatic acid are separated in abundance. If equal bulks of muriatic acid gas, and ammoniacal gas be brought into contact, they immediately combine and condense into sal-ammoniac. These facts, which are well known, show us, that sal-ammoniac is a salt composed of muriatic acid and ammonia. The composition of this salt seems to have been first discovered by Tournefort in 1700. The experiments of Geoffroy junior in 1716, and 1723, were still more decisive, and those of Duhamel, in 1735, left no doubt upon the subject. Various experiments have been made by modern chemists, to determine the proportion of the constituents of this salt. But its analysis is attended with peculiar difficulties, on account of the volatility of the sal-ammoniac, and the want of a simple method of determining the proportion of ammonia. Dr Thomson first pointed out a process by synthesis, which has the advantage of being very simple, and at the same time rigidly accurate. He observed, that when muriatic gas, and ammoniacal gas, both as dry as possible, are brought in contact with each other, they always combine in equal volumes. Therefore, sal-ammoniac is composed of 100 measures of muriatic acid gas, united with 100 measures of ammoniacal gas. Now, 100 cubic inches of muriatic acid weigh 38.979 grains, and 100 cubic inches of ammoniacal gas weigh 18 grains. Hence, sal-ammoniac is composed of

| | | |
|---|---|---|
| Muriatic acid | - | 38.979 |
| Ammonia | - - | 18.000 |
| | | 56.979 |

Or of

| | | | | |
|---|---|---|---|---|
| Muriatic acid | - | 68.41 | - | 100 |
| Ammonia | - - | 31.59 | - | 46.178 |
| | | 100.00 | | |

This gives us the exact proportions of the acid and base. But, at present, we are not in possession of any exact method of determining the quantity of water which the salt contains. From the property which the salt has of deliquescing in a moist air, it is obvious, that the affinity of water must be considerable. Hence, it is probable, that the quantity of water in this salt is pretty great.

An integrant particle of muriatic acid weighs 4.762, and an integrant particle of ammonia 2.149. Hence, it is obvious, that sal-ammoniac is composed of one integrant particle of muriatic acid, united to one integrant particle of ammonia.

But there is another way in which the composition of this salt may be viewed. Muriatic acid is a compound of chlorine and hydrogen. It has been shown, that most of the substances hitherto called *muriates* are in fact *chlorides*, or combinations of chlorine, with the metallic bases of the alkalies, earths, or metallic oxides respectively. Thus, *common salt* is a *chloride of sodium*, or a compound of chlorine and sodium; *horn silver* is a *chloride of silver*, or a compound of chlorine and silver. Now, of all the bases capable of combining with acids, amounting to fifty at least, every one is known to contain oxygen except ammonia. It would be singular if such a solitary exception were to exist. Hence, analogy is in favour of the supposition that ammonia contains oxygen. If a hole be dug in a piece of sal-ammoniac; if this hole be slightly moistened by breathing on it; if a globule of mercury be put into it, and this globule be subjected to the action of a tolerably powerful galvanic battery, the mercury speedily acquires the consistence of butter, and swells up so, as to amount to nearly four times its original bulk. In short, it is converted into an amalgam. Ammonia itself may be substituted for sal-ammoniac; but the experiment, in that case, is attended with greater difficulty. In this case, the ammonia is evidently decomposed by the galvanic energy, and one of its constituents has combined with the mercury, and converted it into an amalgam. If the amalgam be put under water, it is speedily reduced to the state of pure mercury, while, in the meantime, ammonia and hydrogen gas

are evolved. The same thing happens, if the amalgam be put into a glass tube without any water.

Now, no instance can be produced of any substance uniting with mercury, and forming an amalgam which retains the metallic lustre, except a metal. Hence, we are entitled to infer, that the mercury in the preceding experiment has united with a metal, and that the base of ammonia is therefore a metal. Gay-Lussac and Thenard have endeavoured to show, that the amalgam is a compound of hydrogen and mercury. Supposing their experiments correct, the inference would be, that hydrogen in a concrete state is a metal, and that azote, the other constituent of ammonia, is a compound of hydrogen and oxygen. But, whatever shall be the fate of these inferences, it seems reasonable to conclude, from the preceding experiment, that ammonia is a compound of oxygen, and an unknown metallic basis, to which the name of *ammonium* has been given.

Now, supposing this conclusion correct, is it not probable that sal-ammoniac, like the other supposed muriates, is in reality a chloride? This supposition is much strengthened, by comparing sal-ammoniac with the other salts having a base of ammonia. Sulphate of ammonia, sulphite of ammonia, nitrate of ammonia, and, in short, the whole class of ammoniacal salts, are decomposed when exposed to heat. But sal-ammoniac is sublimed unaltered. This difficult decomposition characterizes all the chlorides. But if sal-ammoniac be a chloride, it is obvious, that the hydrogen in the muriatic acid must find a quantity of oxygen in the ammonia, just capable of saturating it, and converting it into water. But 100 muriatic acid contain 2.86 hydrogen, which requires $21\frac{2}{3}$ of oxygen to convert them into water. Therefore, 46.178 ammonia contain $21\frac{2}{3}$ oxygen. Of consequence, ammonia is composed of

| | | |
|---|---|---|
| Ammonium - | 24.511 or | 100 |
| Oxygen - - | 21.666 | 88.39 |
| | 46.177 | |

and chloride of ammonium, or pure sal-ammoniac, is a compound of 97.14 chlorine + 24.511 ammonium, or of one atom of chlorine, and one atom of ammonium.

If this analysis of sal-ammoniac be correct, as we think it is, it follows that this salt, when purest and driest, contains one integrant particle of chloride of ammonium, and thirty-seven integrant particles of water. Or, that it is composed by weight of

| | |
|---|---|
| Chloride of ammonium - | 75.07 |
| Water - - - - - - | 24.93 |
| | 100.00 |

But if the smallest quantity of water which sal-ammoniac, made from perfectly dry muriatic acid gas and ammoniacal gas, can contain, be almost one fourth of its weight, the inconclusiveness of the experiments of Bostock, Trail, and Murray, respecting the possibility of extricating water from sal-ammoniac, made by uniting these two gases, becomes too evident to require any refutation.

The name *sal-ammoniacus* occurs in Pliny. (Lib. xxxi. cap. vii.) He tells us, that it was applied to a kind of fossil-salt found below the sand, in a district of Cyrenaica, from which circumstance its name was derived. It was similar in appearance to the *alumen scissile*, had a disagreeable taste, but was useful in medicine. The general opinion is, that the sal-ammoniac of the ancients was the same as that of the moderns; but the imperfect description of Pliny is far from being sufficient to decide the point. The native sal-ammoniac of Bucharia, as described by Model and Karsten, and which was analyzed by Klaproth, has no resemblance to the salt described by Pliny. The same remark applies to the sal-ammoniac of volcanoes. Dioscorides, in mentioning sal-ammoniac, (Book v. chap. cxxvi.) makes use of a phrase quite irreconcilable with the description of Pliny, and rather applicable to rock-salt, than to our sal-ammoniac. Sal-ammoniac, he says, is peculiarly prized, if it can be easily split into rectangular fragments. Finally, we have no proof whatever, that sal-ammoniac occurs at present, either near the temple of Jupiter Ammon, or in any part of Cyrenaica. These circumstances induce us to conclude, that the term sal-ammoniac was applied as indefinitely by the ancients, as most of their other chemical words. It may have been given to the same salt, which is known to the moderns by that appellation, but was not confined to it.

The name "sal-ammoniac" is derived, according to some, from the temple of Jupiter Ammon, in the neighbourhood of which it was found; according to others, from a district of Cyrenaica called *Ammonia;* but, according to Pliny, from the sand in which it occured,—the Greek name for sand being ἀμμος.

But whether our sal-ammoniac was known to the ancients or not, there can be no doubt that it was well known to the Alchemists. Albertus Magnus, in his treatise *De Alchymia*, informs us, that there were two kinds of sal-ammoniac, a natural and an artificial. The natural was sometimes white, and sometimes red; the artificial was more useful to the chemist. He does not tell us how it was prepared, but he describes the method of subliming it, which can leave no doubt that it was real sal-ammoniac. In the *Opera Mineralia* of Isaac Hollandus the father, addressed to his son, there is likewise a description of the mode of subliming sal-ammoniac. There can be no doubt then, that true sal-ammoniac was known in the thirteenth century. Basil Valentine, in his *Currus Triumphalis Antimonii*, describes some of the peculiar properties of sal-ammoniac in a still less equivocal manner, if possible. But after the two older writers already quoted, his evidence is unnecessary.

Sal-ammoniac occurs native in Bucharia, and probably in other parts of the world. It is found also in small quantities near volcanoes, being formed during the extraordinary convulsions of these mountains. This fact seems in corroboration of an opinion advanced by some mineralogists, that the principal fuel of volcanoes is pit-coal, and that they are always

moistened with sea-water; for sal-ammoniac is sublimed in small quantities during the burning of London bricks, the sand of which is brought from the sea-shore, while the fuel is pit-coal.

In the Latin, English, and French chemical books, published in the seventeenth, and the beginning of the eighteenth century, the name of this salt is usually written *sal-armoniac*. This we conceive to be an old German word; for Agricula has given us an alphabetical catalogue of all the Latin technical terms which he uses in his works, with a German translation of each. Now, the German translation which he gives of *sal-ammoniacus* is *sal-armoniac*. The present German name for this salt is *salmiak*.

Egypt is the country where sal-ammoniac was first manufactured, and from which Europe for many years was supplied with it. This commerce was first carried on by the Venetians, and afterwards by the Dutch. Nothing was known about the method employed by the Egyptians till the year 1719. In 1716, Geoffroy junior read a paper to the French Academy, showing that sal-ammoniac must be formed by sublimation. But his opinion was opposed so violently by Homberg and Lemery, that the paper was not printed. In 1719, M. Lemaire, the French Consul at Cairo, sent the Academy an account of the mode of manufacturing sal-ammoniac in Egypt. The salt it appeared was obtained by simple sublimation from soot. In the year 1760, Linnæus communicated to the Royal Society a correct detail of the whole process, which he had received from Dr Hasselquist, who had travelled in that country as a naturalist. This account is published in the 51st volume of the *Philosophical Transactions* (1760, p. 504.) Almost the only fuel used in Egypt is the dung of cattle. This is collected during the four first months of the year, when the cattle feed on spring grass, which in Egypt is a kind of clover. It is dried, and sold to the common people as fuel. The soot from this fuel is carefully collected and sold to the sal-ammoniac makers, who only work during the months of March and April; for at other periods of the year the dung of their cattle is not fit for their purpose. An oblong oven is built of bricks and moist dung, as long again as broad, and of such a size that the outside or flat part of the top of the arch may hold fifty glass vessels, ten in length, and five in breadth, each vessel having a cavity left for it in the brick work of the arch. These glass vessels are globular, with a neck an inch long, and two inches wide. In general, they are about eighteen inches in diameter. Each vessel is coated over with a fine clay found in the Nile, and afterwards with straw. They are filled two-thirds with soot, and put into their holes at the top of the oven. At first a gentle fire is raised, and the temperature is gradually increased to the highest degree, at which it is kept for three days. A smoke with a sourish smell, not unpleasant, issues first from the glasses, then the salt sublimes, and coats the upper part of the vessel.

It was long supposed, that camels' urine and camels' dung were essential for the success of the above process. But this is a mistake. The dung of black-cattle, horses, sheep, goats, &c. are all used promiscuously. The dung of these animals contains the sal-ammoniac ready formed. This depends upon the food which the animals live on, and accordingly it is only fit for the purpose at one season of the year. The soot contains the sal-ammoniac likewise ready formed, and merely mixed with a quantity of charcoal, oil, &c. from which it is freed by sublimation. Chaptal informs us, that he found sal-ammoniac in the soot obtained by burning the dung of cattle that had fed on the saline plants in the marshes near the Mediterranean. Thus the Egyptian method of obtaining sal-ammoniac is the simplest possible.

The first attempt to manufacture sal-ammoniac in Europe was made by a Mr Goodwin, a chemist of London, about the beginning of the eighteenth century. We do not know his process accurately; but he appears to have used the mother ley of common salt and putrid urine as ingredients. Dossie, in his *Institutes of Experimental Chemistry*, gives it as his opinion, that the salt obtained by this process was not sal-ammoniac, but sulphate of ammoniac, and even describes a process for subliming that salt. But he must have been mistaken; for sulphate of ammoniac, as appears from the experiments of Hatchett, is entirely decomposed when we attempt to sublime it. Goodwin's process, however, whatever it was, did not succeed, and was speedily abandoned. In the year 1740, a patent was taken out for making sal-ammoniac by a London manufacturer. The process was nearly the same as Goodwin's, and was equally unsuccessful. The first successful manufacture of sal-ammoniac in this country was established in Edinburgh by Dr Hutton and Mr Davy. We do not know in what year the manufactory was begun, but as the plan was concerted while these gentlemen were students at the university of Edinburgh, the establishment of the work cannot have been far from the year 1760. From the University of Edinburgh, Dr Hutton went to Paris. During his absence, Mr Davy began the manufactory, and, on his return, admitted him as a partner. This original manufactory existed in Edinburgh till within these few years. The low price of sal-ammoniac during the war with Russia, induced the proprietors to abandon it, as was the case with almost all the sal-ammoniac works in Britain.

Sal-ammoniac was first manufactured in France by Baumé, who established a work about the year 1760; but whether it was posterior or anterior to the work of Hutton and Davy, we do not know. Manufactories of it were afterwards established in Germany, Holland, and Flanders.

Various modes were followed in Europe to procure this salt. But the theory (if we can apply the term here) of most of the manufacturers was the same. They formed a sulphate of ammonia, which they mixed with common salt. A double decomposition took place. The sulphuric acid of the sulphate united with the soda of the common salt, and formed Glauber's salt, which was obtained in great abundance by crystallization, and sold as a medicine. The muriatic acid and ammonia, uniting together, formed sal-ammoniac, which was sublimed. When the British Government imposed a heavy duty on Glauber salts, the manufacture of sal-ammoniac in

Ammoniac, Sal.

this country received so severe a blow, that it is not likely ever to recover it. We shall give a short sketch of the processes followed in different manufactories, in order to afford a more distinct idea of the method of procuring this salt.

Before the French revolution, several manufactures of sal-ammoniac existed in Flanders, which deserve to be described; first, because they were in some measure an imitation of the original Egyptian method. Bricks, or rather balls, were formed of the following materials: twenty-five parts of pounded pit-coal, five parts of soot, two parts of clay, and as much of a saturated aqueous solution of common salt, as was sufficient to convert the whole into a paste; this paste was molded in an iron mould, and the balls suffered to dry. These were burnt in a brick furnace, along with a quantity of dry bones, the proportion of which does not appear to have been accurately determined. The furnace communicated by an aperture, two inches wide, into a vaulted brick chamber above. From the top of this chamber, there was a communication, likewise two inches wide, with a horizontal gallery, which terminated in a perpendicular chimney. The fire was kept up with these materials for five or six months, and then allowed to go out. By the combustion of the pit-coals, soot, and bones, a quantity of carbonate of ammonia is formed. The common salt is decomposed by the clay, and muriatic acid disengaged. This acid coming in contact with the carbonate of ammonia, decomposes it, and sal-ammoniac is formed. The sides and roof of the vaulted chamber are found coated with this impure sal-ammoniac, which is carefully removed. The bottom of the chamber, and the horizontal gallery above, contain likewise sal-ammoniac; but so much loaded with bitumen, that it requires to be burnt a second time before the sal-ammoniac can be extracted. The impure sal-ammoniac is put into egg-shaped clay vessels, twenty inches long, and sixteen in diameter. Each is filled to within three inches of the top. The lower part of these vessels is exposed to a graduated heat for forty-eight hours, while the upper part, being left in the air, is comparatively cool. The oily matter is first driven off; and then the sal-ammoniac is sublimed in a cake in the upper part of the vessel. The charcoal, and any other fixed matter present, remains at the bottom. Finally, the clay vessels are broken, and the cakes of sal-ammoniac taken out. There is a small hole in the upper part of the clay vessels, and care is taken to keep this hole open during the whole process, to prevent the vessels from bursting. Fifteen parts of the sooty matter, taken from the vaulted chambers, yield about five parts of sal-ammoniac. *Journal des Mines*, No. x. p. 3.

The original process of Baumé was to distil animal substances, in order to procure from them carbonate of ammonia. With this salt he decomposed the muriate of magnesia, which exists in considerable quantity in the mother ley of common salt, when that substance is procured from sea water; the liquid containing the sal-ammoniac was evaporated, and the sal-ammoniac sublimed.

This process was speedily abandoned, and another substituted in its place, by MM. Leblanc and Dizé. They brought into contact, in a leaden chamber, vapours of ammonia and of muriatic acid. The ammonia was procured by distilling animal substances, and the muriatic acid by decomposing common salt by means of sulphuric acid. But this method, though it yielded a very pure sal-ammoniac, was speedily abandoned on account of its expence.

The process of Hutton and Davy was to procure ammonia, which they did chiefly from soot. This they converted into sulphate of ammonia. The sulphate was mixed with common salt, and thus two salts were procured; Glauber's salt, which they obtained by crystallization, and sal-ammoniac, which was sublimed.

Almost all the manufactures of sal-ammoniac, whether in Britain, France, or Germany, were similar in principle to that of Hutton and Davy. The only difference consisted in the means employed to procure the sulphate of ammonia. We shall describe a manufacture, formerly existing in London, in which the methods employed were both scientific and economical.

The material from which the ammonia was extracted was bones. These were collected in the streets, and from dunghills, chiefly by old women. The bones were bruised and boiled, in order to extract the fat which they contained, which was sold to the soap-makers. They were then put into iron cylinders eight feet long, and three feet in diameter, placed horizontally over a fire-place, so that they could be made red hot. At one end of the cylinder was a mouth, about fourteen inches in diameter, by which the bones were introduced. This mouth was accurately shut by a cover, and made air-tight by means of lute. From the other end of the cylinder proceeded a cast-iron pipe, from six to eight inches in diameter, and twenty feet long, terminating in one or more oblong leaden receivers, which were kept cool by water placed in a leaden vessel, the bottom of which formed their cover, the juncture being secured by lute. Of these receivers there were commonly two to each still, or three to two stills. Every receiver was about twelve feet long, one foot deep, and fourteen inches wide; and the refrigeratory that covered it held about four inches in depth of water. At the end most remote from the still was a pipe, fitted with a wooden plug, for the purpose of drawing off the condensed liquor; and above this was a hole through which the gas and uncondensible vapour passed off into the open air.

A single charge of each still yielded about 36 pounds of impure alkaline liquor, and about 30 pounds of black fetid oil floating on its surface. This latter being skimmed off, the ammonia was saturated with sulphuric acid, either by means of the mother liquor from the green vitriol makers, or still more economically by means of calcined and pulverized gypsum. In this last case the materials were mixed, and left in contact for some hours. A double decomposition took place; the sulphuric acid of the gypsum uniting with the ammonia, while the carbonic acid of the carbonate combined with the lime of the gypsum. The solution of sulphate of ammonia thus produced was mixed with common salt, by which Glauber's salt and sal-ammoniac were formed, and separated from each other.

For this purpose the liquid, clarified by subsidence and decantation, was transferred into oblong leaden boilers, about nine feet long, three wide, and nine inches deep. Two-thirds of the length of these boilers were set upon iron plates heated by a fire beneath; the remaining part was supported by flat tiles, and defended from the heat by a solid brick work. As the water evaporates, the Glauber's salt begins to crystallize. It is swept from time to time to the cool extremity of the boiler, whence it is shovelled into baskets placed over the end of the boiler, that the liquid which drains off may not be lost. The evaporation is continued till feathered crystals of sal-ammoniac begin to appear on the surface. The liquid is then run into coolers, and deposits little else than sal-ammoniac till the temperature sinks to 70°. The crystals must now be removed, that they may not be mixed with the Glauber's salt, which begins at that temperature to be deposited. The sal-ammoniac thus obtained is first drained in baskets, and then exposed to heat in a kind of oven, till the water of crystallization is driven off. It becomes spongy, friable, of an ash-colour, mixed with small white filaments.

This salt is introduced, while still hot, into globular grey earthen jars, fitted with a cover (with a hole of about half an inch diameter in its centre), luted on with a mixture of clay and horse-dung. These are set in earthen pots over a strong fire, in a furnace of either a circular or oval form, and capable of containing from six to eighteen, surrounded with sand up to the edge of the pot, and also having about 2½ inches of sand on the cover, confined by an iron ring about three inches deep, and two inches less in diameter than the cover, in order that the luting, should it give way, may be repaired without suffering the covers to be cooled by the removal of the sand; for, during the sublimation, their temperature should be about 320°. These earthen vessels may be filled with the dried salt, to within two inches of the top. It may be gently pressed in, but not rammed close. The fire, which has been lighted some time before, is now to be raised gradually till the iron pots are of a pretty strong red heat all round. They are so placed in the furnace, that the upper part is first heated; the bottoms resting on solid brick work. At first, a quantity of aqueous vapour, carrying with it a portion of the salt, escapes through the hole in the cover. The hole must be left open as long as any moisture exhales. This is known by bringing a cold smooth iron plate near the hole, in order to condense the sublimate. When the water is gone, the salt attaches itself to this plate, in the form of a dry semi-transparent crust. The hole is now to be stopped up with lute, and more sand put upon the cover. The heat is to be kept up till it is judged that most of the sal-ammoniac, but not the whole, has sublimed. The time requisite for this depending on the furnace, can only be learned by experience. If the heat be continued too long, the cake of sal-ammoniac acquires a yellow colour, and a scorched, opaque, crackled appearance, which, injuring its saleability, ought to be avoided. When the lute gives way, and requires repairing during the process, the appearance of the cake of sal-ammoniac is injured. On this account, glass vessels would be preferable to those of clay. But, in this country, the expence of glass is so great, on account of the high duty laid upon it, that manufacturers are scarcely able to use it in those cases where the vessels must be broken at the end of every process, as is the case in the sublimation of sal-ammoniac. Aikin's *Dictionary of Chemistry*, art. Sal-Ammoniac.

One process more deserves to be mentioned, on account of its ingenuity and simplicity. It is the invention of Mr Astley, who has secured the exclusive privilege by a patent, and has a manufactory at Borrowstowness on the Firth of Forth, and another at Portobello, near Edinburgh. He mixes together animal matters (chiefly woollen rags), with what in Scotland is called *spirit of salt*. It is the mother ley that remains after all the crystals of common salt that can be got have been separated from sea water. It consists chiefly of muriate of magnesia. This mixture is burnt in furnaces, and the produce received in small chambers placed over the furnaces. This produce contains abundance of sal-ammoniac, which is obtained pure by sublimation. We conceive the theory of this process to be, that carbonate of ammonia is formed by the combustion of the animal matter. This carbonate immediately decomposes the muriate of magnesia, and sal-ammoniac sublimes. In principle, therefore, it does not differ from Baumé's original process, though, in point of economy, it is probably greatly superior to it. We have little doubt that Baumé's method yields a greater return from the same quantity of materials; but this is probably much more than counterbalanced by the much greater expence attending his process. Nothing can demonstrate this more clearly than the circumstance that his method was abandoned in France as too expensive, though labour be much cheaper in that country than in this, while Mr Astley manufactures his sal-ammoniac with profit in the neighbourhood of Edinburgh. (J.)

AMPHIBIA. See Reptilia in *Index* to the article Vertebrosa.

ANA, a Latin plural termination, appropriated to various Collections of the observations and criticisms of eminent characters delivered in conversation, and recorded by their friends, or discovered among their papers after their decease. Though the term Ana is but of modern origin, the species of composition to which it has been applied, is not of such recent date as some persons have imagined. It appears from D'Herbelot's *Bibliotheque Orientale*, that, since the earliest periods, the Eastern nations have been in the habit of preserving the maxims of their sages. From them this practice passed to the Greeks and Romans. Plato and Xenophon treasured up and recorded the sayings of their master Socrates. From their example, Arrian, in the concluding books of his *Enchiridion*, which have not descended to posterity, collected the casual observations which had dropped from Epictetus. The numerous apophthegms scattered in Plutarch, Diogenes Laertius, and other writers, evince that it had been customary in Greece to preserve the ideas deliver-

Ana.

ed by illustrious characters. It appears that Julius Cæsar compiled a book of apophthegms, in which he related the *bon-mots* of Cicero; and Quintilian informs us, that a freedman of that celebrated wit and orator composed three books of a work entitled *De Jocis Ciceronis.* We are told by Suetonius that Caius Melissus, originally the slave, but afterwards the freedman and Librarian of Mæcenas, collected the sayings of his master; and Aulus Gellius has filled his *Noctes Atticæ* with anecdotes which he heard from those distinguished characters whose society he frequented in Rome. Were the books compiled by the freedmen of Cicero and Mæcenas now extant, they might be entitled Ana; and it is certainly to be regretted, that we possess no authentic record of the conversational remarks or hints which dropped from the sages, orators, or statesmen of Greece and Rome. How interesting would be a *Colloquia Mensalia* of Atticus or Cæsar!

But, though vestiges of this species of composition may be traced in the classical ages, it is only in modern times that it has attained to full popularity and perfection. Literary anecdotes, critical reflections, and historical incidents, came to be mingled with the detail of *bon-mots* and ludicrous tales; so that instruction and entertainment were agreeably blended. The term Ana seems to have been applied to such collections as far back as the beginning of the fifteenth century. Thus, Francesco Barbaro, in a letter to Poggio, says, that the information and anecdotes which Poggio and Barthelemi Montepolitiano had picked up during a literary excursion through Germany, will be called *Ana:* "Quemadmodum Mala ab Appio e Claudia gente *Appiana*, et pira a Mallio *Malliana* cognominata sunt, sic hæc literarum quæ vestra ope et opera Germania in Italia deferetur, aliquando et *Poggiana* et *Montepolitiana* vocabuntur."

Poggio Bracciolini, to whom this letter is addressed, and to whom the world is indebted for the preservation of so many classical remains, is the first eminent person of modern times whose jests and opinions have been transmitted to posterity. Poggio was secretary to five successive Popes. During the pontificate of Martin V. who was chosen in 1417, Poggio and other members of the Roman Chancery were in the habit of assembling in a common hall adjoining the Vatican, in order to converse freely on all subjects. Being more studious of wit than of truth, they termed this apartment *Buggiale;* a word signifying a place of recreation where tales are related, and which Poggio himself interprets *Mendaciorum Officina.* At these meetings Poggio and his friends discussed the news and scandal of the day, and communicated to each other entertaining anecdotes; they attacked what they did not approve, and they approved of little: they also indulged in the utmost latitude of satiric remark; dealing out their sarcasms with such impartiality, that they did not spare even the Pope and Cardinals. The pointed jests and humorous stories which occurred in these unrestrained conversations were collected by Poggio, and formed the chief materials of his *Facetiæ*, first printed, according to De Bure, in 1470. This celebrated collection, which forms a principal part of the *Poggiana*, is chiefly valuable as recording interesting anecdotes of eminent men of the fourteenth and fifteenth centuries. It also contains a number of quibbles or *jeux-de-mots*, and a still greater number of idle and licentious stories. Many of these, however, are not original, some of them being taken from ancient authors, and a still greater number from the *Fabliaux* of the *Trouveurs.* Thus the *Fabliau La Culotte des Cordeliers*, is the *Braccæ Divi Francisci* of Poggio. *Le Meunier d'Aleus*, is Poggio's *Quinque Ova. Du Vilain et de sa Femme*, is his *Mulier Demersa*, and *du Pré Tondu*, is the *Pertinacia Muliebris* of the *Facetiæ.* On the other hand, Poggio has suggested much to succeeding writers. Hans Carvel's *Ring*, is his *Visio Francisci Filelfi;* and Fontaine's fables,—*Le Charlatan, Le Coq et le Renard*, and that of the *Wolf and Fox* pleading before the Ape, are from stories originally related by Poggio. The *Facetiæ* forms, upon the whole, the most amusing and interesting part of the *Poggiana* printed at Amsterdam in 1720; but this collection also comprehends some farther anecdotes of his life, and a few scattered maxims extracted from his graver compositions.

Poggiana.

Though Poggio was the first person whose remarks and *bon-mots* were collected under the name of Ana, the *Scaligerana*, which contains the opinions of Joseph Scaliger, was the first work *published* under that appellation; and accordingly may be regarded as having led the way to that class of publications.

Scaligerana.

There are two collections called Scaligerana—a *prima* and *secunda* Scaligerana. The first was compiled by a Physician, named Francis Vertunien, Sieur de Lavau, who attended the family of the Messieurs Chateigner, in whose house Joseph Scaliger resided. He, in consequence, had frequent opportunities of meeting that celebrated critic, and was in the custom of committing to paper the learned or ingenious observations which dropped from him in the course of conversation; to which he occasionally added remarks of his own. This collection, which was chiefly in Latin, remained in manuscript many years after the death of the compiler. It was at length purchased by M. de Sigogne, who published it in 1669, under the title of *Prima Scaligerana, nusquam antehac edita;* bestowing upon it the title *prima*, in order to preserve its claim of priority over another Scaligerana, which had been published three years before, but had been more recently compiled. This second work, known by the name of *Secunda Scaligerana*, was collected by two brothers of the name of Vassan, who went to complete their studies at the University of Leyden, of which Scaliger was at that time one of the Professors. Being particularly recommended to Scaliger, they were received in his house, and daily enjoyed his conversation; in the course of which, he gave them much information concerning various topics of history and criticism. The Vassans immediately wrote down what they had heard, and soon made up a large manuscript volume, in which, however, there was neither connection nor arrangement of any description. In this state, the manuscript was delivered by one of the Vassans, on his retirement to a monastery, to M. de Puy; and after passing through various hands, it came into the possession of M. Daillé, who, for his own use, arranged the articles it contained in alphabetical order. Isaac

Ana.

Vossius having come to Paris on a visit to M. Daillé, obtained the loan of the manuscript, which he transcribed, and afterwards published at the Hague, under the title of *Scaligerana, sive excerpta ex ore Josephi Scaligeri.* This edition was full of inaccuracies and blunders; but a more correct impression was afterwards published by M. Daillé, with a preface complaining of the use Vossius had made of the manuscript, which he declares was never intended for publication, and was not of a nature to be given to the world. Indeed, most literary men in that age conceived, that the *Scaligerana*, particularly the *second*, detracted considerably from the reputation of the great scholar whose sentiments they recorded. They are full of mistakes and contradictions; and Bayle has remarked, that the Vassans attribute to him observations which it is almost impossible he could have uttered. Joseph Scaliger, with more extensive erudition, but less genius than his father, Julius Cæsar Scaliger, had inherited his ridiculous vanity and dogmatical spirit. He wished it to be thought that he knew everything, and that his opinions were infallible. Conversing with two young students of an university, of which he formed the principal ornament, he would probably be but little cautious in the opinions he expressed, as his literary errors could not be detected or exposed. Unfortunately, the blind admiration of his pupils led them to regard even his most absurd opinions as the responses of an oracle, and his most unmerited censures as just condemnations. The *Scaligerana*, accordingly, contain many falsehoods, with much unworthy personal abuse, of the most distinguished characters of the age. Thus, he calls Cardinal Bellarmin a mere atheist (*plane atheus*), and compares the Duke of Sully to Sejanus. Indeed, M. Daillé, in his preface to the *Secunda Scaligerana*, confesses that it contains "multa futilia, scurrilia, obscæna; quædam manifeste falsa. Ubique de se suisque magnifice, ne dicam, thrasonice, loquitur—laudum parcus, convitiorum largus, in omnes contumeliosissime invehitur—denique neminem sibi de manibus elabi patitur, cujus non errata, vitia, nævos etiam levissimos, acerrime insectetur, et plusquam cynica licentia arrodat."

In imitation of the *Scaligerana*, a prodigious number of similar works appeared in France, towards the end of the seventeenth, and beginning of the eighteenth century. At first, these collections were confined to what had fallen from eminent men in conversation; but they were afterwards made to embrace fragments found among their papers, and even passages extracted from their works, and epistolary correspondence. Of those which merely record the conversations of eminent men, the best known, the fullest, and most valuable, is the *Menagiana*. Menage was a person of good sense, of various and extensive information, and of the most communicative disposition. He lived during the greater part of his life in the best society. An assembly of literary characters met, during a long period of time, at his house every Wednesday; and, during his latter years, he daily received persons of that description. Much of his time was thus spent in conversation; and those of his friends who habitually enjoyed it were at pains to record his opinions, which were generally founded on a correct taste and judgment; and were always delivered in a manner the most interesting and lively. A collection of his oral opinions was published in 1693, soon after his death; and this collection, which was entitled *Menagiana*, was afterwards corrected and enlarged by M. La Monnoye, in an edition published by him in 1715. Among the most curious articles in the *Menagiana* may be numbered the dissertation on *Le Moyen de Parvenir*, a work attributed to Beroalde de Verreville; that on *Le Songe de Poliphile*; as also a letter of La Monnoye on the existence of a book supposed to have been entitled *De Tribus Impostoribus*, concerning which there has been much discussion and controversy.

Perroniana.

The *Perroniana*, which exhibits the opinions of Cardinal Perron, was composed from his familiar conversation, by M. de Puy, and published by Vossius, by the same contrivance which put him in possession of the *Scaligerana*. Some parts of this collection are useful in illustrating the literary and ecclesiastical history of the age in which Perron lived; but it also contains many puerile, imprudent, and absurd remarks, which it is generally supposed he never uttered, and many of which were proved by M. Chevreau (*Chevraeana*) to have been the interpolations of his friends. Some of his assertions,—as that Luther denied the immortality of the soul, and that every English peasant drinks from a silver goblet,—are evidently false. Nor can much reliance be placed on the judgment or taste of an author, who has elsewhere declared, that a page of Quintus Curtius is worth thirty of Tacitus, and that, next to Quintus Curtius, Florus is the greatest Roman Historian.

Thuana.

The *Thuana*, or observations of the President De Thou, have usually been published along with the *Perroniana*. This collection is not extensive, and by no means of such value as might have been expected from a man so able and distinguished.

Valesiana.

The *Valesiana* is a collection of the literary opinions of the historiographer Adrian Valois, published by his son. M. Valois was a great student of history, and the Valesiana, accordingly, comprehends many valuable historical observations, particularly on the works of Du Cange.

Fureteriana.

The *Fureteriana* contains the *bon-mots* of M. Furetiere, of the French Academy, the stories which he was in the habit of telling, and a number of anecdotes and remarks found among his papers after his decease. This production, however, consists chiefly of short stories, and comprehends but few thoughts, opinions, or criticisms on books. Furetiere, it is well known, had a violent quarrel with the French Academy, of which he was a member, concerning his *Dictionnaire Universel de la Langue Françoise*. Having published a preliminary discourse, the farther printing was interdicted by the French Academy, which accused him of purloining materials they had amassed for a similar work. This controversy subsisted during the rest of the life of Furetiere, who spent his concluding years in writing and publishing libels on his associates. The *Fureteriana*, accordingly, is replete with allusions to a subject with which his thoughts were so completely engrossed. In particular, we find there the plan

Ana.

and outline of an allegorical and burlesque poem, entitled *Les Couches de l'Académie;* in which he has satirized different members of the academy, especially M. Charpentier, one of his bitterest foes, whom he has designated by the name of *Marmentier*.

Chevraeana.

The *Chevraeana*, so called from M. Chevreau, exhibits more research than most works of a similar description; and is probably more accurate, as it was published during the life of the author, and revised by himself. Among other interesting articles, it contains a learned and ingenious commentary on the works of Malherbe, to whom the French language and poetry were highly indebted for the perfection to which they attained.

Parrhasiana.

*Parrhasiana* is the work of Jean Le Clerc, a Professor of Amsterdam, who bestowed this appellation on his miscellaneous productions, with the view of discussing various topics of philosophy and politics, with more freedom than he could have employed under his own name. This work is not of the light and unconnected description of most of the Ana which have been above enumerated; as it contains much learned philological disquisition, and a long dissertation on poetry and eloquence. In the first volume, there is a list of his published works, and a bitter reply to all those who had censured them.

Huetiana.

The *Huetiana*, which has always held a distinguished place among the Ana, contains the detached thoughts and criticisms of Huet, Bishop of Avranches, which he himself committed to writing during his life. This author was well fitted to produce a valuable work in this department of literature. He enjoyed the friendship of a number of distinguished characters, and his reading was various and extensive. This collection, however, was not begun by him till he was far advanced in life. Huet was born in 1630, and, in 1712, he was attacked by a malady which impaired his memory, and rendered him incapable of the sustained attention necessary for the completion of a long or laborious work. In this situation, he employed himself during the concluding years of his life in throwing his detached observations on paper. These were published by the Abbé d'Olivet the year after his death, under the name of *Huetiana;* a work which is not, like some other Ana, a succession of *bon-mots* or anecdotes; but forms a series of thoughts and criticisms on various topics of morals, philosophy, and literature; and also comprehends pretty long dissertations on the origin of rhyme, the comparative merit of the ancients and moderns, with similar topics. One of the most instructive discussions to a scholar, in this collection, is that on the Latinization of names and surnames; in which he points out and criticises the different modes of this process. His critical judgments on Montaigne, Rochefoucauld, and Tacitus, seem also well founded; and if some of his opinions in matters of taste betray singular or defective feelings, there are others which appear equally just and refined. But were there no other literary memorials of the Bishop of Avranches, he certainly would not derive high reputation from the *Huetiana*. D'Alembert has treated this collection with contempt; and has selected some articles to show the Bishop's incompetent judgment and frivolous taste. It may be suspected, indeed, from the circumstances in which the articles contained in the *Huetiana* were composed, that they do not always display that correct judgment which distinguishes many of the other works of this learned writer.

Casauboniana.

The *Casauboniana* presents us with the miscellaneous observations, chiefly philological, of the celebrated Isaac Casaubon. During the course of a long life, that eminent commentator was in the daily practice of committing to paper any thing remarkable which he heard in conversation with his friends, especially if it bore on the studies in which he was engaged. He also made diurnal annotations on the works he was employed in reading, with which he connected his judgments concerning the author and his writings. This compilation, which was styled *Ephemerides*, together with his *Adversaria*, and materials amassed for a refutation of the *Ecclesiastical Annals of Baronius*, came, at his death, into the possession of his son, Meric Casaubon, who bequeathed the whole to the Bodleian Library at Oxford. These were shown to Christopher Wolfius, during a visit which he paid to that university, and having been transcribed by him, were published under the title of *Casauboniana*. This collection consists of opinions concerning various eminent writers; illustrations of passages in scripture; and philological observations and animadversions on the thirty-four first years of the *Annals of Baronius*. The materials and information which it contains are probably more accurate than is usually the case in works of the same description; as they were not communicated in casual conversation, and reported by others, but were daily committed to writing by Casaubon himself, while the works from which they were derived remained fresh in his recollection.

Besides the above, a great many works, under the title of Ana, appeared in France about the same period. Thus, the opinions and conversation of Charpentier, Colomesius, and St Evremond, were recorded in the *Carpenteriana*, *Colomesiana*, and *St Evremoniana;* and those of Segrais in the *Segraisiana;*—a collection formed by a person stationed behind the tapestry in a house where Segrais was accustomed to visit, and of which Voltaire has declared, "que de tous les Ana c'est celui qui merite le plus d'être mis au rang des mensonges imprimés, et surtout des mensonges insipides." The Ana, indeed, from the popularity which they now enjoyed, were compiled in such numbers, and with so little care, that they became almost proverbial for inaccuracy. About the middle of the eighteenth century, they were sometimes made the vehicles of political squibs,—as in the *Maupeouana*, and of heretical opinions,—as in the *Longueruana*. Thus, the evil naturally began to cure itself, and by a re-action, which is very general in regard to all productions of literature, the French Ana sunk in public esteem, as much below their intrinsic value, as they had formerly been exalted above it.

Carpenteriana. Colomesiana. Evremoniana. Segraisiana

Maupeouana. Longueruana.

Although these collections have been chiefly formed from the oral opinions of eminent men on the Continent, particularly in France, England has also produced one or two examples of this species of composition, which are not altogether undeserving

Ana. Walpoliana.

of attention. Of these, perhaps, the most curious is the *Walpoliana*, which is a transcript of the literary conversation of Horace Walpole. That multifarious author was distinguished for his resources of anecdote, wit, and judicious remark, as well as for his epistolary qualifications. From his father, Sir Robert Walpole, he had learned many anecdotes concerning the political characters who figured during the period of his administration. He was himself personally acquainted with all the eminent literary characters of his own day in England; and his repeated visits to Paris, and constant correspondence with friends in that Capital, supplied him with the most interesting information with regard to France. A great part of his life was devoted to conversation. While residing at Strawberry-hill, he generally rose from table about five o'clock, and taking his place on his drawing-room sofa, to which his gout in a great measure confined him, he passed the time till two o'clock in the morning, in miscellaneous chit-chat, full of singular anecdotes, strokes of wit, and acute observations. As he possessed, and was daily communicating such stores of instruction and amusement, it was suggested to him that he ought to form a collection of these anecdotes and observations. This he declined, but he furnished the editor of the *Walpoliana* with many anecdotes in his own hand-writing. After his death, several specimens of this miscellany were published in the *Monthly Magazine;* and being afterwards enlarged by anecdotes, retained in the memory of the editor, or communicated by others, were published in two volumes, under the title of *Walpoliana*. Most other works, which, in this country, have been published under the name of *Ana*,—as *Baconiana*, *Atterburyana*,—are rather extracts from the writings and correspondence of eminent men, than memorials of their conversation.

There are some works which, though they do not bear the title, belong more strictly to the class of Ana than many of those collections which are known under that appellation. Such are the *Mélange d'Histoire et de Litterature*, published under the name of *Vigneul Marville;* and the *Locorum Communium collectanea, ex Lectionibus Philippi Melanchthonis;*—a work which was published as far back as the sixteenth century, and has obtained considerable reputation on account of its theological learning, and the information it communicates concerning the early state of the reformed church. But of those productions which belong to the class, though they do not bear the name of Ana, the most celebrated are the *Colloquia Mensalia* of Luther, and Selden's *Table-Talk*,—both of which merit particular notice. The first, which comprehends the conversation of Luther with his friends, and coadjutors in the great work of the Reformation, was first published in 1566. Captain Henry Bell, who translated it into English, in the time of the Commonwealth, informs us, that, at the instigation of the Pope, the Emperor of Germany had promulgated an edict commanding the works of Luther to be destroyed. It was for some time supposed that all the copies of the *Colloquia Mensalia* had been burned in consequence of this order; but at length, in 1626, a German called Van Sparr, having occasion to build on the old foundation of a house in which his grandfather dwelt, when the imperial edict was issued, he found lying in a deep hole, and wrapped up in a linen cloth, a printed copy of the *Colloquia Mensalia*. Captain Bell, having formerly become acquainted with Van Sparr during a long residence in Germany, his friend transmitted the work to him in England, where he executed a translation of it; an undertaking to which he pretends that he was urged by the vision of an old man with a long white beard, arrayed in white, who spoke these words: "Sirrah, will you not take time to translate that book?" The extraordinary book translated by Bell, at the instance of this vision, is said to have been originally collected by Dr Anthony Lauterbach, "out of the holy mouth of Luther;" and was afterwards digested into common-places by Dr John Aurifaber. It chiefly contains observations and discussions on idolatry, auricular confession, mass, excommunication, clerical jurisdiction, general councils, and all the points agitated by the reformed church in those early periods. With such topics, there is intermixed many diatribes against Antichrist and the Cardinals, and much sarcasm on popish miracles and relics. Occasionally, however, it must be confessed, that our great reformer expresses a belief in superstitions fully as wild and monstrous as those which he derides, and which he was called to overthrow. Thus, he asserted that he was repeatedly kept from sleep, by the Devil cracking nuts in his chamber; and he affirmed that there was a child at Dessaw, which had been substituted by the Arch-Fiend instead of one he had stolen away, and which child Luther earnestly advised the Prince of Anhalt to throw into the river Moldaw.

Luther's Colloquia Mensalia.

Selden's Table-Talk.

If the collection of Selden's apophthegms and sayings, entitled *Table-Talk*, be regarded of good authority, we shall find in it a more genuine and undisguised expression of the sentiments of that eminent man, than in his more studied productions. This work was published, after the death of Selden, by Richard Milward, his Amanuensis; who, in his dedication to Selden's executors, affirms, that, for twenty years, he enjoyed the opportunity of daily hearing his discourse, during which long period he made it his practice, from time to time, faithfully to commit to writing "the excellent things that usually fell from him." Dr Wilkins, in his introductory discourse to the works of Selden, has attempted to throw discredit on the authenticity of this compilation; asserting, that it contains many things derogatory from Selden's erudition, and foreign from his manners and principles. It is not improbable, indeed, that the memory of the Amanuensis may have occasionally failed him, and that he may have recorded sayings which inadvertently escaped his master in the heat of conversation, and such as he probably would not have deliberately maintained. But, on the whole, the work has completely an air of genuineness; and although the familiarity of his illustrations and parallels may appear to clash with the idea formed of so great a scholar, they are characteristic of a man who had been conversant with scenes of common life, no less than the speculations

Ana.

of the closet. That such was the usual manner of Selden's conversation, the Editor of the *Table-Talk* recalls to the recollection of those friends of his patron, to whom the work is dedicated; and this appeal forms a presumption of his veracity. The *Table-Talk* contains many curious facts and opinions concerning the political and ecclesiastical history of the interesting period during which Selden lived, and in the important events of which he bore a considerable share. To judge from this work, Selden had great contempt for the theologians of his day; and seems to have been of opinion that the State should invariably keep a rein on the Church. He was partial to the Episcopal form of worship; but was evidently not very strict in doctrinal points, as appears from what he is reported to have said on the subject of *heresy*. In his political opinions, he seems to have entertained a high respect for the sacredness of the social contract; and he justified the resistance to the Stewarts, on the ground that they had infringed and violated this compact between prince and people. Besides religious and political opinions, the *Table-Talk* contains much of a lighter description; in consequence of which, Selden has been accused of showing more laxness, in point of moral principle, than might have been expected from so grave and respectable a character. Many of those sentiments, however, which have been considered objectionable, may have been merely advanced as plausible deductions from principles assumed for the sake of argument. But whatever difference of opinion may exist, with regard to the matter of the *Table-Talk*, the manner in which the sentiments are there expressed must be universally admitted to be perspicuous and agreeable. The style of Selden, in most of the works published under his own care, is harsh and obscure; but Clarendon, who differed from him so widely in political opinions, acknowledges that he was "a clear discourser; and that he possessed the faculty of making difficult things easy, and presenting them clearly to the understanding." Accordingly, this talent for elucidation shines chiefly in his *Table-Talk;* which is filled with the stores of his extensive reading, delivered without any pretensions to that order and method, the want of which has been attributed to his other productions.

It thus appears, that although the compilations designated by the name of Ana belong more particularly to France, they have not been wholly unknown in this country. In their *Motti e Burle*, and sometimes in their Novels, the Italians also have recorded the witticisms of their distinguished poets and artists. The novels of Sacchetti are full of repartees attributed to Dante, and the Painters Giotto and Buffalmacco. Almost every Italian biographical work, of the sixteenth and seventeenth centuries, like Boswell's *Life of Johnson*, records at great length the conversational remarks of the individual whose life is detailed. Thus, Manso has dedicated one of the books of his life of Torquato Tasso to an account of the wise and witty sayings of that illustrious poet, who, towards the close of his days, had become the intimate friend of his biographer. The conversation of the poet, however, was neither gay nor brilliant: One of the characters in Goldoni's drama of Torquato Tasso thus contrasts his writings and conversation:

> Ammiro il suo talento, gradisco i carmi suoi;
> Ma piacer non trovo a conversar con lui.

It also unfortunately happens, that the greater part of the sayings recorded by Manso may be found in the Apophthegms of Erasmus, which were published before the birth of Tasso. Indeed, Manso seems to have been aware of the want of originality in the *bon-mots* of his friend; for, after mentioning one, he says, "questo motto fu da alcuni ad *Epiteto* attribuito." It was usual, indeed, among the biographers of those times, to pillage Xenophon or Plutarch, for good things to put into the mouths of their heroes; a practice from which Machiavel could not abstain in his short account of the illiterate soldier Castruccio Castracani. In these ages of pedantry, however, it is not improbable, that many sayings of the old philosophers might have been repeated as their own by the learned men of the times; and that the Italian *literati* might occasionally attempt to make their hearers merry with the jests of Socrates or Diogenes. The genius and character of the people rendered any collection of this nature less agreeable than the Ana of the neighbouring nation. In Italy, gravity was numbered among the virtues, and, in the eulogy of any illustrious man, is always mentioned as one of his most commendable qualities. There seems, in that country, to have been no medium between the most fantastic buffoonery, and a certain tragic solemnity. The Italians wanted that "mobility of imagination," that facility, rapidity, abandonment and gaiety, which seems almost peculiar to the French, and forms the chief charm of social intercourse, as well as of those works in which it is represented; though, no doubt, when reduced into writing, much of its grace and spirit must evaporate and disappear.

The existence of similar causes, and perhaps in a stronger degree, prevented the popularity of Ana among the Spaniards; though they too have related the jests and opinions of the Duke d'Ossuna, and of some others. Indeed, whatever may be the genius or disposition of a people, traces of this mode of composition may in some shape or other be discovered among them.

When presented in their most perfect form, which is that of the French Ana, these Collections are certainly entertaining from their variety, and curious, as presenting a lively image of the distinguished characters whose sentiments they record. If men reason more correctly on paper, they usually display their feelings and convictions with more truth in unpremeditated conversation. Few are so cautious or hypocritical, that they do not sometimes drop the mask in the society of their friends, and express what they think or feel, when they no longer entertain apprehensions that their sentiments will be communicated to the vulgar. In general, however, the Ana should rather be regarded as affording a notion of the spirit and turn of thinking of those whose conversation they detail, than as authorities for particular opinions. A spirit of contradiction,—a wish to display ingenuity,—to astonish by

paradoxes,—or even to support conversation, may often lead men to maintain opinions in colloquial intercourse which they perhaps never seriously held, or at least would be ready to disclaim on mature consideration. It also unfortunately happens, that in many of the Ana, those who collected the conversations which they presented to the world, interpolated their own opinions; which, of course, greatly diminishes their authority as characteristical records. It has also been objected to this species of composition, that every subject is treated superficially; but it should be recollected that the Ana do not profess to contain profound dissertations; and in fact no one consults them with the view of being deeply informed on any topic. A better founded objection is, that many subjects are treated, not merely superficially, but inaccurately. Such compositions are liable to a double risk of error; first, of the person who delivers opinions in the heat of discourse, or relates anecdotes from vague recollection; and, secondly, of the person who records them, who must be liable to mistake, what he has only heard in the course of conversation. From these causes, and from their wide and general circulation, many of the most current literary errors may be traced to the Ana. When read, however, with discrimination, they may prove highly useful, in illustrating various points of literary history; as they certainly contain a great deal which is not to be found in the formal compositions of the learned.

Wolfius has given a history of the ANA, in a preliminary discourse to his edition of the *Casauboniana*, published in 1710. In the *Répertoire de Bibliographies spéciales, curieuses et instructives*, by Peignot, there is a *Notice Bibliographique* of these Collections; but many of the books there enumerated consist of mere extracts from the writings of popular authors, and do not, therefore, belong to that class of literary works described in the preceding article. (M.)

# ANATOMY.

THE provinces of Anatomy and Physiology may now, we believe, be looked upon as distinctly and permanently defined. Anatomy is understood to treat solely of the Structure of Living Bodies, and Physiology solely of their Functions.

We shall observe this arrangement strictly in the following article. It is one which, in our opinion, has already been productive of material advantages to the science of Vital Economy. The descriptive detail of the structure of Living Bodies is no longer distracted and obscured by superficial and unconnected views of their functions; nor their functions carelessly discussed, in the form of occasional and uninstructive commentaries on the descriptions of their structure. Each is made the subject of separate and particular investigation; and not only has Anatomy been thus rendered more accurate and precise, but a more regular and philosophical form has been given to Physiology, and its progressive improvement rendered more sure.

Living Bodies being arranged into two grand classes, Animals and Vegetables, the science of Anatomy, of course, comprehends two great divisions corresponding to these; viz. ANIMAL ANATOMY and VEGETABLE ANATOMY.

In the two following articles, we propose not only to trace the progress of improvement in each of those departments within these few years, but to correct several errors, and to supply many deficiencies, in the dissertations which relate to them in the body of the work.

## ANIMAL ANATOMY.

### I. HUMAN ANATOMY.

1. In our supplementary remarks on this first and most important department of Animal Anatomy, we shall endeavour, by the arrangement we intend to follow, to exhibit the outline of a plan better adapted, we conceive, for an elementary view of the structure of the Human Body, than that which has usually been observed in the schools of medicine, or in anatomical works.

But it will be necessary to premise a few observations on the acceptation of certain terms, which will occur very frequently in the descriptions that are to follow.

2. By the *period of impregnation* or *conception*, is uniformly meant the moment at which a child, or infant-being, begins to be formed within the womb of the mother.

While the child is yet retained within the womb, it is denominated a *fœtus* or *embryo*; the term *embryo*, however, being chiefly applied to it in its earlier stages.

The end of the ninth month after *conception*, which is the natural *period of birth*, is often denominated the *full time*.

The inhabitants of Great Britain, and perhaps of Europe in general, are usually *full-grown*, or *adult*, at the age of twenty-five or thirty years. This is the

Anatomy, Human.

period of life, therefore, which we wish to be understood as denoted by the term *adult age*, or *maturity*.

Our descriptions are to be considered as applicable to the *adult male*, unless when the contrary is expressly specified.

To regulate the interpretation of the terms *above*, *below*, *before*, *behind*, &c. we shall uniformly suppose the body to be in the erect posture, with the arms hanging parallel to the trunk, and the palms of the hands, and the toes, turned directly forwards. This is a simple remedy, and the only effectual one, for the trifling ambiguity which might otherwise attend the use of these terms.

Any part of the body, or the surface of any part, which is capable of being divided, in one or more directions, into two portions or halves exactly alike, is said to be *symmetrical ;* and the line or plane separating them is called the *median line*, or *median plane*.

## PART I.

### OF THE EXTERNAL FORM, STATURE, AND WEIGHT OF THE BODY.

#### *External Form.*

Of the Fœtus.

3. There are very few anatomists who enjoy opportunities of ascertaining the gradual changes which take place in the external form of the fœtus during the earlier periods of its developement. The admirable series of engravings, therefore, in which Soemmerring has represented these changes, from the first to the fifth month after impregnation, will be consulted with great interest. (See *Icones Embryonum Humanorum.*)

An embryo of three or four weeks appears in these representations to the naked eye, somewhat like a mustard seed just beginning to grow ; the head being like the body of the seed, and the trunk and remaining parts like the radicle. With the magnifying-glass, however, a little dark circle can be distinctly seen in the regions of the eyes, and a small slit, corresponding to the orifice of the mouth. Four little prominences are observable on the trunk, in the situation of the four extremities ; and between the two lower, there is a curious prolongation like a tail, which has been called the *coccygeal protuberance*.

In an embryo of about seven weeks, the proportional size of the head is so much less, that the peculiar form of the human body is quite apparent. Two small pores are perceptible in the region of the nose ; and the superior extremities seem divided into arm and fore-arm.

In an embryo of about eight weeks, a small pore may be discovered, by the microscope, in the region of each auricle ; a shoulder, arm, fore-arm, and hand, with five small tubercles in the situation of the fingers, can be easily distinguished with the naked eye ; and in the lower extremities, parts can be seen corresponding to the thigh, leg, and foot ; but there is no appearance of toes.

In an embryo of about nine weeks, there is a projection in the region of the nose ; part of the auricles is formed ; the toes have appeared ; the pudenda begin to be distinguished ; and the coccygeal protuberance can no longer be seen.

After this, considerable changes take place in the external appearance of the fœtus, in proportion as the developement of the different parts advances ; but it would be impossible to convey an idea of these without the aid of engravings. Hair generally begins to appear on the eye-brows, and in the regions of the hind-head and temples, about the end of the fifth month.

4. Soemmerring has accompanied these representations with some remarks, which are worth attending to. The younger the fœtus, he finds, the larger is its head, compared to the other parts of the body ; the smaller its face, in proportion to the other parts of the head ; and the smaller its limbs, relatively to the trunk. During the first, second, and third months, he has remarked, that the upper extremities are larger than the lower ; but that, about the fourth, they are equal ; and that, towards the fifth, the lower have become larger than the upper.

Male and Female Fœtus compared.

5. He has also pointed out the following curious distinctions, in external form, between the male and the female fœtus. The head of the male differs from that of the female, in being larger in proportion to the whole body, less rounded, flatter in the crown, and more prominent behind. In the male, the breast is considerably more prominent than the umbilical region, while in the female it is the reverse ; and this is a distinction perceptible in the youngest fœtuses. The trunk of the body, between the upper parts of the loins, is arched in the male, but hollow in the female ; and this, too, is a distinction very early observable. The upper extremities in the male are a little longer, in proportion to the trunk, than in the female ; the arms are less cylindrical ; the fore-arms fuller ; the wrists broader ; and the ends of the fingers less pointed. The circumference of the body, at the haunches, is less in the male than in the female ; the thighs are more slender ; the feet longer ; the malleoli and heels more prominent ; and the great toe exceeds the others much more in length.

#### *Stature.*

Of the Male.

6. We believe the mean height of the male, at the period of maturity, to be about five feet eight inches English measure ; and the following are the comparative average dimensions of particular parts of the body :

| | *Inch.* |
|---|---|
| Total height of the body - - - - - - - | 68.00 |
| From the tip of one middle-finger to the tip of the other, the upper extremities being extended laterally to a right angle with the trunk - - - - - - - - - - - - | 68.00 |
| From the crown of the head to the top of the pubes - - - - - - - - - - - - | 34.00 |
| From the crown of the head to the lower margin of the chin - - - - - - - - | 9.75 |
| From the lower margin of the chin to the top of the breast - - - - - - - - - - | 3.85 |
| From the top of the breast to the pit of the stomach - - - - - - - - - - - | 6.08 |
| From the pit of the stomach to the navel - | 6.08 |
| From the navel to the top of the pubes - - | 6.08 |
| From the top of the prominence of the shoulder to the fold of the elbow - - - - | 12.06 |

Anatomy, Human.

| | |
|---|---|
| From the fold of the elbow to the top of the hand | 10.02 |
| The hand, measured in the palm, from the lower fold of the wrist to the point of the middle-finger | 7.75 |
| From the top of the inside of the thigh to the inside of the joint of the knee | 14.06 |
| From the inside of the joint of the knee to the sole of the foot | 18.05 |
| The foot, measured on the sole, from the posterior margin of the heel to the point of the great toe | 9.75 |

Of the Female.

7. The average height of the female seems to be about five feet five inches; and the length of the different regions proportionally less than in the male.

Of the Fœtus.

8. The length of an embryo of three or four weeks represented by Soemmerring, is only about one-eighth of an inch; one of eight weeks is about an inch; and one at the end of the fifth month about ten inches. According to Mr Burns, (*Principles of Midwifery*, p. 121.) however, the fœtus, in the fifth month, is only about six or seven inches in length.

The same intelligent author states the length of the fœtus in the sixth month to be about eight or nine inches; in the seventh about twelve inches; and in the eighth about fifteen inches.

According to the observations of Roederer (*Comment. Reg. Soc. Scien. Gotting.* 1753), the length of the fœtus at the period of birth is, on an average, about $20\frac{1}{2}$ inches.

Of the Head of the Fœtus.

9. The only individual part of the fœtus, of which it is important to ascertain the average dimensions at the period of birth, is the head. Now, the longest diameter of the head, at this period, is that from the crown to the chin; and this seems in general to measure about five inches. The breadth of the head, at the same time, from one parietal protuberance to the other, is usually about $3\frac{1}{2}$ inches. In an exceedingly interesting paper in the *Philosophical Transactions* (*Phil. Trans.* 1786), Dr Clarke has stated, that he measured the heads of sixty male, and sixty female children, born at the full time; and that he found the circumference passing through the occipital protuberance, and the middle of the brow, to be, on an average, 13.8 inches; while the arch from ear to ear over the crown was 7.32 inches. One measured fifteen inches in circumference, and one $8\frac{1}{2}$ inches from ear to ear; but none were under twelve inches in the one direction, or $6\frac{1}{4}$ inches in the other.

Ratio of the Growth of Fœtus.

10. There are some general remarks on the progressive growth of the fœtus by Soemmerring, accompanying the engravings to which we have already referred, which present some singular results. According to him, the most rapid increase of the fœtus takes place during the first weeks after conception. He has observed, however, that the growth does not proceed in a uniform ratio; but that it is a little retarded during the second month; accelerated during the third; again somewhat retarded at the beginning of the fourth; from the middle of the fourth to the sixth again accelerated; and from this period till the end of the ninth month once more retarded.

Dimensions of the Male and Female Fœtus compared.

11. It seems to be well established, that there is a difference in the average dimensions of the male and female, even in the fœtal state. Roederer found the mean length of sixteen male children born at the full time to be $20\frac{10}{12}$ inches; and of eight females only $20\frac{4}{12}$; and Dr Clarke, in his measurement of the heads of sixty male, and sixty female children, born at the natural period, found that the circumference was, on an average, 14 inches in the males, and only $13\frac{5}{8}$ inches in the females, and the arch from ear to ear over the crown $7\frac{1}{4}$ inches in the males, and only $7\frac{1}{5}$ in the females. Out of one hundred and twenty children, there were only six in whom the circumference of the head exceeded $14\frac{1}{2}$ inches, and these six were males.

### *Weight.*

Of the Male.

12. We have examined a register of the weights of about fifty full grown males of the average stature, and find their mean weight to be about 140 lbs. English Troy. The average weight of an equal number of adult females, we suppose, would be found to be about 30 or 40 lbs. less; but we have had no opportunity of ascertaining this.

Of the Fœtus.

13. The average weight of the fœtus in the earlier months is uncertain. According to Mr Burns (*Principles of Midwifery*, p. 121), however, it generally weighs about 2 oz. in the twelfth week; about 1 lb. in the sixth month, and about 4 or 5 lbs. Troy in the eighth month.

At Birth.

14. Its mean weight at the natural period of birth has been better ascertained. It seems to be about 7 lbs. avoirdupois. The celebrated Dr Hunter (*Anatomical Description of the Gravid Uterus*, p. 68) states, that of several thousand new-born and perfect children, which were weighed at the British Hospital in London by Dr Macaulay, the smallest was about 4 lbs., and the largest about 11 lbs. 2 oz; but by far the greater number were from 5 to 8 lbs. avoirdupois. He adds, that he never knew an instance of a child born at the natural period that weighed 12 lbs. avoirdupois. Of sixty male and sixty female children, born at the full time, which were weighed by Dr Clarke, the lightest was 4 lbs., and the heaviest 10 lbs.; and the average weight was 7 lbs. 13 dr. avoirdupois. The average weight of twenty-six children, born at the natural period, which were weighed by Roederer, seems to have been about $6\frac{1}{2}$ lbs.; the heaviest being 8 lbs., and the lightest about $5\frac{1}{4}$ lbs.; but we are uncertain as to the scale of the weights which he employed.

15. Dr Clarke estimates the difference between the average weight of the male and female at birth at about 9 oz. avoirdupois; and the results of Roederer's observations do not appear to differ materially from this estimate.

Of Twins.

16. In cases of *twins*, it would seem that the weight of each twin is in general less than the average weight of *single children*, though their combined weight is greater. Dr Clarke found the average weight of twelve twins to be 11 lbs. avoirdupois a pair; the heaviest pair weighing 13 lbs., and the lightest $8\frac{1}{2}$ lbs. Mr Burns, however, states, that he has known instances, in which each twin was rather above than under the usual weight of a single child.

## PART II.

### OF THE ANATOMY IN GENERAL OF THE COMMON SYSTEMS AND COMMON TEXTURES OF THE BODY.

17. By the COMMON SYSTEMS of the body, we mean the *Circulating System*, the *Absorbent System*, and the *Nervous System*; and by the COMMON TEXTURES, *Cellular Substance, Adipose Substance, Muscle, Skin, Hair, Cartilage, Bone, Tendon, Serous Membrane*, and *Synovial Membrane*.

18. We have applied the term *Common* to these *Systems* and *Textures*, because they are common to many parts of the body.

A general view of their structure and distribution, forms a proper introduction to the anatomy of individual parts.

### ARTICLE I.

### OF THE ANATOMY IN GENERAL OF THE COMMON SYSTEMS.

#### I. OF THE CIRCULATING SYSTEM.

This system consists of two parts; *viz.* the *Heart* and the *Blood-vessels*.

#### 1. *Of the Heart.*

#### A. *The Heart of the Adult Male.*

The Oval Fossa.

19. When the cavity of the right auricle of the heart is laid open, we observe, on the lower part of its posterior surface, an elliptical, but very superficial depression, which slopes a little backwards, and is called the *oval fossa*. This fossa is about half an inch long, and the third of an inch broad, with smooth edges, and having its long diameter turned upwards and downwards. Its size, however, varies very much in different individuals, and frequently it is entirely wanting.

Several Continental anatomists have lately affirmed, that there is, in general, a small slit, sufficient to admit the point of a probe, immediately behind the upper margin of this fossa, which inclines upwards, and a little to the left, and opens into the left auricle. We have seen this passage only in a few instances; but the authorities are so respectable, by whom it has been said to occur in a majority of cases, that we cannot doubt the statement to be correct.

The Eustachian Valve.

20. The *Eustachian Valve* has not hitherto been described with sufficient accuracy. This is a thin, whitish, crescentic fold, situated immediately to the left of the opening of the inferior vena cava into the right auricle. Its posterior horn is connected with the left edge of the oval fossa, and its anterior with the right surface of the auricle, directly above the opening of the lower cava; so that it runs from behind obliquely forwards, and to the right. Its free curved edge looks upwards, and a little backwards; and one surface of it is continuous with the left and anterior side of the inferior cava, while the other is turned towards the left and fore part of the auricle. Were it prolonged straight upwards, it would run into the upper margin of the oval fossa; and, even as it is, when we look into the auricle from before, it cuts off from our view the lower half of this fossa. Its breadth and thickness vary extremely. Sometimes it is nearly half an inch broad, at other times scarcely perceptible; in some it is as thick as a wafer at its attachment, but tapering towards its edge, and without any holes in it; in others, it is as thin as silk-paper, transparent, and quite reticulated.

Capacity of the Cavities of the Heart.

21. In the heart, as we usually find it after death, the cavities of the ventricles always appear larger than those of the auricles. In general, also, the cavities of the right side appear to be more capacious than those of the left; the difference between them, however, being less in some cases than in others. In some instances they seem pretty nearly alike.

22. A variety of experiments have been made, with a view to ascertain precisely the capacities of these cavities after death; * but none of them can be regarded as quite satisfactory. In some, it is uncertain, whether precautions were taken to prevent the fluid employed in the measurement, from escaping by some of the blood-vessels communicating with the cavities. In others, it is doubtful whether certain coagula of blood, which generally form in these cavities after death, had been carefully removed; and in others, again, allowance is not said to have been made, for the extension of the cavities, which the weight of the fluid employed would necessarily produce.

In several experiments, in which we endeavoured to guard as much as possible against these sources of fallacy, we found, that the right ventricle of an adult heart contained two and a half ounces of water, while the left had only two ounces. Still, however, we are not disposed to place much reliance upon these, or any experiments of the kind.

Coats of the Heart.

23. The whole external surface of the heart is covered with *serous membrane*, which is thickest and strongest in the auricles.

Under this, at particular parts, is a quantity of *adipose substance*, which, shining through the serous membrane, gives the heart a straw colour at those parts.

Under both these is situated what is called the *muscular coat*; and within this, and lining the whole inner surface of the heart, is found the *inner membrane*.

The Inner Membrane.

24. This inner membrane in the cavities of the ventricles is as thin as silk-paper, perfectly transparent, and without the slightest appearance of fibres. Neither blood-vessels, absorbents, nor nerves, have yet been seen in it. Maceration in water renders it slightly opaque. It is easily detached from the muscular fibres which it lines, but no intermediate cellular substance can be seen between them. It is too tender to admit of being peeled off in large patches.

In the right auricle, the inner membrane lining the fleshy cords is quite similar to that in the ventricles; but in all other parts of this auricle, and over

* See Senac, *Traité*, &c. I. p. 189. Haller, *Elem. Physiol.* I. p. 323-7. Le Gallois, *Diction. des Scien. Medic.* V. p. 434.

the whole of the left also, it has a different appearance. It is whiter, and considerably thicker and stronger, than serous membrane. After slight maceration, it is disposed to peel in laminæ; but no fibres are perceptible in it, and, so far as we know, no one has yet seen in it, either vessels or nerves. It is firmly connected to the muscular coat by a fine cellular substance.

The Eustachian valve, and the valve of the coronary vein, appear to be formed of doublings of the inner membrane of the auricle. The former, however, generally contains a fasciculus of muscular fibres at its basis, which is included between the folds of the membrane.

Structure of the Tricuspid and Mitral Valves.

25. The structure of the tricuspid and mitral valves is not so simple. A delicate prolongation of the inner membrane of the auricles can indeed be traced over their inner surface; but we have never been able to detect any similar continuation of the membrane of the ventricles over their outer surface. They seem to consist of a fine but dense web of slender fibres continued from the tendinous cords. These cords, as their name imports, are composed of *tendinous substance;* and, after they have been inserted into the valves, they spread out and are interwoven in every direction, as may be easily seen by holding the valves between the eye and the light. It is the intersections of these cords, just after their insertion, that causes those knots and ridges which are so common on the valves, particularly on the mitral valve.

### B. *The Heart before Maturity.*

Shape of Fœtal Heart.

26. There is a considerable difference, in point of shape, between the heart of a fœtus and that of an adult, resulting from the greater proportional size of the tips of the auricles in the latter. In a fœtus of three or four months, these are so large, that they almost come into contact over the anterior part of the root of the pulmonary artery. As the fœtus grows older, however, they gradually diminish proportionally; so that after birth there is scarcely any peculiarity in this respect.

The Oval Hole of the Fœtal Heart.

27. The most striking and important peculiarity of the fœtal heart is the *oval hole* in the septum, between the auricles. This occupies exactly the situation of the oval fossa in the adult heart. The communication, however, between the auricles through it, is not direct. For, if we examine the heart of a fœtus about the fourth month, we shall find, that there is a thin pellucid membrane laid over the oval hole, like a valve, on the side next the left auricle. The insertion of this valve below, is into the very edge of the lower third of the oval hole itself; but above this, its attachment is into the surface of the septum next the left auricle; extending farther and farther out from the margin of the hole as it ascends. When it gets on a level with the upper border of the hole, it begins to incline inwards again, and, after running a short way, stops; leaving a free curved edge, turned upwards, and a little to the left.

As this valve, then, is longer than the oval hole, it is obvious that, if it were stretched tight across it, like the parchment of a drum, it would prevent all communication between the auricles. But it is twice as broad as the space included within the line of its insertion, so that it admits of being pushed a considerable way towards the cavity of the left auricle. When this is done, a short canal is formed, between the upper part of the valve and the portion of the septum immediately above the oval hole, opening into the left auricle by an orifice, of which the floating edge of the valve forms fully two-thirds. The axis of this canal corresponds exactly with the axis of the inferior vena cava.

Whether there be any period prior to the fourth month, at which the oval hole has no valve, or at which it is smaller, we have not had satisfactory means of ascertaining. But Haller (*Elem. Physiol.* VIII. Pars I. p. 375.) mentions, that his friend Bergen had found none in a fœtus of two months; and Senac (*Traité*, &c. Vol. I. p. 231.) believes that there is none prior to this at least, and expresses himself certain, that if its rudiments exist at two months, they are extremely small. After this period, according to him, it grows by degrees, and its margin approaches nearer and nearer to the upper border of the hole.

It is very probable that this description is correct; but, as we have found that the valve, even in the fourth month, is very easily broken, unless the heart be dissected with great care, nothing but actual observation will satisfy us on this point.

The hole and the valve remain pretty nearly in the state we have described, until about the commencement of the ninth month; when a considerable change begins to take place. The valve becomes thicker and tighter, and its free margin narrower; consequently the passage between the auricles becomes smaller. The sides of the hole itself are at same time thickened. The valve at last becomes so much tighter, and its upper border so much narrower, that the parts assume the appearance of the oval fossa, with a small slit at top, as already described. How long this process is of being completed, we have not ascertained; but we suspect, from an examination of several hearts, that it is not until two or three months after birth at least.

28. The Eustachian valve in the fœtal heart is subject to as much variety, in point of size, almost as in the adult. Eustachian Valve in the Fœtus.

29. The auricles of the fœtal heart are obviously larger, in proportion to the ventricles, than those of the adult; but the relative capacities of the right and left cavities, at this early period, have not been ascertained. They have generally appeared to us to be pretty nearly the same; or, if there was any difference between them, the left auricle and ventricle seemed rather the larger. Le Gallois has lately made some experiments on this subject (*Diction. des Scienc. Médic.* V. p. 440.); but they can hardly be regarded as satisfactory. Capacity of the Fœtal Heart.

## 2. *Of the Blood-Vessels in general.*

### A. *Of the Arteries in general.*

30. The arterial system of the human body resembles the trunks and branches of two trees. One trunk, called the pulmonary artery, arises from the right ventricle of the heart; and the other, denomi-

Anatomy, Human.

nated the aorta, springs from the left ventricle. They are both about an inch and a quarter in diameter; and their sides are about a twelfth of an inch thick. Immediately after their origin they begin to ramify; and by successive ramifications of the branches, the whole body is at last supplied.

31. After the arteries have ramified to a certain degree of minuteness, they become so thin and transparent, that it is impossible to follow them, either with the naked eye, or with the microscope. In order, therefore, to render these very small vessels visible, anatomists inject into them thin coloured fluids, such as a weak solution of glue mixed with vermilion; and all our knowledge of the ultimate ramifications of arteries is derived from these injections.

Their Modes of Termination.

32. Some arteries are seen distinctly terminating in veins; others vanish from our sight; but in what manner they end is uncertain. The termination in veins, therefore, is the only one capable of demonstration; every other is matter of opinion.

Their Coats.

33. All arteries, which are not less than the twelfth of an inch, may easily be shewn to be composed of three coats, an inner, middle, and outer.

The inner Coat.

34. The inner coat resembles exactly the inner membrane of the ventricles of the heart. It is equally thin, and perfectly transparent and colourless; and its inner surface is smooth.. No vessels or nerves have yet been seen in it. It may be peeled off from the middle coat with the forceps; but it is too tender to separate in large patches. It differs from the inner membrane of the ventricles of the heart, in being a good deal more elastic.

The middle Coat.

35. The middle coat of an artery is the thickest; being about twice the thickness of the outer one. It consists of slender fibres laid closely together, side by side, without any apparent connecting medium, and placed uniformly in a circular direction, surrounding the artery, and in a plane perpendicular to its axis. Those which are more internally situated, may be easily seen through the transparent inner coat, when the artery is slit open; and if this coat be peeled off, the fibres of the middle one may be easily raised with the forceps in successive strips, all of which separate in a transverse or circular direction, exactly like the outer bark of a birch tree.

In the larger arteries, the fibres are of a yellowish or straw colour, and firm in their consistence; but, in the smaller vessels, they are softer and more flesh-coloured.

The outer Coat.

36. The outer coat of arteries differs extremely from the other two. It consists of slender, white, shining fibres, very dense and tough, closely compacted together, and interwoven in every direction. It is very difficult to separate them from each other, and impossible to make them peel in any regular manner.

37. Many arteries are surrounded with cellular substance externally; but this is merely an accidental covering. It is not a necessary part of the arterial tube; and cannot, therefore, with propriety be described as one of the coats of an artery.

38. In arteries which are less than the twelfth of an inch, it is not easy to distinguish the different parts which compose them. But there is every reason to believe that they have the same structure as the larger vessels.

### B. *Of the Veins in general.*

39. The distribution of the veins throughout the body, like that of the arteries, resembles the ramification of a tree; but, in describing them, it is usual to invert the order observed in tracing the arteries, and to consider the trunks as successively formed by the union of the branches.

Their Origin.

40. When we apply the microscope to a thin or transparent part of the body, which has been properly injected, we can perceive many of the most minute veins, arising from the extremities of equally minute arteries, and distinctly continuous with these. Any other origin of veins than this is quite uncertain.

Their Valves.

41. Many of the larger veins, and veins of middle size, are provided with valves. These are membranes of a semilunar shape, perfectly transparent and colourless, and though scarcely the thickness of a hair, yet very dense and strong. They are attached by the whole of their curved margin to the inner surface of the vein; and this margin is uniformly turned towards the branches of the vein, while their free straight edge looks towards the trunks. They are inserted into the sides of the vein in such a manner, as to be in a certain degree loose within the tube; and, accordingly, when any fluid is forced from the trunks towards the branches, they are pushed inwards from the sides of the vessel towards its axis. They vary very much in their dimensions, even in vessels of the same calibre. Sometimes they occur single, particularly in the smaller vessels; sometimes, though very rarely, three are found together; but, in general, they are disposed in pairs, one exactly opposite to the other. They are very seldom so large, or so precisely adapted to each other, as to shut up the tube of the vessel completely. The number of them occurring either singly or in pairs, within any given extent, is very various in different veins. They are found at intervals of from four or five inches to a quarter of an inch, or even less. In general, they are most numerous in veins of small size.

Their Coats.

In all veins that are not less than a twelfth of an inch in diameter, two coats can be distinctly demonstrated; and in some, portions of a third texture intervene between these two.

Their inner Coat.

42. The inner coat of veins is transparent like that of arteries. It is a little thick r, however, and greatly stronger; and it differs also from the inner coat of arteries in this, that it can be distinctly separated into slender dense fibres.

Their outer Coat.

43. The outer coat of veins has the same structure as the outer coat of arteries. It is thinner, however, proportionally, and its fibres are not so close.

Their partial middle Coat.

44. In almost all the trunks and larger branches of veins, a substance is found intervening between these two coats; sometimes surrounding the vein entirely, but in general occurring in patches of different sizes. It varies a good deal in its thickness; being as thick in some parts as the outer coat, and only

half as thick in others. It seems to be of a texture intermediate between the external and middle coat of an artery.

### II. OF THE ABSORBENT SYSTEM.

45. The Absorbent System of the human body consists of *Absorbent Vessels* and *Absorbent Glands.*

#### 1. *Of the Absorbent Vessels in general.*

Their Terminations.

46. The absorbent vessels are a system of tubes, distributed throughout the body in the manner of the blood-vessels. They are described in the same manner as the veins. Exceedingly minute at first, they unite one with another, and at last form two trunks, each about a quarter of an inch in diameter, which open into two veins called *subclavio-jugular veins*, one on each side of the neck; the left trunk being denominated the *thoracic duct*.

Their Origins.

47. There is no part of the body, in which the absorbent vessels can be traced to their beginnings with the naked eye. Cruikshank was fortunate enough, in one case, to find the absorbents of the alimentary canal so turgid with a milky substance after death, that, with the microscope, he could distinctly trace hundreds of them to their origins, which had the appearance of circular orifices, (*Anat. of Absorb. Vessels*, p. 56.) But this is the only part of the body, in which the commencements of these vessels have been seen, even with the microscope.

Their Structure.

48. Little is known respecting the structure of the absorbent vessels; they are too delicate to admit of satisfactory dissection. We have examined, however, pretty minutely, the thoracic duct; and it seems to us to consist of one coat only. This resembles the inner coat of veins; and the valves of the absorbents appear to be merely prolongations of it.

#### 2. *Of the Absorbent Glands in general.*

49. These bodies may be regarded as consisting of a peculiar *substance* enclosed in a *capsule.*

50. We are inclined to regard Mascagni's description of the structure of the former, as by far the most accurate which we yet possess. (*Vas. Lymph. Hist.* p. 30.)

Structure of their Substance.

51. According to this very respectable authority, the vasa inferentia, before entering a gland, divide into branches. Some of these penetrate directly into the central parts of its substance, while others are distributed towards the surface. The larger branches are bent, convoluted, and interwoven, in every direction; they communicate freely with each other; and become suddenly narrow in some parts, while they swell out into little cells at others; so that when the gland is injected with quicksilver, its whole outer surface seems as if covered with little rounded eminences. The smaller branches subdivide, and form a net-work on the surface, and then either dip down between the cells of the larger ones, or open into them. Various small vessels, on the other hand, are seen, either arising from these cells, or ascending from between them, and after winding about, uniting together into larger branches, which at last constitute the vasa efferentia.

Sometimes the absorbent vessels of a gland preserve a pretty uniform diameter throughout; so that there is little or no appearance of cells in any part of it.

Their Capsule.

52. The capsule of absorbent glands is a thin, pellucid, and colourless membrane, very vascular, and resolvable by maceration into fine whitish fibres.

### III. OF THE NERVOUS SYSTEM.

53. The Nervous System may be divided into two parts; the *Central Mass*, and the *Nerves.*

#### 1. *Of the Central Mass.*

54. The central mass of the Nervous System is composed of the *Brain* and the *Spinal Cord.* We shall offer a few remarks on each of these separately.

#### A. *Of the Brain.*

##### a. *The Brain of the Adult Male.*

55. The brain weighs, in general, about $2\frac{1}{2}$ lbs. or 3 lbs. avoirdupois. Both its weight, however, and its volume, vary a little in different individuals; but without any fixed relation to the weight or stature of the individual.

56. It is almost symmetrical; its median plane corresponding to the median plane of the whole body; so that it is divisible into two halves, right and left, very nearly alike.

57. It is usually regarded as consisting of two parts; an upper part, denominated the *Brain Proper*, and a lower one, called the *Cerebellum.*

58. The brain proper weighs in general from 35 to 45 oz. and the cerebellum from 5 to 8 oz. avoirdupois.

59. The brain is composed almost entirely of a peculiar substance, which we shall call *nervous matter*, embraced by delicate *membranes.*

##### *α. The Nervous Matter of the Brain.*

60. There are two kinds of this matter; the one usually denominated medullary, and the other cineritious. We prefer, however, to distinguish them by the terms *white* and *brown.*

The White Nervous Matter.

61. The white nervous matter is of different shades, in different parts of the brain. In most parts, its colour resembles a mixture of orange-white, and wine-yellow (see Syme's *Nomenclature of Colours*); and this kind we shall call orange-white. In others, it approaches more nearly to the wine-yellow; and this species may be denominated yellowish-white.

Its Consistence.

62. The consistence of the white nervous matter varies a little in different parts. In general, it is less elastic than jelly, but somewhat more glutinous or viscid.

Appearance when divided.

63. When we make a section of it in any direction, with a sharp scalpel, it appears perfectly smooth, and of a uniform colour. A few reddish points and striæ may be observed here and there; but there is no appearance whatever of cells, or globules, or fibres.

Microscopical Appearance.

64. It has been subjected to very minute microscopical examination by Prochaska. (*Oper. Min.* Pars I. p. 342.) When he took a small portion of it, either from the brain proper or the cerebellum, and spread it on a thin plate of glass, so that it became pellucid, and then examined it with a powerful microscope, he

Anatomy, Human.

found that it resembled a sort of pulp, consisting of innumerable globules, or particles of a roundish form. A little water added to this pulp, divided it into a number of flocculi; but he observed that each flocculus was still composed of a number of globules. He very rarely found one globule by itself, or even two, floating in water, apart from the rest. Maceration in water, even for three months, was insufficient to separate them from each other. He concluded, therefore, that they were united by means of a very delicate and pellucid cellular substance The globules, he observed, were not all of the same size; but varied a little in dimension, even in the same part of the brain. In general, however, he found them, both in the brain proper and in the cerebellum, to be more than eight times smaller than a globule of the blood. The most powerful microscopes did not enable him to discover anything satisfactory respecting their structure.

65. These observations have, within these few years, been prosecuted, on a much more extensive scale, by Joseph and Charles Wenzel. (*De Penitior. Struct. Cereb.* p. 24.) They have uniformly found that the white nervous matter seemed as if entirely composed of extremely small globules, or corpuscules of a roundish form, putting on the appearance of little cells, filled with proper medullary substance.

No estimate is given of the dimensions of the globules; but they describe them as being exceedingly minute, and as being all pretty nearly of the same size. They seemed to adhere very closely to each other, without any apparent connecting medium. The globular appearance continued distinctly perceptible, in portions of the substance, which had been long exposed to the action of rectified spirit of wine and muriatic acid; nor was it even destroyed by steeping the matter in alcohol, and then drying it.

Its Blood-vessels.

66. White nervous matter possesses considerable vascularity. The arterial branches, however, which supply it, are seldom much larger in diameter than a common pin; and the veins are for the most part equally small. It is the division of blood-vessels which produces the appearance of red points and red striæ in this matter, when incisions are made through it.

Effects of Coagulation on it.

67. When a portion of white nervous matter has been immersed in boiling oil for a few minutes, or steeped for a few days in alcohol, or diluted muriatic or nitric acids, or a mixture of alcohol and acids, or a solution of corrosive sublimate, its consistence is greatly increased; and if we tear it into fragments, we find that the surfaces of the fragments exhibit a fibrous appearance. White threads, as slender as a hair, may be raised from these surfaces with the point of a pin; and the whole substance seems to be formed of such fibrils placed close to each other. The delicacy of these threads, and the closeness with which they are compacted together, render it quite impossible to ascertain their actual length, or even to form a conjecture as to the extent to which they may be subdivided.

Whether the white nervous matter in all parts of the brain be susceptible of this change on coagulation, does not seem to us satisfactorily established.

Its Chemical Properties.

68. In the chemical analyses which have hitherto been made of the nervous matter, the white species does not seem to have been distinguished from the brown. This circumstance deserves to be attended to, in reading the fullest analysis of the nervous matter which has yet been made, viz. that by Vauquelin. (*Annal. de Chim.* Tom. LXXXI.)

The Brown Nervous Matter.

69. The brown nervous matter varies a little in its hue also. Its most common colour is wood-brown; but sometimes it is like a mixture of wood-brown and lead-grey; and this last colour we may call greyish-brown.

70. It is softer than white nervous matter, and in many parts is more vascular. It exhibits the same appearances, however, when divided with the scalpel; and seems to be composed of similar globules when examined with the microscope. In certain parts, too, of the brain, we have found, that when coagulated by boiling oil, or acids, &c. it appears fibrous on laceration; but whether or not the brown matter generally be susceptible of this change, we have not ascertained.

Distribution of the White and Brown Nervous Matter.

71. These two kinds of nervous matter, the white and the brown, are intermingled within the brain in various ways. In some parts, a covering of the one surrounds a mass of the other, as a capsule encloses a nucleus; in others, they are alternated in laminæ or strata; and in others, they traverse each other in the form of cords or fibres of various sizes. Yet, notwithstanding this diversity in their arrangement in different parts, their disposition in each particular part is observed to be remarkably uniform.

72. The only attempt, worthy of notice, which has yet been made to represent the proportions and arrangement of those two kinds of matter in the brain, in a series of coloured engravings, is that by Vicq d'Azyr, in his folio work, entitled *Traité d'Anatomie et de Physiologie*, published at Paris in 1786. The chief merit of this work, however, consists, not in the engravings themselves, which are seldom entitled to the praise of accuracy, either in point of form or colouring, but in the minute explanations and details which accompany them.

73. There are peculiarities in the structure of the pituitary gland and pineal gland, which deserve to be farther investigated.

The Pituitary Gland.

The pituitary gland is a good deal firmer than the other parts of the brain, and seems to be intersected by a texture different from common nervous matter. When it is pressed between the fingers, the nervous matter appears as if it were forced out of a sponge. In general, two distinct masses may be perceived in it; one occupying the fore part, approaching rather to purple in its colour; and another behind, softer in its consistence, and of a lighter hue.

The Pineal Gland.

74. The pineal gland also contains two substances very different from each other. One is a matter somewhat like brown nervous matter, but softer than that matter generally is; and the great bulk of the gland is made up of this substance. The other is like grains of sand, consisting of hard, semitransparent, yellowish particles, varying a little in size, but seldom larger than the head of a pin. Sometimes these particles are grouped together into a heap or acervulus on the upper surface of the gland, close to its base; at other times they form a sort of chain

or ridge along its margin; and at other times again they are irregularly scattered through its substance. There is the greatest variety in their number. In two or three instances, after the strictest search, we have not been able to find more than a single particle within the whole gland. We have made a few chemical experiments on these particles, and are rather inclined to think that they have the same composition as bone.

*β. The Membranes of the Brain.*

75. The membranes of the brain are two in number, the *Pia Mater* and the *Arachnoid Membrane.*

** The Pia Mater.*

76. All the arterial vessels which enter into the composition of this membrane, seem destined ultimately to supply the nervous matter of the brain; and this matter appears to derive arterial vessels from no other source. The same remark applies to the veins of the pia mater; so that we may regard this membrane as a vascular covering formed of blood-vessels, which are just about to penetrate the nervous matter of the brain; and of blood-vessels which have just emerged from it.

77. After a minute injection, it is difficult to perceive anything in the pia mater but blood-vessels; and these are interwoven in every direction. We have not yet been able to discover any absorbents or nerves in it. There is an appearance of very fine dense white threads in it, at particular parts, where it happens to be but loosely connected to the arachnoid membrane; but it is uncertain whether these are not blood-vessels. We cannot perceive any cellular tissue in it, such as Bichât has described, *Anat. Descrip.* III. p. 27.

*** The Arachnoid Membrane.*

78. This differs very much from the former, both in structure and distribution.

It is as thin as a cobweb, dense, colourless, and almost perfectly transparent. Its outer surface is quite smooth; its inner, more or less thready or flocculent, according to its connection with the pia mater.

Nothing is known respecting its structure. We have never seen blood-vessels in it, either in its healthy or diseased states, with or without previous injection. It has hitherto proved equally impracticable to demonstrate in it either absorbents or nerves. Bichât classes it with the serous membranes (*Anat. Descrip.* III. p. 32.); but it is so little analogous to these in point of structure, that we prefer to regard it as a peculiar membrane.

b. *The Brain of the Adult Female.*

79. It has been often affirmed that the brain of the female differs from that of the male, slightly, both in form and dimensions. We cannot say, however, that we are satisfied of the truth of this observation. The point requires to be further investigated.

c. *The Brain before and after Maturity.*

80. On this subject, hardly anything satisfactory was known, until within these few years.

81. We have already had occasion to refer to a work by the Wenzels, entitled *De Penitiori Structura Creberi Hominis et Brutorum*, which was published, in folio, at Tubingen, in 1812. We strongly recommend this treatise to the attention of our readers. It appears to us the best and most original work on the structure of the brain, which has appeared for more than a century. The authors seem to have employed themselves, unremittingly, in investigations relating to the anatomy of this organ, for upwards of twelve years, and in circumstances singularly favourable for observation. There is little of importance relative to the state of the brain at different periods of life, at present known, for which we are not indebted to their labour and ingenuity.

82. From a variety of facts, which our limits will not permit us to give in detail, we select the following respecting the dimensions and weight of the brain, which seem to be the results of an immense number of observations.

83. First, with respect to dimensions, they find that both the brain proper and the cerebellum increase rather more in length and in breadth, during the six months immediately preceding birth, than during the first seven years after birth; that these dimensions arrive at their maximum at the age of seven; and that they suffer no change during the whole of after-life. Its Dimensions.

84. Secondly, with regard to weight, they ascertained, that the weight of the whole brain, most commonly arrives at its maximum, at the age of three years, and remains without diminution, during the whole of after-life; the maximum being in general from 20,000 to 22,000 grains, and seldom exceeding 24,000. The weight of the brain proper, at the age of three years, they found, does not exceed, in general, 21,000 grains; nor that of the cerebellum 2000 grains. The younger the fœtus, they observed, the greater was the ratio of the weight of the brain proper to that of the cerebellum. This ratio, it appeared, was usually about seven to one, at the age of three years, and remained so ever after. Its Weight.

B. *Of the Spinal Cord.*

a. *The Spinal Cord of the Adult Male.*

85. We regard the spinal cord as beginning at the lower margin of the annular protuberance of the cerebellum. The arrangement which includes a portion of its upper extremity, along with the brain, under the name of medulla oblongata, seems to us neither so precise nor so natural.

86. From a few actual measurements of it, we are inclined to think, that its length, in general, is about thirty inches. Chaussier says, its weight is from about a nineteenth to a twenty-fifth of that of the whole brain. (*Exposit. Sommaire*, p. 119.) Its Length and Weight.

87. Like the brain, it consists of *nervous matter*, enclosed in *membranes.*

*α. The Nervous Matter.*

88. This differs very little, apparently, from that of the brain. The cord contains both kinds of it.

89. The white matter is chiefly of the orange-white species, and is firmer than the same kind of substance in any part of the brain, except the annular protu-

Anatomy, Human.

berance. The brown matter is chiefly of the greyish species.

90. The nervous matter does not extend the whole length of the cord; it ceases within nine inches of its extremity, and the membranes alone form the rest.

Divided into Three Portions.

91. It may be divided into three portions. The first portion may be called the top of the cord or cranial portion, and is about an inch in length. This is what is denominated by many the medulla oblongata. The second is about five inches in length, and may be denominated the cervical portion; and the third, which is about fifteen inches long, we shall call the dorsal portion.

92. The arrangement of the two kinds of nervous matter in the cord, has not hitherto been described or represented with sufficient accuracy. The whole of the cervical and dorsal portions, and the lower part of the top of the cord, consist of a central column of greyish-brown matter, surrounded by a stratum of orange-white. The upper half of the top, contains a much larger proportion of white nervous matter, than any other part of the cord.

Rendered Fibrous by Coagulation.

93. We have found that considerable portions of the nervous matter of the cord, are rendered fibrous in the longitudinal direction by coagulation.

*β. The Membranes.*

94. The Membranes of the spinal cord are three in number; the *Pia Mater*, the *Serrated Membrane* or *Ligamentum Dentatum*, and the *Arachnoid Membrane*.

It will be necessary only, on the present occasion, to say a few words with respect to the second of these.

The Serrated Membrane.

95. The serrated membrane is whitish and semi-transparent in its appearance, and thinner than the pia mater, yet fully stronger. Its inner border, which is straight, is intimately connected with the pia mater; while its outer one presents a series of angular projections or teeth, each of which is attached firmly to the dura mater of the spinal canal.

96. In its internal structure, it most resembles the substance called tendon.

97. It begins at the top of the cervical portion of the cord, and ends, in general, just where the swelling commences on the lower part of the dorsal portion. After it has terminated, a very slight ridge may be seen running down from it, on the surface of the pia mater, and exactly in the same direction, for about an inch and a half. We have never seen it, however, reach the extremity of the cord.

b. *The Spinal Cord of the Adult Female.*

98. We are not acquainted with any material circumstances in which the spinal cord of the female differs from that of the male; but, according to Chaussier (*Exposit. Som.* p. 117.), its nervous matter is softer.

c. *The Spinal Cord before and after Maturity.*

99. The nervous matter of the cord has been said to be proportionally shorter in the child than in the adult; but this has not been established.

100. Chaussier concludes, from a great many observations, that this matter is firmer at birth than at any other period of life, and that it gradually becomes softer as the individual advances in years. We suspect some fallacy in this remark.

Anatomy, Human.

101. We are inclined to think, that the central column of brown nervous matter in the cord, is larger proportionally, and darker in its colour, at birth, than at any after period of life. We have often observed, in old persons, that it had entirely disappeared; its place being occupied by white matter; and we find that Chaussier states this to be a constant occurrence in the decline of life. (*Exposit. Som.* p. 146.)

2. *Of the Nerves.*

102. The nerves are cords of a peculiar structure, connected either directly, or indirectly, with the central mass.

Their Mode of Distribution.

103. There is the utmost variety in the mode of their distribution. Many of them may be seen spreading themselves out by regular ramification. Others divide into branches, and then soon after unite into trunks again. Others may be traced into a net-work or *plexus*, formed of various nerves interwoven in every direction, but in which each individual nerve is in a manner lost; and which sends off new branches to be expended by new ramification, or to unite with new plexuses. There is but one nerve in the body which neither exhibits ramification, nor is connected with any other nerve by plexus throughout the whole of its course. This is the optic nerve.

Plexus.

Ganglion.

104. At the union of two or more nervous branches with each other, certain knots or tumours frequently present themselves, which have been called *ganglia*; and the same name has been extended to similar swellings, which very often occur on single nerves. These *ganglia* are of various shapes and sizes; none of them exceeding three quarters of an inch, or an inch.

Nerves divided into Primary and Secondary.

105. Many nerves are attached directly to the central mass; and in such cases, the extremity of the nerve which happens to be connected to the brain or spinal cord, is invariably considered as its *origin*. We propose to denominate all those nerves which have such an origin, *primary nerves*. Those which take their origin in plexuses, or ganglia, or in other nerves of which they constitute branches, we may call *secondary nerves*.

106. The primary nerves communicate, more or less intimately, with all the secondary nerves, by means either of ramification, or plexus, or ganglion. Hence, all the nerves in the body are said to be connected, either directly or indirectly, with the central mass of the nervous system.

Structure of Nerves.

107. Nerves are composed of filaments of nervous matter enclosed in sheaths of a peculiar substance, hence called *neurilema*. The structure and arrangement of these were first well described by the late Professor Reil. (*Exercitat. Anatom.* Fascic. Prim.)

108. The filaments of nervous matter are of different sizes in different nerves, and sometimes even in the same nerve. They seldom, however, exceed the thickness of a hair; and in most instances, are smaller than the finest fibre of silk or cotton, so that it requires a microscope to see them distinctly. They are placed side by side; and in their course, divide, and subdivide, and reunite, and run into each other, forming the most intimate connection. The greater

number of the nerves in the body, consist of several separate fasciculi of these filaments; some of only one fasciculus.

109. The neurilema, or substance which surrounds each filament, and ties the filaments into fasciculi, &c. is, in most instances, so like cellular substance, that we may regard it as a species of that texture.

Structure of Ganglia.

110. Scarpa's description and representations of the structure of the ganglia, are by far the most accurate which we yet possess. (*Anatom. Annotat.* Lib. Prim.) There is a good deal, however, connected with this subject which requires to be farther investigated.

111. In these bodies, the fasciculi of nervous filaments attached to them, suffer a temporary subdivision and separation from each other, and are then combined anew. The intermixture of fasciculi which takes place within them, is in general so intimate, that it looks as if every fasciculus of every nerve, which emerges from a ganglion, contained more or fewer filaments from every fasciculus of every nerve which entered it.

112. Each fasciculus, in its progress through a ganglion, seems to be provided with its proper neurilema. But, besides this, the spaces left between the intersections of the fasciculi, are filled up with a peculiar soft substance, of a greyish, sometimes a yellowish, colour. This substance does not seem to us to have the slightest resemblance to the brown nervous matter of the brain and spinal cord; although it has been very confidently pronounced to be the same by some anatomists. Scarpa regards it as a peculiar cellular substance, filled with a mucilaginous or oily matter.

Enumeration and Classification of Nerves.

113. There are eighty-four primary nerves in all; forming forty-two pairs. The nerves of each pair arise, one from each half of the central mass, at corresponding points.

114. Some of these arise from the brain, others from the spinal cord; they may, therefore, be divided into *cerebral* and *spinal*.

115. There are eight pairs of cerebral nerves. These are the following:

The Olfactory nerves.
The Optic nerves.
The Common Oculo-muscular nerves. *
The Internal Oculo-muscular nerves. †
The External Oculo-muscular nerves. ‡
The Trigeminal nerves. §
The Facial nerves. ||
The Auditory nerves. ¶

116. There are thirty-four pairs of spinal nerves; and, these are:

The Glosso-pharyngeal nerves.
The Pneumo-gastric nerves. **
The Hypo-glossal nerves. ††
The Accessory nerves. ‡‡
The Sub-occipital nerves.
The Cervical nerves, - Seven pairs.
The Dorsal nerves, - Twelve pairs.
The Lumbar nerves, - Five pairs.
The Sacral nerves, - - Five pairs.

117. We have purposely avoided applying any numerical appellations to the primary nerves, which arise from the brain, and the top of the spinal cord; in order that there might be the less risk of their being mistaken by those who have long been accustomed to the old, but very inaccurate, numerical nomenclature.

## Article II.

### OF THE ANATOMY IN GENERAL OF THE COMMON TEXTURES.

### I. THE ANATOMY IN GENERAL OF CELLULAR SUBSTANCE.

118. From the term *cellular*, which has long been applied to this texture, one would naturally be led to suppose, that it was a substance formed into cells, admitting of easy demonstration. But this is far from being the case. In a mass of it, examined with the microscope, we can perceive nothing but exceedingly delicate fibres, interwoven in every direction. It is only when it is distended, or when we endeavour to tear its parts asunder, that it exhibits a cellular appearance.

119. If we lay hold of a mass of it between the fingers, and pull it gently, it immediately separates itself into innumerable transparent laminæ, finer than the finest cobweb, which intersect each other in every direction, and leave spaces or *cells* between them of various shapes. The same effect may be produced, by inserting the point of a blow-pipe into the midst of the substance, and blowing into it; or by an injection of water, or any thin fluid. In proportion as we pull or distend the substance, the smaller laminæ successively give way, and several cells are thus united into one; until at last the whole are torn. The instant the distention is discontinued, the parts collapse, and the cellular appearance vanishes.

120. It remains, therefore, to be determined, whether this substance consists, in its natural, undistended state, of numberless fine laminæ, of a definite size and form, closely applied to each other; or whether the cells which it exhibits, when distended, be not merely the effect of the accidental separation of layers of the substance, always accompanied with greater or less laceration of parts, and of course varying with the direction and degree of the distending force.

---

* Synonym. *Lat.* Motores communes oculorum.

† Synonyms. The fourth pair, according to the old enumeration. *Lat.* Nervi pathetici.

‡ Synonym. *Lat.* Abductores oculorum.

§ Synonyms. The fifth pair, according to the old enumeration. *Fr.* Les nerfs trifaciaux.

|| Synonym. The portio dura of the seventh pair, according to the old enumeration.

¶ Synonym. The portio mollis of the seventh pair.

** Synonyms. The eighth pair of cerebral nerves, according to the old enumeration. *Lat.* Par vagum; nervi vagi. *Fr.* Les nerfs vocaux.

†† Synonym. *Fr.* Les nerfs linguaux.

‡‡ Synonyms. *Fr.* Les nerfs spinaux; les nerfs spino-cranio-trapeziens.

121. Bichât has devoted a long chapter of his *Anatomie Générale* to the description of this texture. (Tom. I. p. 11.) It contains a great deal of matter, however, which is quite foreign to the subject; and, in other respects, is often vague and incorrect.

The most original remarks on this substance are to be found, in a paper by the celebrated Dr William Hunter, in the second volume of the *Medical Observations and Inquiries.*

### II. THE ANATOMY IN GENERAL OF ADIPOSE SUBSTANCE.

122. This texture is obviously composed of two distinct substances; an oily matter, and a vascular texture formed into cells, in which this matter is contained.

123. The oily matter possesses all the characters of the fixed oils. It seems to us most probable, that it exists in the living body in a fluid state. We are led to entertain this opinion chiefly from some experiments, in which we raised portions of the adipose texture taken from the dead body, to the temperature of the living. But we have further observed, in surgical operations, that, when a thick portion of adipose substance happens to be divided, minute globules of oil may be seen swimming, in great abundance, in the stream of blood that flows from the wound.

124. The vascular texture which contains the oily matter, appears to be composed of a substance fully more delicate than cellular substance, and to consist of little spherical cells placed closely together side by side. These cannot be distinctly seen without a magnifying-glass. They vary a little in their size, but are all exceedingly minute. According to Dr Monro, none of them exceed the eight-hundredth part of an inch, nor are less than the six-hundredth. (*Descrip. of the Bursæ Mucosæ.*)

The cells of adipose substance have no resemblance whatever to the cells formerly described in cellular substance.

### III. THE ANATOMY IN GENERAL OF MUSCLE.

125. Muscle seems to be composed of delicate fibres of a peculiar nature, surrounded and united together by a substance like cellular substance; and supplied with blood-vessels, absorbents, and nerves.

126. Prochaska's description of the fibres is still not only the most accurate, but the clearest which we possess. (See *Oper. Min.* Pars I. p. 160.)

127. According to this author, muscle in all parts of the body may be resolved by careful dissection into fibres of great delicacy, but pretty uniform in form and general appearance, as well as in dimensions. Their diameter does not seem to exceed the forty-thousandth part of an inch; and although they are very variable in their length, some of them, it would seem from Prochaska's observations, extending nearly three feet, they preserve the same diameter throughout. They seem all more or less flattened or angular, and have no appearance of hollowness, but are solid diaphanous filaments. Prochaska seems to have no doubt that these fibres, or *fila carnea*, as he calls them, are incapable of farther division. On this supposition we may call them the *primary muscular fibres.*

128. The *primary fibres* are placed parallel and close to each other, and in every species of muscle, it would seem, are united, in the first place, into fasciculi of a certain size. These, in a transverse section, always appear polyedrous; and in the representation which Prochaska has given of them, as seen through a microscope magnifying the diameter two hundred times, the largest of them does not exceed an eighth of an inch, and the smallest is not below a sixteenth. In point of length they are various; but Prochaska affirms, that he has traced them extending, unbroken, and unconnected with any other fasciculi, from one end to the other of the *sartorius muscle*, which is one of the longest in the body.

129. These fasciculi, which we may call *primary*, are generally found united together into longer fasciculi; which may be denominated *secondary*, and these often into *ternary*, and so on.

130. A chemical analysis of human muscle is still a desideratum.

### IV. THE ANATOMY IN GENERAL OF SKIN.

131. Except the mouths of the sebaceous follicles, we do not believe that any pores are visible on the external surface of the skin, either with the naked eye or with the microscope. We can perceive no appearance of them even at the points from which the hairs spring; the hairs seem to fill up completely the canals through which they pass.

132. The inner surface of the skin, in almost all parts of the body, exhibits a number of depressions, varying in size from a twelfth to a tenth of an inch or more, producing a sort of areolar appearance.

133. The skin consists of two substances, placed one above the other, in the form of layers or laminæ. The inner lamina is called *true skin*, the outer, *cuticle, epidermis*, or *scarf-skin.*

134. We have found that the best and easiest mode of separating these two from each other, for particular examination, is to preserve a piece of skin, either on the recent subject or detached from it, carefully from moisture, but not so as to render it dry and hard. At the end of a week, or ten days, or more, according to the temperature of the air, such a degree of decomposition has in general taken place between the cuticle and true skin, as enables us to separate the former, with the slightest oblique pressure with the point of the finger.

135. The intimate structure of the true skin is quite peculiar. It seems chiefly made up of a species of very small dense fibres, somewhat resembling the fibres which compose the outer coat of an artery, which are closely interwoven with each other, and more firmly compacted together the nearer they are to the outer surface.

136. The outer surface of the true skin is more vascular than the internal parts; and this surface seems to owe its colour entirely to the blood circulating in its vessels.

137. The absorbent vessels of the true skin are so large and so numerous, that after they have been injected with mercury, the outer surface exhibits an exceedingly minute net-work of tubes. We

Anatomy, Human.

have never seen, however, the smallest particle of the quicksilver escape from the outer surface, even in the most minute injections.

The Cuticle.

138. The *cuticle* is transparent, and of a slightly yellowish-grey colour. The colour of the outer surface of the true skin is, therefore, seen through it; and we have no doubt that the colour of the surface of the body, in the inhabitants of this country, and of Europe in general, depends entirely on the colour of the outer surface of the true skin, blended with the slight tinge of grey from the cuticle.

139. In almost all persons in health, there are certain parts of the soles of the feet, in which the epidermis is divisible into layers; but this seems to be purely the effect of compression; which accumulates into a thick stratum those portions of the cuticle which are constantly separating from its surface, and which, in other parts of the body, are immediately removed. This laminated appearance is never seen in the soles of persons who have been long confined to bed, or in those who, from accident or disease, have not been able to put the foot to the ground. The cuticle, in other parts of the body, does not exhibit the slightest appearance either of laminæ or fibres.

140. This part of the skin is entirely destitute of blood-vessels, absorbents, and nerves. It is truly a *non-vascular* part, like the enamel of the teeth.

141. It is well known that when a piece of cuticle is plunged into pure nitric acid, it instantly acquires a yellow colour. In the course of twenty minutes or so, we have found, that it becomes thicker, softer, and more opaque; in twenty-four hours it is reduced to a yellowish pulp; and in about a month or six weeks it is almost entirely dissolved. Pure muriatic acid acts upon it somewhat in the same way; but less powerfully, and less speedily. Pure sulphuric acid immediately gives it a deep brown colour; in the course of twenty hours, renders it thicker and more elastic; and, after the lapse of several weeks, reduces it to the state of a very thin deep brown pulp.

Black Membrane.

142. We have satisfied ourselves, by a variety of dissections, that there is in the Negro, Caffre, and Malay, a *black membrane* interposed between the epidermis and the true skin, upon which the dark colour of these people entirely depends. This membrane sometimes peels off with the cuticle, and sometimes adheres to the true skin. It is more tender than the cuticle, and thinner; but, like it, is entirely without vessels, and without any appearance of holes, or plates, or fibres. We conclude, that in all black men there is a similar membrane, to which their dark colour is owing.

Rete Mucosum.

143. After the strictest examination, however, we have not been able to discover any light-coloured membrane or pigment, such as has been described under the name of *rete mucosum*, between the cuticle and true skin, in the inhabitants of this country, nor in those of other European nations resembling them in colour. We have sought for it in every way, but without success. We are disposed, therefore, to deny its existence. The cause of the light colour of the skin in fair people has been already explained. (Sect. 138.)

144. Whether there be any brownish membrane in tawny people, like the black membrane in the negro, we have had no opportunity of ascertaining.

### V. THE ANATOMY IN GENERAL OF HAIR.

145. We call the *root* of a hair, not only that part of it which is contained in the bulb, but the portion which is lodged in the skin. The *middle part* and the *point* are the parts which project beyond the surface of the skin.

146. All the hairs in the body seem to be cylindrical, and taper regularly from the root to the point.

147. Of whatever colour they be, the root is always whitish, and transparent, particularly that part of it which is lodged in the bulb. This part, too, is always much softer than the rest; the very extremity being almost fluid.

148. As far as we can judge from microscopical observations, the hairs seem to be quite solid. We have never seen any appearance of cells, or canals, or laminæ, or fibres, in any part of them. In the whiskers of the seal, however, the part of the root of the hair which is lodged in the bulb, contains a conical cavity: and we suspect it is the same in human hair.

149. Dr Brewster has ascertained that hairs depolarise light, and possess the most perfect neutral axes; the axes being parallel and perpendicular to the axis of the hair. (*Phil. Trans.* 1815.)

150. The chemical properties of hair have been very minutely investigated by Vauquelin. (See *Annales de Chimie*, Vol. LVIII. and *Nicholson's Journal*, Vol. XV.)

151. Judging by analogy, from the structure of the *bulbs* of those large hairs which form the whiskers of such animals as the seal, we should imagine that the *bulbs* of the human hairs consisted of two coats or tunics; an inner one of a tender consistence, very vascular, and embracing immediately the root of the hair; and an outer, firmer, and less vascular one, closely surrounding the former.

152. The bulbs of the hairs are always situate under the true skin; but so close to its inner surface, that no part of the hair is perceptible between it and the bulb. Immediately after leaving the bulb, the hair is received into a canal in the true skin, which is constantly observed to be more or less oblique. A small hole in the cuticle corresponds to this canal; and the hair passing through it also, reaches the outer surface of the skin. In its passage through the true skin, we believe that it adheres to the sides of the canal, just as epidermis would do.

### VI. THE ANATOMY IN GENERAL OF CARTILAGE.

153. On careful examination of this substance with the microscope, it appears to us to be uniform and homogeneous in its structure, like jelly, and without fibres, or laminæ, or cells.

154. In its purest form, no blood-vessels are seen in it, nor can they be injected even with the finest colouring matter. In those pieces of cartilage, however, which are attached to the edges or extremities of growing bones, blood-vessels of considerable size may often be seen ramifying, even without the aid of injection.

155. The chemical properties of cartilage have not yet been sufficiently investigated. In its purest form, we believe that it is entirely soluble in boiling water, and acids seem to act on thin dried slices of it nearly as they do on cuticle.

### VII. THE ANATOMY IN GENERAL OF BONE.

156. The structure of this substance is exceedingly simple. Divide it, and examine its surfaces with a common magnifying-glass, or cut off slender films of it, and inspect them in a powerful microscope, and it will appear to be a uniform substance without fibres, plates, or cells, penetrated everywhere by delicate blood-vessels.

157. The sulphuric, nitric, muriatic, and acetic acids, when properly diluted, soften bone, and render it pliable, without its being possible to discover, by the most minute inspection, that a single particle of its substance has been removed.

158. Calcination produces just the reverse effects. If a bit of bone be placed in a charcoal fire, and the heat be gradually raised to whiteness, it will first burn with a flame, and then become quite red. If it be now removed carefully, and slowly cooled, it will be found to have been rendered as white as chalk, and exceedingly brittle. Still not a particle of the substance will appear to have been destroyed.

159. With respect to the chemical properties of this substance, we have only to remark, that we are convinced from experiment, that the *fat* which has been considered as an ingredient in bone, and which is extracted from it by boiling in water, is no part of the osseous substance, but an adventitious admixture either from adipose substance without, or from marrow within.

160. We have often endeavoured to discover sulphate of lime in the acid solution both of calcined and uncalcined bone; but always without success.

### VIII. THE ANATOMY IN GENERAL OF TENDON.

161. Bichât has described this common texture under the name of *Système Fibreux.* (*Anat. Génér.* III.) The term is objectionable, however, because it is equally applicable to nerve, muscle, or even cellular substance, as to the texture to which he has applied it.

162. Its distribution is very various, and very extensive. It forms not only those appendages to muscular fasciculi, called *tendons*, from which it has received its name, but also *ligaments, periosteum, aponeuroses, fasciæ, membranes, &c.*

163. It appears to be chiefly composed of very delicate, white, silvery-looking fibres, collected into fasciculi, which are united with each other in various ways. Sometimes they are tied together longitudinally; at other times, interwoven almost with the same regularity as the threads in a piece of cloth; and at other times intermingled in every direction.

164. The sulphuric, nitric, and muriatic acids, act upon it very nearly as they do upon cuticle. The instant it is plunged into either of them, it shrinks up, and becomes semitransparent and elastic, just as it does in boiling water, but in a much greater degree. The effects of the pure fixed alkalies upon it are singular. At first, they operate upon it somewhat like the acids just mentioned; but, instead of dissolving it after a little while, as these do, they seem to produce very little further change upon it for a considerable length of time. If, in this state, we remove it from the alkali, and pull its parts gently asunder, its delicate fibres will unfold themselves very readily, exhibiting at same time very bright prismatic colours.

### IX. THE ANATOMY IN GENERAL OF SEROUS MEMBRANE.

165. A successful injection of size or turpentine, coloured with vermilion, brings into view so many capillary blood-vessels in this membrane, that one would be almost inclined to suppose, that it was entirely composed of arteries and veins. By proper management, however, absorbents may be injected in it with quicksilver to an equal degree of minuteness. There can be no doubt, therefore, that it is chiefly composed of these two systems of vessels. Whether it contain any thing else but vessels, remains to be ascertained. Nerves have not yet been traced into it, although they may be often seen ramifying abundantly on the parts with which its external surface is connected.

### X. THE ANATOMY IN GENERAL OF SYNOVIAL MEMBRANE.

166. Bichât has enumerated a variety of circumstances, in which he conceives, that the *serous* and *synovial membrane* differ from each other. (*Anat. Génér.* IV.) It seems to us very doubtful, however, whether all these points be well founded; at all events, we do not think that any of them can with propriety be adopted as the basis of an *anatomical* distinction.

167. Synovial membrane resembles serous membrane, in so far as it is a thin substance, having one smooth free surface, turned towards certain cavities of the body, and another connected by delicate cellular substance to the sides of these cavities, or to the parts contained in them. It resembles this substance also in being transparent.

168. But it differs from serous membrane in the following circumstances:—In the first place, it is a substance possessing very little vascularity in its healthy state; none of its blood-vessels are almost ever seen filled with blood after death, nor can they be made to receive the finest injection. In the second place, its absorbents are quite incapable of demonstration. Thirdly, very delicate fibres, like those of cellular substance, or like the finest filaments of tendon, are distinctly perceptible in it after slight maceration. Fourthly, it is considerably inferior in strength to serous membrane.

## PART III.

### THE ANATOMY OF THE SKELETON.

### Article I.

### GENERAL OBSERVATIONS ON THE SKELETON.

#### I. *In the Adult Male.*

169. The skeleton of the body may be regarded as the solid frame-work which supports and contains the softer parts.

170. It is made up of 254 separate pieces of *osseous substance*, most of which contain a quantity of a matter called *marrow*, and are surrounded with a membrane denominated *periosteum*. These separate pieces, with their appendages, have the appellation of *bones* usually applied to them; and they are connected to each other in various ways.

#### 1. *Of Bones in their separate State.*

##### A. *Their Osseous Substance.*

171. In almost all bones, the osseous part presents itself under two forms. Externally it assumes the form of an uninterrupted shell or covering, which is called the *compact part*, and a very delicate texture of fine plates or fibres intersecting each other, and leaving small spaces between them, projects internally from this, which is called the *cellular* or *reticulated part*. The proportion of these two, varies in different bones.

##### B. *Of the Marrow.*

172. The chemical properties of the oily matter of the marrow, have not yet been sufficiently investigated.

##### C. *The Periosteum.*

173. This covering distinctly possesses the structure of tendinous substance.

174. We cannot regard it as correct, that it is prolonged from one bone to another over joints. In general it covers the whole outer surface of the compact substance, except at those points where one bone is united to another.

#### 2. *The Connections of Bones.*

175. The connections between bones are of two kinds; some admit of motion, others do not.

##### A. *Connections admitting Motion.*

176. It may be remarked of those bones which are united in such a manner as to enjoy motion on each other, that their touching surfaces never consist of bare osseous substance, nor even of osseous substance covered with periosteum. They are either provided with separate crusts or prolongations of cartilage, the surfaces of which play directly on each other, constituting what is denominated a *joint* or *articulation*; or they are united to one common intermediate substance, which is flexible, or admits of compression.

###### a. *Articulations or Joints.*

###### α. *The Cartilages.*

177. The surfaces of the portions of cartilage, which are in contact with each other in this mode of connection, are always as smooth as the finest polished ivory.

178. It was affirmed long ago by Dr Nesbit (*Human Osteology*), and Dr Hunter (*Phil. Trans.* 1743), and has been much insisted on of late years by Bichât (*Anat. Génér.*), that these surfaces are covered with a very delicate prolongation of synovial membrane. We are very much inclined to think, however, from a number of experiments, that these anatomists have been mistaken.

###### β. *The Ligaments.*

179. All articulated bones are partly held together by means of ligaments. These are composed of tendinous substance, and may be divided into *fascicular* and *capsular*. The *fascicular ligaments* are disposed in cords, at intervals, around the joint; the *capsular* form a continuous web, including the united surfaces in a kind of shut sac.

###### γ. *The Synovial Membrane.*

180. In all the intervals between fascicular ligaments, portions of synovial membrane may be distinctly seen filling up these intervals. They are attached to the ligaments on the one hand, and to the articulated bones on the other, just at the edge of the cartilaginous surfaces.

181. It does not seem to us, however, to have been yet satisfactorily ascertained, whether this synovial membrane be continued over the inner surface of the fascicular ligaments; or how it is disposed in joints, of which the ligaments are of the capsular kind.

###### b. *Without Articulation.*

182. The small bones of the spine called vertebræ, are united to each other chiefly in this way. The portions of them denominated their bodies, are directly connected to pieces of a flexible and compressible substance, somewhat between cartilage and tendon in its nature, one piece being common to two vertebræ.

##### B. *Connections not admitting Motion.*

183. These may be divided into two kinds, *suture* and *synchondrosis*.

###### a. *Suture.*

184. In this species, the bones are united by direct contact of their osseous substance. The contiguous parts, however, are in general more or less indented or serrated, the projecting parts of the one being fixed into holes or grooves in the other. The periosteum passes across the line of junction, and does not dip down between the united surfaces.

###### b. *Synchondrosis.*

185. In this mode, a piece of cartilage, or some

Anatomy, Human.

similar substance, is interposed between the surfaces of the bones which are joined together; and their connection is further strengthened by ligaments, as in the junction of the ossa innominata with the sacrum.

3. *Dimensions and Weight of the Skeleton.*

186. The height of the skeleton of a person five feet eight inches, we believe, will be found in general to be about five feet seven inches.

187. Soemmerring (*De Corp. Hum.* Tab. I.) has made some trials of the weight of the skeleton; and, according to him, it varies from 150 to 200 ounces. But we are uncertain as to the weights he employed, and ignorant of the manner in which his estimates were made.

II. *In the Adult Female.*

188. The same general remarks which have just been made with respect to the skeleton of the adult male, apply equally to that of the adult female; only the skeleton of the latter is a little lower, and not so heavy. According to Soemmerring, it weighs in general only from 100 to 150 ounces.

III. *Before and after Maturity.*

The Osseous Substance.

189. Parts corresponding to the skeleton may be distinctly perceived in an embryo of seven or eight weeks. At this early period, however, osseous substance has not yet appeared. In the place of the future bones, we find either a pellucid substance like jelly, moulded into their general form, and surrounded with periosteum, or else a simple membrane resembling the periosteum in structure. Some bones are wholly gelatinous, others wholly membranous, and others partly in the one state and partly in the other.

190. About the end of the second month after conception, the process of ossification begins. It does not commence, however, in all parts of the skeleton at once, but takes place at different periods in different bones, or even in different parts of the same bone. Its commencement in some is delayed until a considerable time after birth.

191. When we attend to the progress of ossification in those parts of the fœtal skeleton which are at first gelatinous, we observe, that if any of these parts are converted into osseous substance so early as the second or third month after conception, they seem to undergo very little previous change of consistence. If they are not ossified, however, till the fourth or fifth month, they gradually lose their resemblance to jelly, becoming firmer, more elastic, and more opaque; and if the ossification is still further delayed, their opacity, firmness, and elasticity, rapidly increase, they acquire a pearly colour, and are converted into a substance in every respect the same as cartilage.

192. When the ossification commences in this gelatinous or cartilaginous basis, the first part which is ossified is always observed to be situated towards the centre of the jelly or cartilage; and from this point the process gradually extends in every direction. In early ossifications, the parts are so minute, that it is difficult to perceive the appearances in the gelatinous basis which immediately precede the formation of the osseous substance. But in those which commence at a later period, the parts of the cartilage which are just about to be converted into bone, uniformly exhibit a considerable degree of vascularity; and a number of little red specks are observed in them, in each of which a capillary blood-vessel seems to terminate, and in which the first bony particles that are formed generally appear.

193. When ossification commences in a membranous part of the fœtal skeleton, the osseous substance first appears in the form of a fine net-work of slender fibres, confined to a small spot in the middle of the membrane. But by the formation of additional osseous particles, this net-work is converted into a plate of bone of extreme thinness and delicacy, and having a layer of the membrane covering each surface, which may be regarded as its periosteum. Innumerable bony fibres are then observed to shoot out, in a radiated direction, from the margins of this little plate, and these are soon connected by short transverse threads of osseous substance, in such a manner, as to give the bone for a time a slightly reticular appearance. The spaces between the fibres seem entirely filled up by blood-vessels.

194. In this manner, the ossification extends through the whole membrane, splitting it, as it proceeds, into two layers, which become the periosteum of the opposite surfaces of the new bone, but remain united into one single membrane around the whole of its margin. At the same time, however, that the bone is thus enlarging in breadth, it is also increasing in solidity, from the deposition of new osseous particles between those already formed. At last, it assumes the form of a continuous plate of compact substance, the different parts of which are proportioned in their thickness to the corresponding parts of the future bone; and if the adult bone contains any reticulated substance, the cells are generally developed in the middle of this compact plate.

195. No sooner are the *cancelli* developed in any part of a young bone, than they are lined with a very vascular medullary membrane. This membrane, however, contains only a slightly viscid, reddish, and transparent fluid. It does not appear to begin to receive any admixture of oil till after birth. At first, the proportion of oily matter is small, and it increases in general so gradually, that the fluid does not acquire the consistence or composition of true medullary oil, until the period of maturity.

The Marrow.

196. In old persons, the medullary membrane seems to become less vascular, and the oil acquires a yellower colour.

197. The periosteum in the fœtus is much thicker, and more tender than in the adult. It is more vascular too, and particularly at those parts of a bone where active ossification is going on. In old persons, it is thinner and less vascular.

The Periosteum.

198. As soon as the soft rudiments of the future bones are visible in the fœtus, divisions may be observed in them corresponding to the articulations and synchondroses, but none to the sutures.

The Joints, and other Connections.

199. The ligaments and synovial membranes in the young person seem to differ in size only from those of the adult.

Anatomy, Human.

200. For a considerable time after the margins of bones, that are intended to be united by suture, first come into contact, they adhere so slightly to each other, that the bones seem chiefly held together by the periosteum which passes from the one to the other. By degrees, however, as the bones are more fully developed, they are locked more firmly into each other.

201. The apparatus of the articulations seems to undergo very little change in the decline of life. But it is not unusual, in very advanced age, to find the cartilages partially converted into osseous substance. On the approach of old age too, we may almost always observe that the sutures begin to be obliterated. Particles of osseous substance are formed between the margins of the bones, the line of the suture is gradually filled up, and at last the bones are fairly continued into each other.

### Article II.

#### THE ANATOMY OF PARTICULAR PARTS OF THE SKELETON.

202. On this subject we have nothing which we think it necessary to add, at present, to what has been said in the body of the work. See *Anatomy*, from § 11. to § 72.

## PART IV.

### OF THE ANATOMY OF MUSCLES ATTACHED BY BOTH EXTREMITIES TO THE SKELETON.

203. In the article Anatomy, Part I. Chap. II. Sect. II. in the body of the work, the names and attachments of those muscles, which are connected to the skeleton by both their extremities, are given in the form of a table. No description accompanies this tabular view, of the form or structure of the muscles; but considering the length to which such a description would necessarily extend, we are rather inclined to think that the subject has been treated in that article with a sufficient degree of minuteness for a work like the present.

## PART V.

1. OF THE ANATOMY OF THE EYE, EAR, NOSE, MOUTH, PHARYNX, FASCIÆ, AND INTEGUMENTS, &c. OF THE HEAD.—2. OF THE CAVITIES OF THE THORAX AND ABDOMEN; OF THE VISCERA CONTAINED IN, AND CONNECTED WITH, THESE CAVITIES; AND OF THE FASCIÆ, INTEGUMENTS, &c. OF THE TRUNK.—3. OF THE FASCIÆ, INTEGUMENTS, &c. OF THE EXTREMITIES.

We have a few observations to offer on some of the subjects comprehended in the first and second sections of this title.

## BOOK I.

### OF THE ANATOMY OF THE EYE, EAR, NOSE, MOUTH, AND PHARYNX.

## CHAP. I.

### OF THE EYE.

204. Under the general denomination of the eye is included the *eye-ball*, the *optic nerve*, the *muscles of the eye-ball*, the *eye-lids*, the *eye-brows*, the *lachrymal gland*, and the *lachrymal passages*. We have only a few observations to offer on the eye-ball.

### *Of the Eye-ball.*

Its Dimensions.

205. The average dimensions of the eye-ball have not yet been satisfactorily ascertained.

Chemical Analysis of the Vitreous Humour.

206. By chemical analysis, Berzelius obtained from the fluid of the vitreous humour the following ingredients:

| | |
|---|---|
| Water, - - - - - | 98.40 |
| Albumen, - - - - - | 0.16 |
| Muriates and lactates, - - | 1.42 |
| Soda, with animal matter soluble only in water, - - - | 0.02 |
| | 100.00 |

The particulars of the analysis, however, are not detailed. (See *Med. Chir. Transact.* III.)

Measurements of the Lens.

207. We are not yet in possession of any measurements of the lens that are more accurate or particular than those of Petit. According to him the breadth of the lens is 4 lines, and the thickness 2 lines; the radius of the anterior surface is from 6 to 8 lines, and of the posterior from $4\frac{1}{2}$ to $5\frac{1}{2}$ lines. (*Mém. Roy. Acad. Scien.* Par. 1730.)

Morgagnian Liquor.

208. We have ascertained, by many experiments, that the *Morgagnian liquor*, which has been so often described as surrounding the substance of the lens, immediately within the capsule, does not exist in the eye immediately after death. It seems to be the product either of transudation or decomposition.

Analysis of Lens.

209. By chemical analysis, Berzelius obtained the following ingredients from the substance of the lens:

| | |
|---|---|
| Water, - - - - - | 58.0 |
| A peculiar matter, - - | 35.9 |
| Muriates, lactates, and animal matter, all soluble in alcohol, - | 02.4 |
| Animal matter soluble only in water, with some phospate, - - | 01.3 |
| Residuum of cellular membrane, | 2.4 |
| | 100.0 |

210. With respect to the peculiar matter here mentioned, Berzelius remarks, that when coagulated by boiling, the coagulum possesses all the chemical properties of the colouring matter of the blood. (*Med. Chir. Transact.* III.)

Analysis of Aqueous Humour.

211. The result of his analysis of the aqueous humour is the following:

| | |
|---|---|
| Water, - - - - - | 98.10 |
| Albumen, - - - - - | a trace |
| Muriates and lactates, - - | 1.15 |
| Soda, with mineral matter, soluble only in water, - - - | 0.75 |
| | 100.00 |

Central Hole of Retina.

212. We have been led of late, from some physiological considerations, to entertain doubts whether the little dark spot in the retina, which has usually been described under the name of the central hole, be really a hole or not. Is it certain that it is not a spot which is more transparent than the other parts; so that the dark surface of the choroid coat is better seen through it, giving it the appearance of a hole?

Composition of Black Pigment.

213. The black pigment lining the inner surface of the choroid coat and iris, is, according to Berzelius, a powder, insoluble in water and acids, but slightly soluble in alkalies. When dried and ignited, it burns as easily as a vegetable substance, and the ashes contain much iron.

Colour of the Iris.

214. The colour of the iris does not seem to depend in the least on this pigment; but entirely on the structure of its anterior surface.

Supposed Coverings of the Cornea.

215. A delicate membrane was many years ago described by Demours and Descemet, as lining the whole inner surface of the cornea, and prolonged over the anterior surface of the iris; and the merit of having discovered this membrane was the subject of very keen controversy between these two individuals. (Portal's *Hist. de l'Anat.* &c. Tom. V. p. 226.) The same description has been repeated by Bichât, in his *Anat. Descrip.* Vol. II.

216. We have many times sought for this membrane, but in vain; and are much disposed to think, that the anatomists mentioned have been deceived by certain appearances which occasionally present themselves on the inner surface of the cornea, when it has been macerated, and begins to decompose.

217. In almost all anatomical writings, the *conjunctiva* is still described as continued over the anterior surface of the cornea. It is impossible, however, to demonstrate this in the recent eye; and the substance which may be peeled off from the anterior surface of the cornea after slight maceration, is obviously a stratum of the cornea itself. This distribution, therefore, of the *conjunctiva*, which has been copied by one author from another, is a mere hypothesis; and one which, in our opinion, is not much more probable, than that the cornea is covered with a crust of bone.

## CHAP. II.

### OF THE EAR.

218. The structure of several of the soft parts of the ear seems to us to require further investigation. We have most doubts, however, as to the accuracy of the descriptions hitherto given of the contents of the labyrinth.

219. Soemmerring has, within these few years, published a very elegant and very interesting work in German, on the structure of the human ear; in which all the parts of this complicated organ are represented in engravings.

220. His description of the labyrinth corresponds pretty nearly with that which had before been given by Scarpa. We believe it, however, to be more accurate; and his representations are certainly more natural.

221. The whole inner surface of the labyrinth is said to be lined with a very delicate membrane, which sometimes exhibits an appearance of considerable vascularity, and adheres everywhere to the bone. Within this are found, in the vestibule, two membranous sacs, which do not seem to have any communication with each other; but from the larger one, which is more oblong than the other, three membranous canals extend into the three semicircular canals of the bone.

222. The membranous sacs, and the membranous canals, appear to contain a thin watery fluid; and between them and the vascular lining of the labyrinth already mentioned, a small quantity of a similar fluid seems to be interposed.

223. The portion of the auditory nerve destined for the vestibule, seems to be entirely lost on these sacs and canals.

224. We are not fully satisfied with the descriptions usually given of the aqueducts of the labyrinth. They have been too generally examined in the young subject. Are they always open in the adult; and, when open, are they distinctly lined with any periosteal covering?

## CHAP. III.

### OF THE NOSE.

225. The membrane lining those parts which contribute directly to form the cavities of the nose, possesses the same structure everywhere. Its free surface is vascular, red, and villous; the surface attached to the bones or cartilages, smooth, and silvery, like tendon. It is obviously composed of two distinct textures; but they are so closely united, that it is impossible to separate them from each other.

226. The membranes lining those cells and sinuses which communicate with the cavities of the nose, is a good deal different. It is thinner, more tender, paler, semitransparent, and promising little vascularity. Its free surface is less villous, and the surface attached to the bones does not exhibit any tendinous appearance.

227. Bichât's description of this membrane (*Anat. Descrip.* II.) is by far the best which has yet appeared.

## CHAP. IV.

### OF THE MOUTH.

228. When the jaws are closely shut, the mouth may be regarded as consisting of two regions; an *external* and an *internal*, separated from each other by the teeth and gums.

229. The *external region* is formed by the cheeks and lips without, and by the teeth and gums within. The *internal region* is bounded before, and laterally by the teeth and gums; below by the tongue; above by the hard palate; and behind by the soft palate. Between the soft palate, however, and the posterior part of the tongue, there is an opening, variable in its dimensions, according to the will of the individual, which leads into the pharynx or fauces. This is called the pharyngæal orifice of the mouth, or the isthmus of the fauces.

230. The cheeks and lips are formed of the following parts. 1. An inner membrane of a peculiar

Anatomy, Human.

structure. 2. Little bodies called labial and buccal glands, situated immediately without the inner membrane; the former opposite the front teeth of both jaws; the latter opposite the grinding teeth of the upper jaw. 3. Various muscles. 4. Bodies called parotid glands, one on each side. 5. Cellular and adipose substance. 6. Skin. 7. Hairs. 8. Branches of various blood-vessels, absorbents, and nerves, supplying these parts.

231. The gums consist of a peculiar membrane attached directly to the alveolar arch of both jaws, and to the collars of the teeth.

232. The tongue is composed of the following parts. 1. A peculiar membrane continuous with the gums. 2. Under this, towards the root of the organ, lingual glands exactly like the labial glands. 3. Various muscles. 4. Two submaxillary, and two sublingual glands; one of each on each side. 5. Cellular and adipose substance. 6. Blood-vessels, absorbents, and nerves, supplying all these parts.

233. The hard palate is formed by the inferior surface of the palatine processes of the palate and upper jaw bones, lined by a membrane continuous with the gum, and similar to it in structure.

234. The soft palate is formed of a peculiar membrane, which lines both its anterior or oral, and its posterior or pharyngæal surface; of little glands, which may be called palatine, similar to the labial glands of various muscles; and of two bodies called tonsils, one on each side.

## CHAP. V.

### OF THE PHARYNX.

235. Into this cavity at the top, and on the fore part, the right and left cavities of the nose open; the two orifices being denominated the pharyngæal orifices of the nose. Immediately below, is the soft palate; and to this succeeds the pharyngæal orifice of the mouth. Below this orifice, again, is situated the opening of the glottis, with the epiglottis on its upper and fore part; and under this, there is a slight convexity, which terminates the pharynx before.

236. On each side of the pharynx, at the very top, are found the orifices of the Eustachian tubes, leading from the tympana of the ears.

237. There are no orifices on the posterior surface of the pharynx. This surface is smooth and slightly convex. A considerable portion of it may be seen through the pharyngæal orifice of the mouth, when the mouth is held wide open, opposite to a mirror.

238. The roof of the pharynx is formed by a membrane similar to that which lines the hard palate; which is attached directly to the lower surface of the basilar process of the occipital bone.

239. The posterior and lateral parts are lined with a membrane like that covering the inner orifice of the cheeks; and exterior to this is a coat of muscular fibres, belonging to three muscles called *constrictors of the pharynx*, two called *stylo-pharyngæal*, and two denominated *palato-pharyngæal*. This muscular coat is connected by means of cellular substance behind, to the bodies of the upper cervical vertebræ; the long and short recti muscles of the head, and the longi colli; and laterally, to the carotid arteries, internal jugular veins, pneumo-gastric nerves, &c.

240. The convexity under the glottis, on the fore part of the pharynx, is covered with a membrane similar to that lining the other parts, but rather paler. This is attached by means of cellular substance to the crico-arytenoid muscles of the larynx, and to the posterior margin of the thyroid cartilage on each side; and it is continuous above with the inner membrane of the glottis.

# BOOK II.

## OF SOME OF THE VISCERA CONTAINED IN THE CAVITIES OF THE THORAX AND ABDOMEN, OR CONNECTED WITH THESE CAVITIES.

## CHAP. I.

### OF THE LUNGS AND THEIR APPENDAGES.

### SECTION I.

#### *Of the Lungs.*

241. These organs may be regarded as consisting of two parts; a peculiar *substance*, and a serous membrane called *pleura*, covering the whole outer surface of this substance.

The Air-Cells.

242. The substance of the lungs is composed of a mass of cells called *air-cells*, through which certain tubes called *bronchial tubes*, together with blood-vessels, absorbents, and nerves, are found ramifying in every direction.

243. Nothing certain is known respecting the form or dimensions of the air-cells. When examined with a magnifying-glass, in their collapsed state, they appear very irregular in their shape.

244. It is still uncertain, too, whether they communicate directly with each other by lateral openings, or otherwise. Towards the surface of the lungs, they are obviously collected into a number of separate clusters, which are surrounded by common cellular substance, and have no communication with each other. For, if air be thrown into the bronchial tube supplying one of these, it will not inflate the other. Whether the arrangement be similar throughout the whole substance, we do not know.

The Bronchial Tubes.

245. The bronchial tubes ramify throughout the substance of the lungs exactly like an artery. There is no doubt that they all terminate at last in the air-cells; but they are too minute to be traced by dissection so far. We are rather inclined to think, from an examination of corroded preparations of the injected bronchial tubes, that each air-cell is supplied with a distinct branch of these vessels.

The Blood-vessels.

246. The arteries and the veins of the lungs admit of being injected to a great degree of minuteness; but no method has yet been discovered by which we can see the precise manner in which they end or begin, and the distribution of their terminations and origins, with respect to the air-cells. We learn nothing satisfactory by injecting a thin fluid, such as water, into either of these systems of vessels, and finding that it flows out by the bronchi; or by throwing it into the bronchi, and observing that it returns by the blood-vessels. Transudation admits of fluids pas-

Anatomy, Human.

sing in the dead body through channels, in which they are never found to flow in the living.

SECTION II.

*Of the Appendages of the Lungs.*

247. These are the larynx, the trachea or windpipe, and the thyroid gland.

The Larynx.

248. The larynx contains two compartments, an *upper* and a *lower*, which communicate with each other by a narrow passage. The upper compartment is usually called *glottis;* and the aperture by which it communicates with the lower one, the *rima* of the *glottis.* The edges of this slit are pretty sharp; and the term *vocal cords* has frequently been applied to them. It seems to us better, however, to relinquish this appellation; since it implies an hypothesis with respect to the functions of the rima of the glottis, which, if not incorrect, is at least very doubtful.

The Trachea.

249. We have not been able to discover any structure resembling longitudinal muscular fibres in the trachea or bronchi. The whitish lines which are seen running along the back part of the windpipe when it is slit open towards its lower end, and which extend into the bronchi, depend on a peculiarity in the structure of the inner membrane. These are the lines, however, which, we suspect, have been mistaken for muscular fibres.

The Thyroid Gland.

250. It is a remark which we believe was first made by Bichât, (*Anat. Desc.* II.) that the thyroid gland, although it be supplied with large arterial trunks, is not a very vascular organ. It always contains less blood after death, than many other organs, which do not seem, proportionally, to have such large blood-vessels. We have had occasion to verify this observation very often.

## CHAP. II.

### OF THE ALIMENTARY CANAL.

251. An exceedingly interesting paper on the appearances of the stomach immediately after death, by Dr Yelloly, will be found in the *Medico-Chirurgical Transactions*, Vol. IV. The facts he has ascertained, seem to us to constitute by far the most important addition to our knowledge in this department of anatomy, which has been made for many years. We had directed our attention to this subject, for some time previous to the appearance of Dr Yelloly's valuable essay; and we have lost no opportunity since, of prosecuting the inquiry. We are happy to find, that our observations correspond almost entirely with those of Dr Yelloly.

Vascularity.

252. This very judicious and intelligent physician has found, that appearances of vascular fulness in the inner surface of the stomach, whether florid or dark-coloured, in distinct vessels, or in extravasations of various sizes, occur in every variety of degree and character, under every circumstance of previous indisposition, and in situations where the most healthy aspect of an organ might be fairly expected. They are found in every part of the stomach, but principally in the posterior part of the great end, and in the lesser curvature; and they cover spaces of various extent, but are generally well defined, and terminate abruptly.

253. These appearances preserve their distinctness for a short time only, being best marked on the first day, and soon after; but at irregular periods, becoming more obscure, the parts which were vascular, acquiring a dark red or purple tinge, which loses itself gradually. This effect more readily takes place, when the villous coat is in contact with a fluid, particularly water. They exist in the body of the villous coat, and, in general, appear to be greatest, where that membrane is the least firm and resisting. Careful dissection discovers a fine net-work of veins, between the villous and the muscular coat, from which the minute vascularity of the former evidently proceeds. The arteries are always empty, or very nearly so.

254. The vascularity now mentioned, often possesses a starred appearance, from the circumstance of its spreading in minute vessels, continually ramifying into smaller ones, so very near the extremity of the villous surface. A slight degree of friction with the point of a scalpel, will open the minute extremities of the vessels; but Dr Yelloly has never observed, that, even by squeezing the larger branches, in a retrograde way, effusion into the cavity of the stomach could be produced, so as to stain a white substance, which might be applied to the villous surface.

Thickness of the Coats.

255. Dr Yelloly has remarked, that the coats of the stomach vary very much in thickness in their different parts; the whole substance being sometimes so thin at the great end, as readily to admit of making out through it, dark figures on a light surface. This difference he conceives is produced by variations, both in its villous and muscular coats; for he found, that of two equal oval portions of the same stomach, one of which was taken at the great end, and the other near the pylorus, in the lesser curvature, the former, weighing six grains, had its villous coat, consisting of $2\frac{1}{2}$ grains, and the peritoneal and muscular together, of $3\frac{1}{2}$ grains; while the latter, weighing $19\frac{1}{2}$ grains, had its villous coat, consisting of 7 grains, and its peritoneal and muscular together, of $12\frac{1}{2}$ grains. The thickness of the peritoneal coat appeared to be pretty uniform; but that of the muscular and villous seemed to vary, not only in different stomachs, and in different parts of the same stomach, but in relative proportion in such different parts.

256. Mr John Hunter seems to have been of opinion, that the greater thinness of the stomach here described, was the consequence of an erosion of the villous coat, by the gastric juice. We think, however, that Dr Yelloly's observations clearly shew, that it is not owing to this cause. At same time, we cannot altogether agree with this ingenious author, in considering it as certain, that the difference is one which exists during life. We have often had occasion to observe, in examining the contents of the abdomen, at various periods after death, that those portions of the small or large intestines, which happened to contain air or thin fluids, or both, were considerably thinner in their coats, than portions directly continuous with them, which were empty and apparently contracted at the time of death. The thinness of the stomach at particular parts, may be owing to the same circumstance; and it is not a little in

Anatomy, Human.

favour of this conjecture, that the parts of this organ which are generally observed to be thinner than the rest, are such as must be exposed, from the usual position of the subject after death, to the contact of any air or fluids, which the stomach may chance to contain at the time death takes place.

## CHAP. III.

### OF THE LIVER.

257. In the descriptions which are usually given of the internal structure of this organ, a good deal is stated as fact, which we apprehend is yet matter of conjecture.

258. Besides the absorbents, which it possesses in common with other organs, four systems of vessels are distributed through it; viz. the ramifications of the hepatic artery, the hepatic veins, the portal vein, and the biliary vessels.

259. Injection enables us to trace each of these systems to a great degree of minuteness within the substance of the liver; but, the exact termination or commencement of any of them is not known.

260. In forming our opinions, in the meanwhile, on this subject, it will be proper to keep in recollection, the direction in which the fluids have been ascertained to flow within these different vessels, in the living body. By two of these systems, viz. the hepatic artery and the portal vein, blood is constantly entering the liver; and by the other two, viz. the hepatic veins and the biliary vessels, fluids are perpetually leaving this organ. It is exceedingly improbable, therefore, that the branches of the two former should communicate with each other, or those of the two latter.

261. Whether the hepatic artery and portal vein communicate with the hepatic veins alone, or with both the hepatic veins and the biliary ducts, cannot, it seems to us, be decided by simply injecting a thin fluid like water into either of the trunks, in the dead body, and observing by what channel it escapes. For, in the first place, transudation is a source of fallacy in all experiments of this kind; and, secondly, allowing that no transudation took place, a direct communication between any two of these opposite systems of vessels, might open an indirect channel for the fluid, through the branches of the other two.

262. The portal vein has been said to resemble an artery somewhat in its structure; but we have never been able to discover any similarity between them. It has always appeared to us to have the same composition as the other veins of the body.

## CHAP. IV.

### OF THE GRAVID UTERUS.

263. The department of this subject, which seems to us most deserving of further investigation, is the structure of the Placenta.

Hunter's Description of the Placenta.

264. According to Dr Hunter's description of this substance (see *Anatomical Description of the Human Gravid Uterus.* Edit. by Dr Baillie. Lond. 1794.), it consists of two portions; a *fœtal* or *umbilical*, and a *maternal* or *uterine part.*

265. The fœtal part is composed entirely of ramifications of the umbilical arteries, and umbilical vein. These, dividing to almost infinite minuteness, extend to all parts of the placenta. The branches of the umbilical arteries finally terminate in the umbilical vein, and they have no other termination; the branches of the umbilical vein all arise from the umbilical arteries, and they have no other commencement.

266. The maternal part, consists of a whitish-coloured substance, which is spread over the outer surface of the placenta, in the form of a membrane, and sends off innumerable irregular processes, which pervade its substance, as deep as its inner surface. These are everywhere so blended and entangled with the ramifications of the umbilical system, that it is impossible to discover the nature of their union. They are interwoven in such a manner, however, as to leave innumerable small vacuities or cells between them, which have free communications with each other, through the whole mass. The maternal part is full of both large and small arteries, and veins, none of which are derived from the vessels of the fœtal part, but all from the arteries and veins of the uterus. The arteries are all much convoluted and serpentine; the larger, when injected, are almost of the size of crow-quills; and, after little or no ramification, they all terminate abruptly in the cells already described. This is their only termination. The veins have frequent anastomoses, pass in a very slanting direction, and generally appear flattened; some of them are at least as big as a goose-quill, but many of them very small; and all of them arise abruptly from the cells of the placenta. This is their only commencement.

Not satisfactory.

267. This description of Dr Hunter's, has been acquiesced in pretty generally by the anatomists of this country, and we believe also by those on the Continent. It is to be observed, however, that it is partly susceptible of demonstration, and partly hypothetical; and we confess that we do not think that the conjectural part is altogether satisfactory.

268. In the first place, the existence of cells in the placenta, we hold to be matter merely of conjecture. If melted wax, it is said, or any similar fluid, be injected into the uterine arteries, it will first fill the cells, and then return by the uterine veins; or if it be thrown in by the uterine veins, it will fill the cells and then pass on into the uterine arteries; or if an injecting pipe be simply thrust into the middle of the placenta, and melted wax injected, the whole cells will be filled, and the uterine veins also. But it does not follow from these experiments, that the cells which appear, are cells naturally existing in the mass. They may be the effect of artificial distention of its parts from extravasation of the injected fluids; and we think it favourable to this hypothesis, that, considering the size which these cells generally have in an injected placenta, there is no appearance of them, either in a collapsed state, or filled with blood, in one which is uninjected.

269. Secondly, we regard it merely as an hypothesis, that the blood-vessels of the fœtal part of the placenta do not communicate with those of the maternal part. The commencements or terminations of either system, cannot be seen; they must be deduced, either from injections in the dead body, or from observations on the state of the circu-

lation in the umbilical cord, during labour, in the living. Now, although it may be found impossible to force even a thin fluid from the umbilical arteries into any of the uterine veins, or from the uterine arteries into any of the umbilical veins, we cannot positively conclude, from this experiment, that these vessels do not communicate with each other. The same experiment often fails when tried on vessels which are known to be connected with each other. For example, there can be no doubt that the arteries and veins of the stomach communicate; yet, it is in general impossible, even with the finest fluids, to inject the one set of vessels from the other.

270. Upon the whole, therefore, we think a new series of observations on the anatomy of the placenta, very desirable. In the meanwhile, nothing seems to us to have been ascertained respecting its structure, at all inconsistent with the hypothesis, that part of the capillary branches of the uterine arteries communicate directly with corresponding branches of the umbilical vein, and part of the capillary branches of the umbilical arteries, with corresponding branches of the uterine veins.

## PART VI.

1. OF THE SITUATION AND CONNECTIONS OF THE HEART, AND THE STRUCTURE AND DISTRIBUTION OF THE TRUNKS AND PRINCIPAL BRANCHES OF THE BLOOD-VESSELS.—2. OF THE STRUCTURE AND DISTRIBUTION OF THE TRUNKS AND PRINCIPAL BRANCHES OF THE ABSORBENTS, AND OF THE GLANDS CONNECTED WITH THEM.—3. OF THE SITUATION AND CONNECTIONS OF THE BRAIN AND SPINAL CORD, AND THE STRUCTURE AND DISTRIBUTION OF NERVES COMMON TO MANY PARTS.

271. We insert this general title here, merely for the sake of pointing out the place, in which we conceive the subjects enumerated in it should be treated of, in a systematic view of Human Anatomy. The progress of the science does not suggest to us any thing of sufficient importance relative to these subjects, to demand notice in the present supplementary pages.

See, for the first division of the title, *Encycl. Britt.* ANATOMY, Part I. Chap. IV. Sect. x. and xi; for the second, Part I. Chap. III. Sect. xiv; and for the third, Part I. Chap. V.

## PART VII.

OF THE MODE OF INSPECTING THE BODY AFTER DEATH; AND OF THE PROCESS OF EMBALMING.

## BOOK I.

OF THE MODE OF INSPECTING THE BODY AFTER DEATH.

272. This process is differently conducted, according as the death of the individual has been natural, or is suspected to have been violent.

### CHAP. I.

OF THE MODE OF INSPECTING THE BODY AFTER NATURAL DEATH.

273. In this case, there is one general rule which the operator ought always to prescribe to himself; which is, that the parts to be examined should be exposed, by means of as few external incisions as possible, consistently with the speedy and complete inspection of these parts.

274. The incisions, of course, will frequently vary, according to the supposed nature of the diseased structure which is to be examined. But a few general directions may be given for conducting the process, in those cases in which inspection is most frequently required.

#### 1. *Inspection of the Cranium.*

275. Make a vertical incision from ear to ear, over the crown of the head, through the scalp; and dissect the anterior flap forwards as far as the glabella, and the posterior one backwards, to a little below the occipital protuberance. Then remove the skull-cap, by sawing through the outer table of the bones, and breaking through the inner table with a chisel and mallet. This is a more expeditious mode than sawing through the whole; and it also ensures the safety of the dura mater.

#### 2. *Inspection of the Pharynx.*

276. Make an incision through the middle of the lower lip down to the jaw-bone, and continue it through the integuments on the fore part of the neck, half way down, or altogether down to the top of the sternum. Saw through the symphysis of the lower jaw. Then detach the tongue completely from its connections with the inside of the jaw on either side, and so expose the pharynx.

#### 3. *Inspection of the Larynx and Trachea.*

277. Make an incision through the skin from the middle of the chin, straight down to the top of the sternum. Dissect off, with the flaps laterally, the parts attached to the larynx and trachea. Then cut completely through the root of the tongue, by an incision from before backwards, beginning a quarter of an inch above the os hyoides. Next revert the larynx and trachea, either by dissecting them from the œsophagus, or taking the œsophagus along with them. The glottis is thus exposed, and the rima. Both larynx and trachea may then be slit open in the middle behind.

#### 4. *Inspection of the Chest.*

278. Make an incision through the integuments, from the top of the sternum to the pit of the stomach. Dissect back with each flap all the soft parts down to the ribs. Carry the flaps backwards an inch, or an inch and a half, beyond the joining of the cartilages with the osseous substance of the ribs. Then cut through these cartilages close to this joining, beginning with the second rib, and ending with the seventh. Pull forwards the lower part of the sternum a little; introduce a scalpel behind it, and

detach the diaphragm and mediastinum from it; then saw it through, or break it, immediately below the connection of the first rib, and the cavities of the chest will be sufficiently exposed.

*5. Inspection of the Abdomen.*

279. Make one straight incision from the pit of the stomach to the pubes, through the whole parietes of the abdomen at once; and then relieve the flaps a little at top, by reverting them, and cutting off the attachments of the oblique, recti, and transversales muscles, to the sternum and cartilages of the ribs. This incision will, in most instances, suffice for an examination of all the viscera in the abdomen; and it is peculiarly well adapted for cases of dropsy of this cavity, as it retains the fluids until they can be completely and conveniently removed.

280. Where a freer opening into this cavity is thought necessary, the incision from the pit of the stomach may be made to terminate at the navel, and then one may be continued on each side from that, to the spinous process of the ilium.

281. If a still freer opening be required, the parietes may be divided by a crucial incision; one part of which extends from the præcordia to the pubes, and the other across this at right angles opposite the navel, from one loin to the other.

282. Cases sometimes occur, in which neither of these incisions admit of a sufficiently accurate inspection of the contents of the pelvis; and, in such instances, it is necessary to remove by the saw the pubal bones on each side.

## CHAP. II.

### OF THE MODE OF INSPECTING THE BODY, WHEN VIOLENT DEATH HAS BEEN SUSPECTED.

283. In these circumstances, there ought to be no restriction, either as to the time employed in the inspection, or the number or extent of the external incisions.

284. The cases of this nature usually requiring a peculiar mode of procedure, are those in which death has been suspected to have been induced, either by poison administered by the mouth or rectum; or by abortion purposely brought on.

285. When poison is suspected to have been introduced into the stomach or rectum, the whole of the alimentary canal must be removed from the œsophagus to the anus, in order that its contents may be carefully examined. For this purpose, a double ligature should, in the first place, be applied to the very commencement of the jejunum, and the intestine divided between the two threads; a similar ligature should then be applied to the ilium, close to its termination in the colon, and the tube divided in the same manner. The root of the mesentery being now cut through, the whole jejunum and ilium are removed together. A double ligature is next to be applied to the rectum, as low down as possible, and the rectum, being divided between the cords, it is to be removed, along with the whole of the colon. The œsophagus, stomach, and duodenum, are then to be extracted together; taking care, first of all, to tie a ligature round the top of the œsophagus.

286. In cases where abortion is suspected to have taken place, we hold it to be a rule which should never be deviated from, that the uterus and all its appendages should be examined *in situ*. For that purpose, therefore, the anterior parietes of the pelvis should be freely removed.

## BOOK II.

### OF THE PROCESS OF EMBALMING.

287. The object of this process is to prevent altogether, or to retard the decomposition of the body after death.

288. The following method of performing it, (which is that recommended by Dr Baillie, *Transactions of a Society*, &c. Vol. III.) with only a few alterations, appears to us the simplest and easiest.

289. In the first place, an antiseptic fluid is to be prepared of essential oil of turpentine, with a small proportion of Venice turpentine dissolved in it; and this is to be well charged with vermilion. The pipe of a syringe, such as is commonly employed in anatomical injections, is then to be introduced into the anterior femoral artery, with its point turned towards the heart; and as much of the antiseptic fluid is to be injected into the vessels of the body, as it is thought they will bear without rupture. A ligature being applied to this vessel, the pipe is then to be withdrawn, and re-introduced at the same opening, with its point downwards, so that the part of the limb below the groin may be completely injected. This done, the pipe is to be removed, the artery tied, and the skin sewed up; and the body is to be allowed to rest for an hour or two.

290. The cavities of the chest and abdomen are then to be laid open in the usual manner.

291. An aperture being made into the pericardium, this bag is to be filled all round the heart, with an antiseptic powder, composed of two parts camphor, one of resin, one of nitre, and a sprinkling of oil of rosemary or lavender.

292. Next, an opening is to be made into the trachea, just below the cricoid cartilage, and the lungs are to be injected with camphorated spirit of wine.

293. A ligature is then to be applied to the œsophagus at the cardia, and another to the rectum, as far down as possible; and the alimentary canal is to be emptied at proper points, between these ligatures, and as much of the air and feculent matter it may happen to contain, as possible. No water should be employed for the purpose of ablution. Camphorated spirits of wine are then to be injected upwards and downwards, so as moderately to distend the whole stomach and intestines.

294. The bladder is next to be slit open, at its upper extremity, and filled with the antiseptic powder.

295. The surface of all the viscera of the thorax and abdomen is then to be washed with camphorated spirit of wine, and all the intestines between them filled with the antiseptic powder; after which, these cavities are to be sewed up.

296. The mouth, nose, and pharynx, are next to be washed out with the camphorated spirit of wine, and stuffed as much as possible with the powder.

297. A sufficient quantity of the same antiseptic

powder, is then to be introduced into the passages of the external ear, rectum and vagina in the female. The humours of the eyes being let out, the powder is also to be employed to fill up the space between the eyes and eye-lids.

298. All these operations being completed, the surface of the body is to be rubbed over with some aromatic oil, such as oil of rosemary or of lavender.

299. Lastly, the body is to be inclosed in such a chest as shall completely exclude the external air. A chest of lead is best adapted for this purpose. Before introducing the body, a quantity of plaster of Paris should be spread on the bottom of the chest, for the purpose of absorbing moisture.

## II. COMPARATIVE ANATOMY.

This department of *Anatomy* has, of late years, been cultivated with so much zeal, both in this country and on the Continent, that we are persuaded nothing more is necessary to render it a very favourite branch of general study, than a more elementary arrangement of the facts which it comprehends, and a more philosophical classification of the living beings to which these facts relate.

Were all the known plants in the world submitted to the examination of a certain number of individuals, accustomed to nice and patient investigation, but altogether ignorant of the botanical arrangements hitherto proposed; and were these individuals required to classify the objects placed before them, solely according to their general external resemblance, in visible and tangible properties; we imagine there can be no doubt, that precisely the same classification would at last be adopted by them all. We apprehend, indeed, that the result of the experiment would be similar, were engravings of the plants merely, substituted for the plants themselves, provided the representations were sufficiently accurate in point of form and colouring. It is to such an arrangement as this, we conceive, that the appellation of *natural* is alone applicable.

No such classification, however, has yet been made, of the objects of the vegetable kingdom. The various *natural methods* which have hitherto been proposed, are all, in truth, more or less *artificial;* that is, founded on partial, instead of general, similitudes. This may appear, at first sight, a little extraordinary; but the causes of the defect may, we believe, be assigned with tolerable certainty.

A series of coloured representations of all the plants hitherto discovered, even if they could have been executed in the earlier periods of the art of engraving, would have constituted a work, by much too unwieldy and expensive, for the greater part of those already ardent in botanical pursuits, or who felt eager to engage in the cultivation of a science, which promises so much innocent pleasure. It became necessary, therefore, to attempt to discriminate plants from each other, by verbal description; so that botanists, in every rank of life, and in every quarter of the world, might be enabled, by the possession of a few small volumes only, to discover the name and properties of any " herb, tree, or flower," out of the multitudes which are scattered over the surface of the earth. It was in a manner, however, essential to the success of this undertaking, that the descriptive detail should be circumscribed within narrow limits; and, accordingly, it has been the constant aim of all the botanists who have successively engaged in it, to discover some circumstances of *partial* resemblance among plants, which might not only form the basis of a methodical arrangement, but admit of sufficiently concise and perspicuous description.

On these principles the Sexual System of Linnæus was constructed; and there can be little doubt, that it owes its almost universal adoption to its being founded on discriminating characters, admitting of so much shorter and more intelligible description, than those of any other method which has yet been proposed. To this system, indeed, we imagine it is generally acknowledged, the science of botany is chiefly indebted, for the rapid progress it has made in modern times. By an appeal to any of those botanical works which are composed according to the Linnæan arrangement, there is no one who, after a little practice, may not be able to discover what name any particular plant he may have gathered has received, or whether any appellation at all has yet been bestowed upon it. These dictionaries, it is true, cannot communicate to him much information respecting the external form or colour, or consistence of the plant, which he has it not in his power to ascertain, in a much more satisfactory manner, by a direct examination of the object itself; and regarding the properties of the plant, they do not, in general, profess to instruct him at all. But as the motives which prompt by far the greater number of persons to the study of botany, are, the love of discovering the names of plants from the shortest possible verbal description of them, (a pleasure nearly allied to that which results from the solution of riddles,)—or a love of displaying to others the knowledge of names thus acquired;—or a great emulation to achieve the glory of detecting a plant without a name at all;—the works we have mentioned may be truly said to serve sufficiently well the general purposes of the botanist. In doing so, too, it is equally undeniable, that they contribute materially to extend our knowledge of plants. By rendering that easy, which would otherwise have been difficult of acquisition, and by converting into a pleasure, what would else have been a toil, they add to the number of those amiable enthusiasts, who are continually employed in exploring the unknown regions of the vegetable world.

To the higher and more difficult investigations of the vegetable economist, however, neither the Linnæan System, nor any classification founded on similar principles, is at all applicable. For his purposes, a perfectly Natural Method is essentially necessary; and how much soever the botanist may feel inclined to smile at the light estimation in which we hold the difficulties of the undertaking, we confess, we cannot suppress our astonishment, that, with the aid of arts, so common and so perfect, as drawing and engraving now are, such a Method should not have been invented long before this time.

The application of these remarks to the subject of the present article, will be obvious, when we state

that not only has no Natural Arrangement of the lower animals been hitherto attempted, but no Artificial Classification of them, even, has yet been proposed, which has met with general adoption.

The imperfections and inaccuracies of the Artificial Classification of the lower animals, by Linnæus, have long been seen and acknowledged; and it is now only matter of surprise, that the same mind which constructed the Sexual System, in one division of the living world, should have proposed an arrangement so defective and incorrect in the other. This Classification, accordingly, has been supplanted in the writings of all the more eminent naturalists of late years, by that of Blumenbach, or Cuvier, or Macartney. Of these three, it has always appeared to us, that the System of Macartney is by far the most perfect, and the most likely to be generally adopted, were its merits more extensively known. It will be found under the article *Classification*, in Rees's *New Cyclopædia*. Zoologists, however, at present, are far from adhering universally, either to this Method of our countryman, or to that of either of the two great Continental anatomists, whom we have just named. Some give the preference to one, some to another, and there are not a few naturalists, we believe, who, in this unsettled state of the science, choose rather still to follow the Method of Linnæus, with all its faults, than to adopt the language of any System less generally known.

Whichever of these Classifications, however, or whatever similar Classification shall hereafter obtain the preference from the majority of naturalists; we apprehend that it can hardly be expected that zoology will derive such advantages from it, as have accrued to botany, from the facilities and precision of the Sexual System of Linnæus. It is an objection to all such zoological Classifications as we have alluded to, that they are founded too much on the internal structure of animals. Most of the discriminating characters hence derived, are, no doubt, sufficiently sure and precise; but some of them, it must be confessed, are very vague; and others are in no small degree uncertain. At all events, we imagine, the number of individuals is very few, out of the multitude of those with whom zoology is a favourite pursuit, who are either skilled enough in anatomy to look for these distinguishing circumstances, or, if they are, and feel an inclination to attempt the dissection, enjoy either the leisure or the dexterity necessary for accomplishing it. This department of natural history is, we fear, destined to make slow progress indeed, if the zoologist, before he can determine whether an animal be a Reptile or an Insect, must satisfy himself by a complete exposure of its interior frame, whether it have a brain and skeleton or no; or if, before ascertaining whether it be a Bird or a Fish, it be absolutely necessary for him to settle the nice question, whether its blood be warm or cold, or whether its heart have one ventricle or two. We will venture to affirm, that the general class to which any individual animal belongs, was never yet ascertained by any one naturalist, merely by an examination of the characters laid down for that class, in any one zoological arrangement that has ever been proposed.

Comparative Anatomy and Physiology, then, it would appear, labour at present under the same disadvantages, as that department of Vital Economy, which treats of the structure and functions of Vegetables. They have no Natural Classification to refer to; no arrangement founded on that principle, which never fails to bring together objects truly allied by nature, in all the circumstances of their economy, viz. a general resemblance in external properties, visible and tangible.

We feel confident, that, if such a method were constructed, it would not only greatly facilitate the study of Comparative Anatomy, but be the means of promoting a much more general investigation of the habits of many of the lower animals. On this account, therefore, we regret the more to learn, that, in the splendid work, which Cuvier has been employed for so many years in preparing for publication at Paris, the arrangement which this great naturalist proposes to follow, although different from that with which anatomists have long been familiar in his *Leçons d'Anatomie Comparée*, is still founded on equally artificial principles. In the article *Animal*, in the *Dictionnaire des Sciences Médicales*, he gives the following sketch of it:

"Dans un traité que nous nous proposons de publier incessament sur le règne animal, et où nous le distribuont d'apres l'ensemble de son organisation, notre première division sera en quatre grandes classes, ou phalanges; savoir: les *animaux vertébrés*, les *animaux mollusques*, les *animaux articulés*, et les *animaux étoilés;* cette division nouvelle, dont nous donerons alors les motifs avec tout le developement qu'ils comportent, nous paraît répondre au plan de la nature beaucoup mieux qu'aucune de celles qui ont été proposées jusqu'â present."

This outline of the New Classification, by the celebrated author himself, is not only sufficient, in our minds, to shew how much it is at variance with the principles of a Natural Method, but enables us also to anticipate certain objections, which cannot fail to be urged to it, considering it even as an Artificial System. We may content ourselves, at present, with remarking, that there are very few of the *animaux vertébrés*, to which the appellation of "*articules*," is not perfectly applicable; and many "*animaux articulés*," that might with as much propriety be denominated "*etoilés*," as those to which that epithet is intended to be restricted.

In the hope, therefore, that some naturalist, availing himself of the aid of engraving (for without this aid we are afraid the work can hardly be accomplished) will soon supply to zoology a perfectly Natural Method, we shall only further observe, that we should then be disposed to arrange the subjects which fall to be treated of in *Comparative Anatomy*, exactly according to the same order as we have already proposed for *Human Anatomy*.

The immense body of facts which this department of science now comprehends, renders it quite impossible to exhibit them in detail, and at same time to observe those limits which it is absolutely necessary to prescribe, even to articles of the utmost importance, in a general Dictionary like the present. A mere outline of the subject is all that can be looked for. Accordingly, in the body of the work (*Anatomy*, Part II. Chap. iv. to xii.), such an

elementary and popular view of *Comparative Anatomy* has been given, as we have no doubt will appear to our readers altogether sufficient for the purposes of the general student. The accession of facts which the science has received within these few years would fill a volume; and, as they relate chiefly to particulars, they are unsusceptible of abridgment. For this reason, nothing remains for us to do, in the present columns, but to refer those who are desirous of prosecuting the subject more minutely, to those works, general or particular, in which the more recent progress of the science has been recorded.

The most useful elementary work on Comparative Anatomy which we yet possess, is the *short system* of Professor Blumenbach. This was translated into English in 1807, in one volume octavo, with numerous additional notes, and an introductory view of the classification of animals, by one of the ablest and most intelligent of British anatomists, Mr Lawrence of London.

A series of admirable treatises on the Anatomy of the animals included in the Linnæan Classes of Mammalia, Birds, Fish, Insects, and Reptiles, will be found under these articles respectively, in *Rees's New Cyclopædia*. The four first, we believe, were written by Dr Macartney, and the last by Mr Lawrence. They contain many original observations; and are, at the same time, remarkable, not only for the extent and accuracy of the information which they display, but for the clearness of all their details.

The more important dissertations, on particular subjects relative to Comparative Anatomy, which have been composed of late years by the Continental Anatomists, are recorded in the *Mémoires de l'Institut*, the *Annales du Museum*, and the *Journal de Physique*; those by British authors, chiefly in the *Transactions* of the *Royal* and *Linnæan Societies* of London. Among these last, the contributions of Sir Everard Home are deserving of particular notice. The subjects of his investigation have been various and important; and, what is of the utmost consequence, he has accompanied almost all his descriptions with very accurate engravings. The prosecution of scientific pursuits like these, necessarily both laborious and expensive, in the midst of the toils and anxieties of extensive medical practice, evinces a degree of zeal equally rare and meritorious.

Mr Carlisle has lately read to the Royal Society of London, a very interesting memoir on the extra-vascular parts of animals. The subject is a curious one, and it has been treated in a very able manner by this ingenious author. (P.)

# INDEX.

# VEGETABLE ANATOMY.

Introductory Remarks.

In the preceding Article, the science which treats of living bodies has been denominated VITAL ECONOMY, under which is comprehended the economy of ANIMALS and VEGETABLES. Each of these departments has farther been stated to embrace two distinct objects of investigation, ANATOMY and PHYSIOLOGY. The former alone will occupy our attention in the present Article; the design of which is to exhibit a general view of the structure of plants. To the botanist, it belongs to describe their *external forms* in such manner as may serve to discriminate species, and assign to each its place in a methodical system of arrangement: It is the province of the anatomist to demonstrate, by dissection, their *internal structure*, and the construction of their several organs, so as to prepare the way for a rational explanation of their functions.

By reference to the several articles BOTANY, PLANT, PHYSIOLOGY, and VEGETABLE PHYSIOLOGY, in the body of the work, the reader will meet with many observations and descriptions which relate to the structure of plants. They occur, however, in a form so detached and scattered, are intermixed with so much extraneous matter, and, in their combined result, exhibit so imperfect an account of the subject, that we have found it necessary, in order to afford a juster view of the science in its present state, to recast the whole, and give it in a different, and we trust an improved and more systematic form. To the above mentioned articles we may occasionally refer; but, in the present, it will be our aim to collect and arrange all the more important facts that relate to the structure of plants; and these we shall submit to the reader nearly in the following order.

We shall divide the subject into two Parts; in the first of which we shall treat of the Elementary Organs, of which the Vegetable appears to be principally composed. These organs have been denominated the *vascular system* and *cellular tissue* of plants, and under these titles we shall describe, first, the nature and kinds of vessels, and then the nature and kinds of cells by which the tissue is formed. The combination of these elementary organs gives rise to certain *textures*, which are common to almost every part of the plant, and appear in the well known forms of skin, of bark, of wood, and of pith. On these we shall bestow the appellation of *common textures*, and exhibit a general view of their structure and disposition in the several parts of the vegetable body. A brief description of some minuter structures, as pores, hairs, and glands, which are also common to many parts of the plant, will conclude this division of the subject.

In the second Part, we shall enter on the consideration of the individual members and more complex organs of the plant. We shall begin with a description of the general structure of *Seeds*, and afterwards treat more particularly of those bodies under the two great divisions of *monocotyledonous*, and *dicotyledonous* seeds, tracing also the changes of form and of structure which they exhibit in their evolution and progress to the state of the mature plant. The structure of the *Mature plant* itself will next claim our attention; and we shall accordingly exhibit the anatomy of its several members, as of the *Trunk*, the *Branch*, and the *Root*, in their more remarkable varieties and forms. After this, the structure of the organs that spring from these several members, as *Buds* and *Bulbs*, *Leaves*, *Flowers*, and *Fruits*, will be separately and distinctly examined; and having thus followed the progressive changes of form and of structure exhibited in the several stages of vegetable existence, we shall terminate our descriptions by anatomical representations of the organs in which the seed was produced, and the series of appearances successively displayed in its formation.

Through the whole of the descriptive detail, we shall adhere as closely as we can to the language of demonstration; supporting and illustrating our representations of anatomical structure by continual reference to figures, selected in great part from authors of repute, and in some instances from dissections made by ourselves. We shall avoid, as much as possible, the introduction of matter of mere reasoning, or even of facts of a physiological nature (proposing to make them the subject of a future article), except in so far as they may be necessary to illustrate anatomical description, and where the better evidence of actual demonstration is not to be obtained. We are aware, that of many reputed anatomical facts very different representations have been given, all equally professing to rest on microscopical observation. In such circumstances, we can do no more than report concisely the statements of different observers; but shall dwell chiefly on those descriptions and representations which seem best entitled to credit, and appear most conformable to the analogies of other organized structures.

When we consider the immense number of species that compose the vegetable kingdom, and call to mind that in form, in size, and in structure, each species differs from every other through every period of its existence, it must appear altogether impracticable to describe and delineate any considerable number. Fortunately, however, these diversities arise not from differences in the elementary organs, but chiefly from their varied proportion, disposition, and texture. In numerous species, the disposition of the internal organs is very similar, where the external form and texture widely differ. In other instances, the arrangement and composition of the internal parts vary not less than that of the external figure. Of these varieties, we shall exhibit different examples; but a more extended and profound view of vegetable organization would, we are persuaded, diminish these apparent anomalies, and break down the limits within which some late writers have attempted to confine the forms of vegetable structure.

In describing individual parts or organs, we might have brought many concurring examples, and exhibited many similar representations, to confirm the

Introductory Remarks.

views of structure under consideration; but, in general, we have dwelt only on one or two examples, and these we have selected from plants which are either important in themselves, or whose structure has been most satisfactorily displayed, or which seemed to afford the best illustration of the peculiarities we were engaged in describing. From one example clearly given, the reader will readily apprehend the nature of analogous structures, and escape the perplexity and fatigue which unnecessary repetitions might occasion.

Instead, also, of describing the Vegetable at one or two stationary points of its existence, in some of which its size is so minute as to be scarcely capable of demonstration, we have followed it through the several stages of its growth. In this way, we really study it as a living body, continually exerting its vegetative powers, and daily exhibiting the most striking variations in external form, and frequently in internal structure. We hope thus to have conferred an interest on the descriptive part, which may, in some measure, relieve the unavoidable dryness of anatomical details; to have exhibited, in some instances, clearer views of vegetable organization; and to have given a continuity to the subject which isolated dissections, at a few stated periods, could not alone have bestowed. If such displays of the growing structure be thought to partake rather of a physiological character, it may be observed, that we exhibit only the anatomical appearances, without entering at all into the nature or operation of the agents or means by which they are produced.

It remains only to add a few remarks on the nomenclature employed in the present article.

We had wished, as far as we could, to adopt that of Grew and Malpighi, the earliest, and still the best writers on this branch of science. But these eminent authors do not often employ the same terms in their descriptions; sometimes their language is vague; sometimes it rests on false analogies and hypothetical conjectures; and not unfrequently they call the same things by very different names, and use a variety of them. We have, therefore, continued only such of their terms as seemed precise and definite, and which have been sanctioned by subsequent use; but have omitted or rejected others which did not possess these recommendations.

In the description of external parts, we have adhered chiefly to the Linnæan nomenclature; but some of the terms employed by Linnæus, in relation to anatomical structure, are exceedingly vague and inappropriate; others are manifestly erroneous, and, however well suited to the purposes of botany, are not at all to be tolerated in anything that aspires to correct anatomical description.

In the anatomy of seeds, we have adopted many of the terms employed by Gærtner, in his excellent work on the *Fruits and Seeds of Plants*, most of which had previously been used by Malpighi and Grew.

Thus, in every instance, we have exercised our own judgment in the selection of terms, and, where it seemed necessary, have subjoined the synonyms of different writers. Though we presume not to say that we have uniformly chosen the best, we trust they will always clearly express the idea we designed to convey; and that, in general, they have been used in one and the same sense, and in no other. Except in one or two trivial instances, we have not ventured to introduce new terms, but have studiously sought to avoid it, retaining even an inappropriate expression, sanctioned by use, if it did not, at the same time, lead to ambiguity, or convey an idea evidently false; and we have, in general, resisted that torrent of new and barbarous terms, founded often on fancied refinements and pretended discoveries, with which several Continental writers have of late attempted to deluge this branch of science.

## PART I.

### OF THE ANATOMY IN GENERAL OF THE ELEMENTARY ORGANS AND COMMON TEXTURES OF VEGETABLES.

### CHAP. I.

#### OF THE ELEMENTARY ORGANS.

Preliminary Observations.

1. Before we proceed to describe the structure of the individual parts of vegetables, it may be useful to exhibit a general view of the elementary organs of which they seem to be composed. Such a view will prepare the reader for understanding more clearly the descriptive language hereafter to be employed, and will even much abridge the extent to which that description must otherwise be carried.

2. Every one is familiar with the natural division of plants into herbs and trees, and is aware that how different soever they may appear in form and texture, they all possess, in common, certain parts or members which we name the root, the trunk, and the branches, from which proceed the leaves, the flowers, the fruits, and seeds. Infinitely varied as these several parts are, in figure, size, and texture, they all originate from a few constituent or elementary organs, whose situation, proportions, and combination, give rise to all the diversity that we see. "Upon the anatomical analysis of all the parts of a plant," says Grew, "I have certainly found, that, in all plants, there are two, and only two, organical parts essentially distinct, viz. the pithy part, and the ligneous part." (*Anatomy of Plants*, p. 19.) "And as every part hath two, so the whole vegetable, taken together," he adds, "is a composition of two only, and no more. All properly woody parts, strings, and fibres, are one body; all simple barks, piths, parenchymas, and pulps, and, as to their substantial nature, peels and skins, are all likewise but one body; the several parts of a vegetable differing from each other only by the various proportions and mixtures, and variated pores and structure of these two bodies." (*Ibid.* p. 47.) In the anatomical descriptions of Malpighi, the compound structure is resolved, in like manner, into two constituent parts, called by him the ligneous and utricular portions.

Elementary Organs.

To these parts may be assigned the general appellations of the *Vascular System* and *Cellular Tissue* of plants, the description of which shall form the first subjects of consideration.

### Section I.

### *Of the Vascular System.*

#### Article I.

#### *General Characters of the Vessels.*

Definition.

3. By the vascular system may be understood, in a general sense, all those parts of a plant which do not exhibit the form either of membrane or of cells. It constitutes almost the entire bulk of the more solid parts of trees; and, by Grew and Malpighi, was denominated the ligneous body, in contradistinction to the cellular tissue which accompanies it, and which forms by far the largest portion of many herbaceous plants. To common observation, a piece of dry wood appears to be a mass of solid fibres, that is, a series of particles arranged in a filiform figure, and destitute of any continuous canal. Thus Tournefort and others, considered the ligneous parts of a plant to be a mass of minute solid filaments, placed parallel to each other, like the threads in a skein of silk, between the interstices of which the sap ascended; but the anatomical researches of Grew conducted him to a different conclusion. "If it be asked," says he, "what all that part of a plant, whether herb or tree, which is properly called the woody part, what all that is? I suppose that it is nothing else but a cluster of innumerable and most extraordinary small vessels or concave fibres." (*Anat. of Plants*, p. 20.) Malpighi held similar opinions concerning the vascularity of plants, which was farther attested by the microscopical observations of Hooke and Leuwenhoeck. Du Hamel, though he admits that, under maceration, the parts of plants seem capable of indefinite subdivision, yet, from many circumstances, avows his conviction of their vascularity; and Hedwig maintains that the oldest and most compact plant is but a congeries of vessels and cells, which have nothing of the character of a fibrous solid, except in the thin membranous coats by which they are formed. (*De Fibræ Vegetab. Ortu*, p. 17.)

Names of the Vessels.

4. Few circumstances have contributed more to perplex and retard our knowledge of the structure of plants, than the vague and erroneous nomenclature that has been employed to designate their constituent organs, more particularly in relation to the vascular system. Thus the several terms filaments, fibres, strings, threads, and nerves, which, in their ordinary acceptation, are understood to express a solid substance, have been constantly made use of in describing the tubes or vessels of plants. The same organs, however, even by the same writers, are frequently called tubular bodies, ligneous tubes, concave fibres, ducts, canals, arteries, veins, and vessels. In our future descriptions, we shall employ the term vessel in a generic sense, to express all the diversity of names just enumerated, and the different kinds or species of vessels we shall hereafter attempt to discriminate by appropriate appellations.

5. Vessels, as we have said, exist in almost every part of a plant. In the higher orders of animals the fluids contained in the vessels are conveyed to a central reservoir called the heart, from which they are again sent out to all parts of the body. Near to this reservoir, the vessels are few in number and large in size; and they gradually lessen in size and increase in number as they recede from it. In plants, there is no such reservoir, but the fluids which enter by innumerable mouths at the root, are at once distributed equally through all parts of the vegetable that are fitted to receive them. Hence in plants, there is little variation in the diameter of the vessels; and their general figure is therefore cylindrical.

Their Size.

6. From the extreme minuteness of the vessels, it is scarcely possible to compute their number with accuracy. By driving off their fluids without destroying their figure, as is done in the preparation of charcoal, Hooke numbered in a line, $\frac{1}{18}$th part of an inch long, not fewer than 150 vessels; therefore, in a line an inch long, there must be 2700, and in a surface of a square inch, 7,290,000 vessels, "which would seem incredible," says he, "were not every one left to believe his own eyes." These facts he verified by other observations on decayed wood, in which the vessels were empty, and also on petrifactions of ligneous bodies, in which the places of the vessels were very conspicuous. In very close and dense wood, as that of Guiacum, the vessels were still more minute than in the examples just quoted. (*Micrographia*, p. 101, 108.) In a piece of Oak of the size of about $\frac{1}{10}$th part of a square inch, Leuwenhoeck reckoned 20,000 vessels; so that in an Oak-tree of no more than one foot in circumference, or about four inches in diameter, there will be found, according to his computation, 200,000,000 of such vessels. (*Select Works, translated by Hoole*, Vol. I. p. 3.) The largest vessel observed by Hedwig (*De Vegetab. Ortu*, p. 26.) in the stem of the Gourd, appeared through his microscope about $\frac{1}{12}$th of an inch in diameter; and as his instrument magnified 290 times, the true diameter must be reckoned the 3480th part of an inch, which would give for the square inch 12,110,400 vessels. In certain plants, however, the vessels are large enough to be discerned by the naked eye, and in some cases acquire a large size.

Form Fasciculi.

7. The vessels of plants do not, like those of animals, exist single, but are collected into fasciculi or bundles, which, however, have often the appearance of single vessels. In the stems of herbs, and in roots, Grew discovered each small fasciculus to be composed of from 30 to 100, or sometimes many hundred vessels. (*Anatomy of Plants*, p. 20.) The direction of these fasciculi in the trunk is generally perpendicular, but in other parts their course is often oblique, and in their smaller ramifications they produce all sorts of figures. In herbs, the fasciculi are more or less numerous, and placed often at considerable distances from each other, exhibiting the appearance of small columns dispersed through the cellular tissue: in other instances, they are much more numerous, but destitute of any symmetrical arrangement; while, in trees, they are disposed regularly around the axis, presenting in their transverse section, the well known appearance of concentric circles in the wood.

8. In some parts, where the fasciculi stand at a distance from each other, some vessels often quit one

Elementary Organs.

Ramify.

parcel to unite with another, and return afterwards to that which they had previously left. In this manner, they are said to ramify, and frequently, by their ramification, a reticulated appearance is produced, as occurs especially in the bark and leaves. In the wood of the trunk, where they stand collaterally in a perpendicular direction, they very seldom, if ever, run into one another, but keep, says Grew, like so many several vessels, all along distinct; as, by cutting, and so following any one fasciculus, may be observed. (*Anatomy of Plants*, p. 20.) In branches and roots, though the direction of the fasciculi be changed, they seem only to break into smaller parcels, and run side by side, never inosculating with each other, nor being ramified, so as to be successively propagated one from another, as in the vessels of animals. Neither, adds he, are they wound together like threads in a rope, but are only contiguous or simply tangent, like the several cords in the braces of a drum. (*Anatomy of Plants*, p. 66.) Even in the leaf, where the vessels seem to ramify out of greater into less, as in the arteries of animals, yet, if the skin and pulp of the leaf be removed, and the vessels laid bare, it will appear that they are all of the same size everywhere in the leaf, and all continued through it, as distinct tubes, like the several threads in a skein of silk. The distribution of the vessels is not effected, therefore, by their ramifying out of greater into less, but by the division of a greater fasciculus into several smaller fasciculi, till at last they come to be single. (*Anatomy of Plants*, p. 155.)

Do not Anastomose.

9. It may be doubted whether, when the vessels of different fasciculi come into contact, they ever actually unite, and are lost in each other, forming that kind of connection which is called inosculation or anastomosis. Grew strenuously contends against any such connection of the vessels in any part of the plant. " On a superficial view, indeed, the vessels of the leaf, says he, seem to be inosculated, not only side to side, but the ends of some into the sides of others: but neither is this ever really done, the lesser fasciculi being only so far diducted as to stand at right angles with the greater; but they are never inosculated, except end to end, or mouth to mouth, after they are come at last to their final distribution." (*Anatomy of Plants*, p. 155.) Malpighi, however, from the fact of the alternate separation and conjunction of the vessels, and from analogy with what occurs in the animal system, speaks always of the anastomosis of the vessels, but he nowhere gives us anything like proof of the fact: and Du Hamel, from actual dissection of several fasciculi, regards them in their union, as resembling more the nerves than the blood-vessels of animals. When, indeed, we consider the extraordinary minuteness of the vessels, and the circumstance of their possessing nearly the same size in every part, there is no room for that continual ramification out of one into another, and consequent diminution of diameter, that occur in the vessels of animals; and the immensity of their number, together with the endless separations and reunions which their fasciculi make, seem calculated to fulfil the purposes of less general distribution in the plant, which successive division and perpetual anastomosis effect in the animal system.

7

Have no Valves.

10. Another general circumstance in the vessels of plants, is, that we do not discover in them any structure which has the true nature and use of valves, similar to what is met with in the veins and absorbent vessels of animals. Dr Hooke could never observe in their canal anything that had the appearance of valves. (*Micrographia*, p. 116.) Did such a structure exist, the absorption of nutrient matter from the lobes of the seed, and its conveyance, in a backward course, to the embryo, could not, says Grew, have place; neither could the root, as it often does, grow upward and downward both at once. (*Anatomy of Plants.*) If the piece of a root of elm-tree be cut in autumn, the juices, says Du Hamel, are found to escape indifferently at either end, as the one or the other is alternately held downward; a circumstance, he observes, inconsistent with the opinion of Mariotte, who maintained the existence of valves. (*Phys. des Arbres*, Tom. I. p. 56.). It is well known, also, that many plants may be made to grow in an inverted position, so as to put forth leaves and flowers from their roots; and large trees have been nourished by juices received through the extremities of their engrafted branches, after all connection between the earth and the roots had been cut off. In general, indeed, the extreme minuteness of the vessels seems almost to preclude the possible existence of valves in their canal: but in some instances, where the vessels in aged trees have become enlarged, membranous productions have been found to occupy their cavities, which some have alleged to perform the office of valves. They occur, however, only at an advanced period of growth, and form no necessary part of the structure of the vessel, and, instead of promoting, contribute only to obstruct the course of the fluids. It was the opinion of Malpighi that the frequent junctions which the fasciculi of vessels make with each other in their ramifications, might be considered to bestow on them a sort of valvular function: but, in most instances, these fasciculi run parallel without forming ramifications, and no such valvular function can then be considered to have place.

Thus far with regard to the general nature of the vessels of plants: let us next discriminate their several species or kinds.

ARTICLE II.

*Of the Common Sap-Vessels.*

Sap-Vessels.

11. To ascertain the nature and situation of the vessels of plants, various means have been employed. The plant has been dissected both in its dry and recent state; the natural qualities and movements of its fluids have been observed, and its vessels have been filled with coloured liquor, by causing it to vegetate in them. By the combined use of these several means, many important particulars have been ascertained; but it must be acknowledged, that the question is still beset with doubts and difficulties, and that, with relation to it, great diversity of opinion continues to prevail. A concise statement of the facts ascertained, with respect to the movements of the vegetable fluids, may perhaps serve best to define the situation and kinds of the vessels that convey them.

12. It has been proved that, early in spring

Elementary Organs.

Course of the Sap.

before the leaves appear, a watery fluid rises abundantly in the woody part of the trunk of trees, and continues visibly to ascend to the very extremity of the branches, until the leaves are developed, when, to appearance, it ceases to flow, and can no longer be collected by perforating or tapping the tree. This fluid has been shewn to ascend through the wood, and to rise, in general, most abundantly through its youngest or outmost circle: but in trees, whose vessels have not been obstructed from age or other causes, it rises through every circle to the very pith, and, as far as can be judged, in all the vessels that compose those circles. At this early period of vegetation no fluid is found in the bark; nor between it and the wood: nor in the pith: but the vessels of the bark are perfectly dry. These facts are deducible from observations on the natural flow of the fluids by Grew, Du Hamel, Walker, and others; and are supported by various experiments of M. De la Baisse, Bonnet, Reichel, and others, made by causing plants and parts of plants to grow in coloured liquors, in which the vessels of the wood alone became filled, but no tinge of colour was communicated to those of the bark. To these vessels the several names of lymphæducts, sap-vessels, ligneous tubes, ascending and adducent vessels, have been applied:—we shall in future denominate them *sap-vessels*.

Kinds of Sap-Vessels.

13. The vessels, which thus form the mass of wood, have by some writers been distributed into different kinds, and supposed to exercise very different functions. At certain periods of vegetation they appear empty; and hence Malpighi supposed two species of vessels to exist in the wood, one destined to carry sap, and the other to convey air; and to these latter, from their supposed office, he gave the name of *tracheæ*, and from their structure called spiral vessels. (*Anatom. Plantar. Idea*, p. 3.) Grew also believed these empty tubes to be air-vessels, but admitted that, at certain seasons, they carried sap. At an early period, however, Ray maintained that the vessels, thus supposed to convey air, were truly sap-vessels; and Du Hamel, in common with Grew, admitted that they carried sap in spring. Hill considered them altogether as sap-vessels, and Reichel, Hedwig, and others, by experiments with coloured fluids, proved that such was their true office. On the other hand, no experiments, says Ludwig, have yet shewn that there exist in vegetables, vessels destined to convey only air: and in this opinion, subsequent writers, with the exception of M. Kieser, have very generally acquiesced. We may therefore reject altogether the existence of air-vessels or *tracheæ* in vegetables; and consider all the vessels of the wood, by whatever name they may be called, as destined to carry sap. It will, however, be convenient to treat of their general nature and form under the distinct appellations of *sap-vessels* and *spiral vessels*, by which they are commonly known.

Opinion of Grew;

14. By Grew and Malpighi the common sap-vessels were regarded as entire tubes, having no apertures but in their direction of the length. The former represents a single vessel as having the appearance exhibited in fig. 1. Plate XV., the aperture or canal of which is not visible, unless highly magnified, as in fig. 2. According to Malpighi, these vessels send off

of Malpighi;

numerous capillary filaments to the cellular tissue, so that the cells are surrounded by a plexus of vessels, as is particularly seen in the pith of Elder and some others: and these ramifications, he adds, spring probably from the perpendicular vessels both in the bark and wood. (*Anatom. Plantar.* p. 29. Lugd. Bat. An. 1688.) These lateral ramifications were observed also by Leuwenhoeck in a piece of fir-wood, newly felled. Of this wood, he procured a longitudinal section so extremely thin, that he could see distinctly the particles of fluid moving in the vessels, as represented in the upper portion of fig. 3. Plate XV.; while lower down, on many parts of these vessels, small points or dots were visible, which he at length discovered to be round apertures: and as he did not see these apertures in any other parts than those in which he had separated the horizontal cellular tissue from the perpendicular vessels, he concluded that, at these points, these two organs were connected. He farther separated two of the vessels from the remainder, and through the microscope they appeared as in fig. 4: but the "engraver," he adds, "said that he could not possibly draw all the jagged parts that he saw, and we both of us perceived, in the broken membrane or coat of the tube, many excessively minute vessels, which, by reason of their smallness, he was unable to express in the drawing." (*Select Works of Leuwenhoeck, by Hoole*, Vol. I. p. 12.) These opinions concerning a direct communication between the vessels and cells of plants, receive countenance from the experiments of De La Baisse and Reichel with coloured liquors; both of whom observed, in some instances, a tint of colour to be communicated from the vessels to the adjacent cells.

of Leuwenhoeck;

15. It may however be said, that this communication between the vessels and cells, is maintained not by ramifications from the vessels, but through apertures or pores in their sides: and, accordingly, many appearances have been remarked as existing on the sides of the vessels, of which different authors have given very different representations, and which some have regarded as pores. Thus, on the vessels of the Fir, Malpighi observed certain dotted appearances, which he describes as roundish tubercles, and which were so numerous that they appeared to cover the vessels. On the vessels of the Elm, the Beech, and the Willow, Leuwenhoeck saw similar particles which resembled small globules. (*Select Works*, Vol. II. p. 1.) Dr Hill, one of those conceited writers who profess to study only nature herself, and affect an entire disregard of the labours of their predecessors, describes the vessels of the alburnum, or newly formed wood of the Willow, as connected with each other by a flocculent interstitial matter. When, by long maceration, this matter is detached, the vessels then exhibit a dotted appearance; and, if examined by a highly magnifying power, these dots, according to him, are so many oval swellings, and each has, as it were, a mouth. Through these mouths, which he represents as innumerable, and existing on all parts of the vessels, he conceives the fluids to be discharged into the cellular tissue (*On the Construction of Timber*, p. 18.); but he has omitted to show that the cells of the tissue possess any corresponding mouths to receive them. In fig. 5. Plate XV. is a repre-

of Hill;

Elementary Organs.

sentation of these vessels connected by flocculent matter, with their extremities collapsed from the escape of their juices, and their sides sprinkled with the little mouths which he mentions. These mouths, if they exist at all, are probably not pores in the sides of the vessels, but the little apertures seen by Leuwenhoeck, and produced by the separation of the cellular tissue, while the parts are still young and tender. The same author, speaking of the vessels of the mature wood of the Pear, states them to be close canals, as in fig. 6., with no lateral apertures in them.

of Mirbel;

16. A still later writer, following closely in the track of Hill, and who sets out with observing, that "the microscopical organization of plants is but little known, and that it is in vain to look for the true principles of the science in the works of Malpighi and Grew," declares, that not fewer than five species of vessels are to be found in the woody part of plants: These he denominates porous tubes, cleft tubes, tracheæ, mixed tubes, and vessels *en chapelet*, from their supposed resemblance to a string of beads. Of these several species, we have given representations in figures 7, 8, 9, 10, 11, and 12, Plate XV. The first species, or porous tubes, according to this writer, exist in every part of the plant, where the sap moves with freedom. Their sides are covered with small eminences or projections, in the centre of which is to be found a small pore. (*Exposition de la Théorie de l'Organisation Végétale*, p. 107.) Improving a little on Hill, he represents these pores not as promiscuously placed, but as ranged in transverse lines (fig. 7.); and through them he conceives the fluids of the plant to percolate; not however into the cells only, but out of one layer of tubes into another, in a lateral direction. In this manner, he conducts the fluids from the centre to the circumference of the wood, and at length, by a route not so easily followed, contrives to get them into the vessels of the bark, the sides of which he declares to be perfectly entire, and alike destitute of pores and clefts. (*Ibid.* p. 297.) Of such physiological notions it may truly be said, that they are every way worthy of the fantastical anatomy on which they appear to be founded.

of Bernhardi and others.

17. Several German writers have attempted to verify the observations of M. Mirbel in regard to the existence of these pores. They all differ from one another, and, as might have been expected, are all at variance with M. Mirbel. Bernhardi, following Malpighi, deems the alleged pores to be elevations on the surface of the vessels; Rudolphi represents them as vesicles attached to their sides; Link regards them as globules contained within the vessels; and Kieser, as we shall afterwards see, knows not what to make of them. These very different opinions, formed on viewing the same objects, sufficiently manifest the difficulty and uncertainty of microscopical observations made with highly magnifying powers. The causes of this uncertainty were long ago pointed out by an experienced and most sagacious observer,—the first who employed the microscope in the examination of the structure of plants. His statement may perhaps account for, though it should fail to reconcile, the differences in question. "Of such minute objects," says Dr Hooke, "there is much more difficulty to discover the true shape by an instrument than of those visible to the naked eye; the same object quite differing in one position to the light, from what it really is, and may be discovered to be, in another: and therefore I never began to make any draught, before, by many examinations in several lights, and in several positions to those lights, I had discovered the true form: For it is exceedingly difficult in some objects to distinguish between a prominency and a depression; between a shadow and a black stain, or a reflection and a whiteness in the colour. Besides, the transparency of most objects renders them yet much more difficult than if they were opaque. The eyes of a fly, in one kind of light, appear almost like a lattice drilled through with abundance of small holes; in the sunshine they look like a surface covered with golden nails; in another posture, like a surface covered with pyramids; in another, with cones; and in other postures of quite other shapes." (*Micrographia*, Preface.)

### Article III.

#### *Of the Spiral Vessels.*

Description.

18. Various as have been the opinions of writers respecting the *common* sap-vessels of plants, they have differed yet more in their views concerning the position, number, size, structure, and uses of those which have been denominated *spiral*. The common fathers of Vegetable Anatomy, Grew and Malpighi, who, at the same time, but in different countries, prosecuted their inquiries, for many years, without any knowledge of or communication with each other, are nearly of one opinion on all the more important points in relation to these vessels. Later writers have differed alike from them, and from each other, on almost every point. As the subject is of fundamental importance in the economy of vegetables, we shall endeavour, at the risk even of a little extension of our plan, to set before the reader the leading facts and opinions concerning it; to canvass their relative merits; and deduce from the whole such conclusions as seem most nearly to approach the truth.

Opinion of Malpighi;

19. Malpighi describes spiral vessels as existing in the ligneous parts of all plants. He called them *spiral tubes*, because, when extended, they were resolved, not into separate rings, but into a single zone, which might be drawn out to a great length. In general, they form continuous tubes, but are sometimes contracted at regular distances, so as to resemble somewhat a series of oblong cells. One of these contracted spiral vessels is represented in fig. 14. Plate XV. at the extremity of which, the spiral filament is in part drawn out, and similar appearances of the spiral structure are exhibited in figures 9. and 10. by Mirbel. In herbs, according to Malpighi, these spiral vessels constantly accompany the common sap-vessels, and are ensheathed by them; in shrubs, they occur in every part of the wood, single or in clusters; and in trees, an intermixture of spiral vessels with the common sap-vessels, is observed in every part of the wood. In the Fir, they are found immediately beneath the bark, and are so numerous as to constitute the chief bulk of the wood. They exist with the sap-vessels in the petioles and ribs of the leaf, and likewise in the petals of the flower. In

Elementary Organs.

the roots, they are also met with, and in some roots are so abundant, as to exceed in bulk all the other parts. They exist, he adds, in every part of the plant except the bark; and are annually formed with the alburnous vessels of trees. (*Anatom. Plantar. passim.*)

of Grew;

20. From the writings of Grew we collect also, that spiral vessels exist in every part of a plant, except the bark. In the root they are numerous, of very various size, and their bore is generally larger than that of the common sap-vessels. In the trunks, both of herbs and trees, they are equally visible; and in position, size, and number, subject to great variation. Sometimes they are collected into fasciculi; at other times they are disposed in rays; and in other instances they are arranged in a circular form: They stand sometimes next to the pith, in other instances next to the bark; and in other cases again, they alternate with the common sap-vessels in every part of the wood. They have a more ample bore than the common vessels, and vary in size to at least twenty different degrees. In the leaf, they always accompany the sap-vessels; and both in its petiole and ribs, are constantly surrounded or ensheathed by them. They have a similar position in the petals of the flower, and in the vascular parts of the fruit. (*Anatomy of Plants, passim.*) Hence, then, it appears, from the dissections of Malpighi and Grew, that, in every plant in which vessels are to be seen, and almost in every part of it, spiral vessels abound; they exist, however, only in the *ligneous portion*, or that part in which the sap *ascends*, and are never to be found in the bark.

of Du Hamel;

21. By Du Hamel, the spiral vessels, supposed to convey air, are described as existing in the leaves and the flowers, the petals of which are almost wholly composed of them. In the herbaceous portion of young branches, they are also well seen; which portion afterwards becomes ligneous; so that it cannot be doubted that they exist in the wood, though he could never discover them but in young branches. (*Phys. des Arbres*, Tom. I. p. 42.) If, however, all the empty vessels, seen in a transverse section of the wood, be deemed air-vessels, and all air-vessels have a spiral structure, then, says this author, they would, in many plants, form a great part of the ligneous body. From these large vessels, however, he has seen, in autumn, fluids to escape; so that they are not properly air-vessels, or, as Grew observed, they sometimes carry sap. They are not to be found in the bark.

of Hill;

22. Under the common name of sap-vessels, Hill delineates all the varieties of vessels that constitute the wood; they are largest in the outer circles, smaller in the others; they contain, says he, in spring and at midsummer, a limpid liquor; but at all other seasons they appear empty, and have therefore been erroneously deemed air-vessels. He says nothing of their spiral construction; but describes the vessels, which form the chief mass of the wood, as possessing solid and firm coats, forming an arrangement of plain and simple tubes; as in fig. 6. Plate XV.; resembling those of the alburnum, except that they have no mouths in their sides. (*On the Construction of Timber*, p. 8. & 19.) But though, with Du Hamel, he was unable to trace their spiral structure in the wood, yet there can be no doubt of their existence in that part; which, as we shall afterwards show, has been recently demonstrated by Kieser.

of Reichel;

23. M. Reichel maintains their existence in all parts of the plant. By causing plants to vegetate in coloured fluids, he traced them from the roots, through the trunk and branches, to the extremity of the leaves, and into all parts of the flower,—as the calyx, the petals, the style, the stamina, and the anthers. In fruits and in seeds, and in the radicle and plume of the latter, they were equally apparent. The coloured liquors, as they rose, communicated a tinge to the cellular tissue of the wood, as was previously observed by De la Baisse; but no trace of colour was ever observed either in the bark or pith, which therefore contains no spiral vessels. He considered the spiral vessels as the organs everywhere conveying nutrient matter to the plant, and as having no title to the appellation of air-vessels. (*Encyclop. Méthodique*, Article *Physiol. Végét.* p. 288.) Similar experiments of Hedwig and others, confirm these facts as to the universal distribution of the spiral vessels, and their bearing to every part the fluids absorbed by the roots. In his late work, M. Kieser, as we shall afterwards see, in describing the vascular system of the ligneous parts of plants, regards it as composed entirely of spiral vessels, and asserts their existence in every part of the plant except the bark and pith.

of Kieser;

of Mirbel

24. Against these combined authorities M. Mirbel opposes his fanciful views. We have already enumerated the five different species of vessels which he regards as constituting the woody part of plants. According to him, true spiral vessels (which he continues to denominate *tracheæ*) are not to be found in the root, but only in the trunk and the parts which are produced from it. Even in the trunk, they are to be found only around the pith, and never in the exterior ligneous layers. He admits that they exist in all soft and succulent parts, and that coloured fluids rise in them as well as in the other varieties of vessels; but they never are to be found either in the bark or pith. (*Exposition de la Théorie de l'Organisation Végétale*, p. 74, 78.) It appears, therefore, that the vessels which are thus erroneously called *tracheæ*, are destined to carry fluids; and as to the parts in which they do or do not occur, the opinion of M. Mirbel weighs as nothing with us, in opposition to the facts observed by so many preceding and subsequent writers.

Spiral Vessels convey Sap.

25. From the combined observations, therefore, of all the preceding writers, with the exception of M. Mirbel, we collect that the vessels heretofore called air-vessels and *tracheæ*, and which possess a spiral conformation, exist together with those called common sap-vessels, in every part and organ of the plant, except the bark. It appears also, that, though they are often found empty, yet their true office is to carry sap. This may be concluded not only from the actual occurrence of sap in them early in spring and again in autumn, and from the entrance of coloured fluids at all seasons; but from the circumstance that, in some parts, no other vessels appear to exist by

Elementary Organs.

which the rising sap can be conveyed. Are we, therefore, with many, to consider them, from the period of their formation, as a species distinct from the common sap-vessels, or are both to be held merely as varieties of one common kind?

Period of their Formation;

26. It is allowed, on all hands, that spiral vessels are most readily visible, and are most numerous in the tender and succulent parts of vegetables, in which they form almost the entire bulk of the vascular portion. In the alburnous part of trees, which is added annually to the pre-existing wood, they are not so readily seen. Even in trees, however, while still succulent, the first circle of vessels formed, contains spiral vessels; as Du Hamel observes, and even Mirbel admits; but, at a later period of vegetable growth, the whole of the vessels, formed annually in trees, are represented by Grew as common vessels, which, he adds, "begin to be formed in spring; but the spiral vessels not till the latter end of summer, or thereabouts, at least not till about that time do they appear." (*Anatomy of Plants*, p. 131.) Malpighi also describes these spiral vessels as gradually appearing in the alburnum, and continually augmenting in size in every successive ring of wood. A similar remark, as to increase of size, is made by Grew: "the spiral vessels," says he, "being amplified in each annual ring, at least for a certain number of years, so as to form a vessel of a wider bore:" (*Anatomy of Plants*, p. 130.) and accordingly, in all the plates of both these writers, and in those of other authors, the spiral vessels are always represented of different sizes in every part of the wood.

27. From the foregoing facts, it would seem, that, in the young and succulent parts of plants, the spiral construction of the vessels is almost, if not actually, coëval with their existence; but that, in more rigid textures, they are not so early formed, or at least are not discoverable in parts in which they are subsequently seen. Hence, therefore, we must suppose a sort of *transformation* to occur with respect to these vessels, or, to use the language of Grew, that they "are post-nate, and seem produced by some alteration in the quality, position, and texture of their fibres." If, indeed, spiral vessels exist in every part of the wood, but are not for some time visible in the alburnum, and if the alburnum be, as it most certainly is, the substance by which the ligneous layers are successively formed, then it follows, that the occurrence of spirals in the wood must be the result of some change induced on the vessels that at first constituted the alburnum. Hedwig, indeed, considered all the alburnous vessels to possess from the first a spiral conformation, and that they gradually acquired the characters they possess in the wood. We shall presently see that the researches of Kieser support the same view, and thus go to establish the doctrine of transformation, first announced by Grew. Mirbel, however, protests against the transformation of one variety of vessel into another, and maintains that each of the five species, which he enumerates, retains, without change, its original character and form. He nevertheless describes his fourth species, or what he calls mixed tubes, (fig. 10.) as composed of the three preceding species; and "such," he adds, "is the simplicity of vegetable organization, that frequently one and the same tube exhibits (as in fig. 12.) all the several species combined." (*Exposit. de la Théorie*, &c. p. 78, 80.) That the same vessel, from the operation of local causes, should sometimes exhibit, in different parts, a variety of appearance and form, is perfectly consistent with the principle of change and transformation which has been supposed to have place; but that nature should from the first combine in one vessel, unsusceptible of future change, five different species of forms, is not quite so credible; and to ordinary minds would certainly afford no proof of the "simplicity" of her operations.

their Transformation;

are a variety of Sap-Vessels.

28. If then we adopt the opinion, that in young and succulent parts the vessels which carry sap have from the first a spiral construction; and if, as seems to be proved by the dissections of Grew, of Hedwig, and of Kieser, no other vessels, destined to such an office are, frequently, to be found, then we must conclude that, in such parts, only one species of sap-vessels exists, to which, from the first, the spiral construction belongs. If, on the other hand, it appear that, in the more rigid texture of the alburnum of trees, no spiral vessels are at first to be found, but that they afterwards become visible in the wood, then it follows, from what has been already stated, that the spiral vessels of the wood are produced from the common sap-vessels of the alburnum, and are consequently to be regarded, not as an original species, but only as a variety of one common kind. That such probably is the fact, will farther appear from the account afterwards to be given of the structure of these vessels, and of the actual transformations which they seem to undergo. Even those who may still be of opinion, that a difference in *external form* warrants a nominal distinction of species, must, we think, admit that, in *office*, no ground for such distinction exists; but that all the vessels in the ligneous parts of plants are destined to exercise one and the same function. In relation to the economy of vegetables, this is a fact of far greater importance than any opinions that may be formed regarding the varieties of appearance or structure in the vessels themselves.

### Article IV.

*Of the Structure of the Sap and Spiral Vessels.*

Structure of Sap-Vessels.

29. We have next to offer a few remarks on the structure of the vessels we have been engaged in describing. On this head, we shall not go much into detail. When we have seen such difficulties attending the correct observation of them in their entire forms, it may fairly be presumed that still greater perplexity must accompany the investigation of their constituent parts. What, therefore, we have to advance, may be regarded rather as matter of opinion than of fact; and, in the present state of the science, this point must be deemed more a subject of curiosity than of use.

Opinion of Malpighi;

30. According to Malpighi, the common sap-vessels of the wood, when viewed longitudinally, appear to be formed of a series of small vesicles or cells mutually opening into each other. These cells possess different forms, but in some vessels there seems to be no trace of such a cellular structure. In the

Elementary Organs.

Oak, the cells are represented to possess a roundish figure, and in the Vine they possess an oblong form; as in Plate XV. fig. 13. (*Anat. Plantar. Idea*, p. 2—24.) In these, and similar instances, Malpighi seems either to have mistaken a series of elongated cells for vessels, or to have conceived that the contractions, occasionally formed in the vessels of certain plants, afforded evidence of their being constructed originally from cells. It is certain that, in the vessels of most parts of plants, no such cellular construction is apparent.

of Grew;

31. Grew, on the other hand, considered the common sap-vessels to be composed of strait fibres, or rather smaller vessels, placed parallel to each other, and set round so as to form a cylindrical tube. (*Anatomy of Plants*, p. 112.) In the opinion of Leuwenhoeck the vessels are composed of two fine transparent coats, formed of other vessels exceedingly minute, which are disposed partly in a longitudinal, and partly in a circular direction. (*Select Works*, by Hoole, Vol. I. p. 11.) Du Hamel attempted to gain a knowledge of their structure, by submitting them to long maceration. By this method, he separated the ligneous layers into leaflets thinner than the finest paper, and the fasciculi of fibres or vessels that composed these layers, were farther separated into minuter filaments, placed parallel to one another, like the threads in a skein; and these filaments again seemed capable of almost indefinite subdivision. (*Phys. des Arbres*, Tom. I. p. 31.) Hill considered the vessels of the alburnum to be formed of the same matter as the cells. He describes them as at first very delicate, and to collapse when emptied of their fluids. Sometimes the coat of which they were formed resembled a thin parchment, in which traces of lines surrounding one another were visible, so that the coat seemed as if composed of several membranes that were vascular. In one instance, where a strong light was made to penetrate the vessel, it appeared as if composed of numerous cells; but, on farther examination, these seeming divisions altered their places, and were found to proceed from small portions of watery sap still retained in the vessel. This appearance, as he properly observes, may be a very necessary lesson against hasty judgments. (*Construction of Timber*, p. 33.)

of Leuwenhoeck; of Du Hamel; of Hill;

of Mirbel.

32. M. Mirbel's opinion concerning the formation of vessels may next be shortly noticed. He sets out with asserting, that "the entire mass of the plant is nothing but cellular tissue, the cells of which differ only in form and dimensions." This he declares to be the basis of his theory; and he may perhaps be right in thinking, that "no one, before himself, had formed a similar conception of vegetable organization." The cells and vessels of this tissue are farther considered to be produced out of one and the same *membranous tissue*. In forming cells, this membrane is supposed to dilate in every direction; in producing vessels, it increases only in length. (*Exposit. de la Théorie de l'Organisat. Vég*. p. 9—103.) Of the structure of this primitive membrane itself, he professes to give no information; and his account of the manner in which the vessels are produced out of it, is so entirely mechanical, so clumsily conceived, and so incapable of execution, that we deem it altogether unworthy of the attention of any one accustomed to contemplate the structure and formation of organized textures.

Structure of Spiral Vessels. Opinion of Malpighi;

33. Concerning the structure of the *spiral* vessels, opinions have varied still more than in relation to those just considered. Malpighi describes them as composed of a thin zone, formed of a pellucid silvery plate, somewhat broad, which, being placed spirally, and united at its edges, constructs a tube, interiorly and exteriorly, somewhat rough. When this tube is drawn out, it does not separate into distinct rings, but is resolved into a continuous spiral zone. At particular places, these vessels are sometimes contracted, so as to exhibit the appearance of oblong cells opening into each other, as in fig. 14 Pl. XV. In size they greatly surpass the ordinary sap-vessels; and their canal is then frequently occupied by membranous vesicles, which nearly fill their cavity. (*Anat. Plantar*. p. 3—26.) These vesicles were also observed by Leuwenhoeck, and their appearance, both in the transverse and longitudinal section of an enlarged vessel, are represented in fig. 15.

of Grew;

34. According to Grew, the thin plate that forms the spiral vessel, is not always of the same breadth, and, instead of being flat, it has sometimes the form of a round thread. When minutely examined, the spiral zone, he adds, is never one single piece, but consists of two or more round filaments placed collaterally, but perfectly distinct. These component filaments he regards as united by other smaller transverse filaments, and the thin plates which they form by their connection, constitute the spiral vessel;—"as if we should imagine," he adds, "a piece of fine narrow ribband to be wound spirally, and edge to edge, round a stick, and the stick being drawn out, the ribband to be left in the figure of a tube, answerable to a spiral vessel." As, however, the ribband is composed of numerous threads, placed parallel to each other, so is the plate that forms the spiral vessel; and it is according to the greater or less delicacy of the vessel examined, and the manner of its dissection, that it appears to be constituted either of a flat plate, or a round filament. The spiration of the filaments he considered to be made in the root, from right to left, and in the trunk, from left to right. (*Anat. of Plants*, p. 73, and 117.)

of Du Hamel; of Hedwig;

35. The opinion of Du Hamel, with respect to the construction of these vessels, was very similar to that of Grew, and he employed the same analogy of a ribband twisted round a stick, to illustrate it. Hedwig gave a very different account of them. He considered the spiral vessel to be composed of two distinct parts; one a membranous canal conveying air, and the other a spiral tube rolled round it, by which the fluids were conveyed. The spires of the tube, in some instances, are represented as close; in others, they are separated, and the intervening portions of the membranous canal exhibit a dotted appearance. He considered all the sap-vessels, from their first formation, to possess this compound structure, and, by a series of changes, which he professes to describe, to be ultimately transformed into the solid fibre of the wood. (*De Fibræ Vegetab. Ortu*, p. 25.) Others, also, have believed the spiral vessel to be formed of a membranous tube, but have denied that it

Elementary Organs.

conveyed air, and the spiral tube of Hedwig they have regarded as a solid plate or filament. From the different appearances which they exhibit, M. Treviranus and Bernhardi distinguish several varieties of spiral vessels, as does also M. Kieser, whose account of these vessels is not only the latest and most elaborate, but that probably which approaches nearest to truth. We shall, therefore, subjoin a brief abstract of his observations on the situation and structure of these vessels, and more particularly on the series of *transformations* which they seem to undergo.

of Kieser.

36. According to M. Kieser (*Mém. sur l'Organisation des Plantes*, p. 115, à Harlem, 1814), spiral vessels are found in all the more perfect plants, from the earliest period of their existence, and in all parts of them except the bark and pith. In herbs, they are collected into fasciculi of thirty or more vessels; in trees they constitute the wood, and are annually augmented in number by a new layer. In different plants, and even in different parts of the same plant, they vary much in size, being generally largest in succulent plants, especially those of rapid growth; and in such plants, they continually augment in size. In some woods, they are extremely small; in others, much larger. In aged plants, both in the root and trunk, they are at length more or less completely obstructed by a species of membranous vesicles, previously observed by Malpighi and Leuwenhoeck, which originate from the sides of the vessels. Nothing but air is commonly found in their cavity; but in the wood of Guiacum, he has seen all the spiral vessels entirely filled with resinous matter, and the whole cellular tissue completely filled with the same matter. He does not know what anatomical relation subsists between the spiral vessels and the other organs; but thinks there is no direct communication between them and the cells.

37. The construction of these vessels M. Kieser professes to have studied with the greatest care, and to have established incontestably the following points. Sometimes, says he, only one fibre, sometimes many, go to form the spire of a vessel. These fibres are commonly round, sometimes a little flattened, and are twisted spirally about an empty space, so as to form a tube. The spiral fibres in young plants, and sometimes in mature ones, are in close contact; in other instances they are separated, and the interstices are then occupied by a dotted or punctuated membrane, as is very frequent in trees; or sometimes they are connected by ramifications which proceed from the spiral fibres themselves. From the minuteness of the spiral fibre, it is difficult to decide whether it is a solid or tubular body, and often, from the same cause, to pronounce whether it is round or flattened. It is transparent; has considerable consistence and tenacity; and, in some plants, appears to possess elasticity.

38. The number of fibres that form the spire of a vessel is very various; sometimes, as before remarked, there is only one, but more often several, which are twisted in the same plane, and the same direction. He has seen nine fibres thus united, and when unrolled, the spires of the vessel then seem to form a kind of ribband. When many fibres are employed to form a spire, they always run parallel, and do not cross; so that the side of the vessel has never more than the thickness of a single fibre. At their first formation, the fibres are not united; it is only in more advanced age that they become united, either by ramifications from their edges, or by a peculiar membrane. The direction of the fibre, in twisting, is sometimes from right to left, and sometimes the contrary. The size also is very various. In young plants it is very small, so that a millimetre comprises the diameter of 2600 of these fibres; and, in some instances, they have little more than half that size. In older vessels they have a larger size. Between the knots of the trunk, they are simple, and do not ramify, but in the knots they undergo great changes of form, and are variously ramified and combined.

### Article V.

*Of the Transformations of the Spiral Vessels.*

Varieties of Spiral Vessels.

39. M. Kieser proceeds next to treat of the transformations or metamorphoses of the *simple spiral vessel* into several varieties; to which, from their peculiarities of construction, he assigns the names of the *annular*, the *punctuated*, the *ramified* and *reticulated* spiral vessels, and another variety he calls vessels *en chapelet*. In essential character and function, however, all these varieties are said to agree; the only difference is, that of external form. Of each of these varieties, we shall subjoin a short description.

Simple Spiral.

40. The first variety, or rather species of vessel, out of which the others are produced, he calls the *simple spiral*. It is constructed of one or more fibres, twisted spirally, and placed contiguous to each other, so as to form a round cavity within. In general, the spires of the fibre are in contact, but sometimes there is a space between them. See *a*, fig. 51. Plate XV. In the latter case, the side of the vessel is closed by the walls of the adjacent cells, but never by any new production of membrane, either without or within the vessel itself. These simple spiral vessels are found in every young plant, and in the newly formed parts of old ones, and give origin to the other varieties. Their size is smaller than that of others; in some instances they have not more than one-eighth or one-tenth of the diameter of other varieties. They are the only variety found in some of the inferior tribes of vegetables. The number of fibres in each spire varies from one to nine.

Annular Spiral.

41. Another form of these vessels is that of the *annular spiral*. In this variety, the component fibre has the form of numerous rings, disposed in a perpendicular line between the ranges of cells; fig. 51. *b*. These rings are very analogous to the spires of the preceding variety, are of the same size, and are often combined with them in the same vessel. They occur in a great many plants, and, in herbaceous plants, occupy the same position as the simple spiral vessels, that is, next to the pith. The rings of which they are constructed are sometimes separated from each other only by a space equal to their own diameter; but, in other instances, they are separated to eight or ten times that distance, forming then the substratum of the third variety, or punctuated spiral vessel.

Elementary Organs.

Punctuated Spiral.

42. From the two simple varieties of form just described, other more complicated forms are produced as the plant advances in age. Thus, the third variety, called the *punctuated spiral vessel*, is constructed by one or more round or flattened spiral fibres; the spires or rings of which, not being connected, leave between them interstices more or less large; which interstices are filled with a membrane more or less thick and transparent, and variously dotted or punctuated, from which circumstance the name is derived.

This structure is imperfectly represented in fig. 51. *c*, and much more clearly by the letter *d* of the same figure, in which the white lines indicate the spiral rings, and the intervening dotted substance represents the punctuated membrane; at the top, a portion of the anterior side of the vessel has been removed, so as to display its inner and posterior surface. In this variety, the rings are never contiguous. Such vessels occur only in the more advanced age of herbaceous plants, but seem to be original formations in the alburnum of trees. Their size is frequently eight or ten times greater than that of the two former varieties, especially in the stem; but they are much smaller in the root. They always occupy the most exterior part of the vascular fasciculus of herbs, while the two preceding varieties are found next to the pith. In trees, on the contrary, the largest vessels of the annual layers occupy the place nearest to the pith; and all the spiral vessels in these layers belong to this punctuated variety, except those immediately next to the pith. The spiral fibre of these vessels is of very various size. In the largest vessels of this class, its size is greatest; in other instances, it is so small as to be scarcely visible. It is often difficult to determine whether its form is spiral or annular; in herbs, it appears to be spiral; in trees, annular.

43. The membrane which fills the interstices of the spires and rings, and connects them together, is not visible in young vessels; but is produced in more mature age, as is proved by the fact that this membrane is often common to two contiguous vessels, and connects respectively their rings together. Hence it is, that the membrane never surrounds the spires, nor is it surrounded by them, but only occupies the interstices between them; and, from the same cause, the spires themselves are always prominent on the surface of the membrane. In this variety of vessel, the spires cannot be unrolled without tearing their connecting membrane. This membrane, at an early period, is transparent, but becomes opaque from age.

44. As to the points or dots on this membrane, they have by some been taken for pores on the surface; by others for clefts produced by the junction of the spires. M. Kieser confesses that he has not yet been able to satisfy himself on this subject. They are clearly not clefts, and it is against the supposition of their being pores, that their position has always a relation to the spires, and not to the adjacent cells. In the wood of Sassafras, however, these points seemed pierced by a hole exceedingly small; but, in other instances, they appear quite dark, and similar to those which are found on the vesicles that fill the cavity of aged vessels, and where there is not the smallest reason for considering them as pores. He thinks there is a great analogy between the formation of these vesicular membranes within the vessels, and that membrane by which the spires are connected in this variety of vessel. In some plants, the size of these dots is large, and they appear transparent at the centre; in other instances, they are extremely small. Their form is oblong or elliptical, and they are always ranged in a determined line, parallel, in general, to the direction of the spires.

Ramified Spiral.

45. The fourth variety of spiral vessel is said to have the same origin as the last, being formed in part by the spires or rings of the two first varieties; but the interstices between these are filled, not by membrane, but by small ramifications, produced from the rings themselves; and these ramifications are often so implicated as to form a net-work; whence the names of *ramified and reticulated spiral vessels*. Like the former variety, they do not exist in the young plant, but are the consequence of the gradual changes of advanced age, and produced by a similar series of actions. They are formed of one or more spiral fibres, the spires of which are contiguous in the young plant, but separate at a later period; and the interstices are filled up by new ramifications from the spiral fibre itself. In the first period of their formation, when there are but few ramifications, he names them *ramified* spirals; and when these become more numerous and implicated, *reticulated* spirals. They are found but in few plants, and those of the more succulent kind; they do not attain the size of the preceding variety; are associated in the same plant with the simple and annular spirals; and in the fasciculi, occupy the same place as the punctuated spirals, that is, next to the bark. They are more transparent than the punctuated spirals, and occur more frequently in the root than the stem. In the representations given of these vessels by M. Kieser, they appear to differ from the preceding variety, chiefly in the position of the spiral rings, which are more or less obliquely situated, and sometimes send off a sort of branch, as is represented near the bottom of the vessel *d* in fig. 51.

Vessels en Chapelet.

46. The last variety, or vessels *en chapelet*, discovered and named by M. Mirbel, are found only in those parts where the perpendicular growth is obstructed, and the vessels, taking a horizontal direction, suffer a complete change of character. It is therefore in the knots of the trunk, in the tubercles of roots, and in similar parts, that such vessels occur. They take their origin occasionally from all the other varieties, and are, in truth, nothing but these varieties changed by the qualities of the knot. They are formed by contractions occurring at short distances, which diminish the diameter of the vessel, and dispose it into the form of irregular oblong cells or utricles threaded on one another, as in fig. 51. *e*; or as in fig. 11. copied from Mirbel, with which the representations of Kieser nearly coincide; but he makes the figure of the utricles much less regular. The vessel itself also has a tortuous course in the knot, and sometimes many are ramified and combined, so as to form a kind of reticulated appearance. This, however, is effected by vessels leaving one fasci-

Elementary Organs.

culus and passing to another, and does not seem to be a true ramification of one vessel out of another. The construction of the sides of this variety of vessels is the same as that from which they take their origin. Thus, if they are formed from simple spiral vessels, their sides have the simple spiral form; if from punctuated spirals, then the vessels *en chapelet* possess the punctuated membrane, and so with respect to the ramified variety of vessels. The contractions in these vessels are not produced by any displacement of the spiral fibres of the other varieties; but their true cause is to be sought in the function of the part, and the action of the knot itself. Every spiral vessel, whether simple, punctuated, or reticulated, may thus be metamorphosed in the knots, into a vessel *en chapelet*, and again lose this character, and resume its original form in the internodial spaces.

47. Such is the account given of the construction and metamorphoses of the spiral vessels by M. Kieser. It is, in every part, amply illustrated by figures, made from dissections of various plants. These drawings everywhere support the descriptive detail; and if the microscopical observations from which they are made be correct, no doubt can exist of the truth of the doctrine. That considerable changes do occur in the vessels of plants, after their formation, seems most certain; and the series of appearances exhibited by M. Kieser, presents, as we think, nothing inconsistent with probability, nor beyond the powers of vegetable organization. Neither do they militate against the previous descriptions of Malpighi, Grew, and Hedwig; but, on the contrary, receive, generally, confirmation from them. M. Kieser, however, has pushed his inquiries much farther, and given to the doctrine of transformation a more precise and systematic form. He has not ventured to speculate on the probable causes of these curious changes; but were this the proper place for such discussion, and were the facts, connected with the functions of these vessels, fairly before us, in addition to those which regard their structure, we think that an explanation, tolerably satisfactory, might be obtained. But the prosecution of this subject we must defer to a future occasion.

Uses of the Spiral Vessels.

48. We collect, then, from the whole of the foregoing statements, that all that part of plants, which is commonly stiled the *ligneous portion*, is composed chiefly of vessels, which, however different in size and external figure, are destined to one and the same office, that of conveying *sap;* and that these sap-vessels extend from the extremities of the roots to the points of the leaves, and exist in all the organized productions of plants.

This, however, is not the conclusion at which M. Kieser arrived. Though he has demonstrated that the great mass of the ligneous part of plants consists of spiral vessels, and admits that they receive and convey coloured fluids, yet, from the circumstance of their appearing sometimes empty, he regards them, with Malpighi, as tubes destined to convey only air; and supposes the sap of plants to be carried, not by what are called the vessels, but by certain little canals, of doubtful existence, hereafter to be described, and which have been named *intercellular canals.* (*Mém. sur l'Organisat. des Plantes*, p. 87, 199.) That, however, he should, at the same time, admit the capacity of the spiral vessels to receive coloured fluids, and reject the belief that fluids, destitute of colour, are received by them, is not a little singular; for the colouring particles in the liquor must, and do oppose obstacles to its reception, which fluids of a more simple nature do not experience; and when once such liquors gain admission, they leave behind them traces of their course, which a colourless fluid does not. M. Kieser has altogether overlooked the facts observed by Grew and Du Hamel, of the actual existence of sap in these vessels, both in spring and in autumn; and he seems to be entirely unacquainted with the influence which the developement of the leaves, as we shall presently show, exerts on the movements of the vegetable fluids.

49. But it has been the fate of these vessels to experience the utmost licence of opinion in regard both to their structure and functions; nor does it seem probable, that these opinions will soon settle into anything like uniformity. While some have supposed the vegetable to be composed almost entirely of spiral vessels, others limit their presence to a few parts only; and others again altogether deny their existence. Some will have them to be solid fibres; others make them sap-vessels, or nutrient vessels; and others again suppose them to convey only air. Hedwig believed them to convey at the same time both nutrient matter and air; and Bonnet was of opinion that they were entitled to be considered not only as the lungs of the plant, but a sort of muscles also, by which many of its parts executed different movements. (*Recherches sur les Feuilles*, p. 138.) A late writer, however, and a Professor, it seems, of medicine in the university of Jena, M. Oken, is of opinion, that they ought not to be deemed either simple fibres, or vessels, or lungs, or muscles; but that they execute a function for the plant analogous to that of the *nerves* of animals; and ought therefore to be named the vegetable nerves. (*Kieser's Mém. sur l'Organisat. des Plantes*, p. 174.) The bare enunciation of such opinions must, we think, be sufficient to ensure their rejection.

Termination of the Vessels.

50. Rejecting these fanciful and extravagant notions, and adhering to the opinion that the spiral vessels are a variety only of the common sap-vessels of the plant, we shall conclude this branch of the subject with a brief notice of their common modes of *termination.* If we begin at the root, we may consider these vessels as terminating at that part, by continuation of canal, in the capillary *absorbents of the rootlet.* As, farther, the vessels of plants, like those of animals, are the only organs which convey the materials out of which, not only the fluid, but the solid parts of the plant are formed; it may, in a general sense, be said, that their modes of termination are as numerous as the kinds of distinct parts or organs which the vegetable system contains. Hence, therefore, as the cellular tissue of plants contains various matters often precisely similar to those which exist in the vessels, it may be inferred, that the vessels have a termination in those organs; and this inference may perhaps carry more weight with many than the attempts before related, of Malpighi and Leuwenhoeck, to demonstrate it

Elementary Organs.

anatomically. Another termination of these vessels must be in certain minute and ill-defined organs called *glands*, which separate from the mass of fluids peculiar secretions; and a fourth mode may, in the leaves, be in other vessels, which carry back the juices from those organs. The last and fifth mode of termination is into transpiring or exhalent organs, by which a certain portion of the contents of the vessels is discharged: So that in plants, the sap-vessels terminate externally at one extremity in absorbents, by which fluids are received; and at the other in exhalents, by which these fluids are discharged.

### Article VI.

#### *Of the Proper Vessels.*

51. By observation of the natural flow of the sap, combined with the results of experiments made with coloured liquors, we have endeavoured to determine the situation and kinds of vessels by which it is conveyed. The same method will best assist us in ascertaining the nature and place of those which have been called *Proper Vessels.* Of these also, many species have been described by authors, the existence and characters of which we shall afterwards attempt to ascertain.

Course of the Sap,

52. It was before stated, that, early in spring, the sap of plants rises through the wood alone, and that no fluid whatever is then to be found in the bark. At a later period, however, the case is completely reversed; for the vessels of the wood no longer appear to carry sap, and those of the bark then become abundantly supplied with it. This difference is very clearly and concisely stated by Grew. "The sap," says he, "in many plants, as the Vine, ascends visibly through the wood for a month, in March and April, and rises through every ring of wood to the very centre, yet, at the same time, there ariseth no sap at all out of the bark, nor between it and the wood." "But late in spring," he continues, "and in summer, the sap is no longer visible in the wood, but is abundant in the bark, in the inner margin adjacent to the wood." Du Hamel too remarks, that when the lymph rises abundantly through the wood in spring, the bark is dry, and adheres to the wood, and no sap then issues from it, nor from between it and the wood; but, later in the season, he adds, the bark yields abundance of sap. These statements have been verified by the multiplied observations of various subsequent authors.

modified by the developement of the Leaves;

53. But why is the sap thus present only in the wood at its first rising in spring? Why at a later period does it cease to be visible in that part? And how and why does it afterwards find a passage into the bark? Some observations of Du Hamel, Hales, and Walker, point, we think, to the true cause. In spring, says Du Hamel, when the sap rises vigorously, the buds have not appeared; when they begin to open, the sap then flows less freely; and when the leaves are fully developed, then the flow of sap entirely ceases. Dr Hales also remarks, that, towards the end of April, when the young shoots come forth, and the surface of the Vine is greatly increased by the expansion of the leaves, the sap then ceases to flow in a visible manner till the return of the next spring. All bleeding trees, he adds, cease to bleed, as soon as the young leaves begin to expand enough to perspire plentifully, and draw off the redundant sap. The bark of Oak, too, separates easily when lubricated with sap; but before the leaves appear and perspire, the bark will no longer run (as they term it), but adheres most firmly to the wood. (*Vegetable Statics*, 3d edit. p. 126.) In like manner, in an experiment of Dr Walker, a Birch-tree bled from every perforation in its trunk, and from every cut extremity of its branches, until vernation or budding began; then the bleeding was almost immediately checked, and when the young leaves had pushed beyond the *hybernaculum*, the bleeding entirely ceased. (*Edin. Phil. Trans.* Vol. I. p. 31.)

It is however certain, that though the sap was no longer visible in the wood after the leaves were developed, it continued nevertheless to rise through it; for in no other way could the leaves obtain the large portion of fluid which it is known that they constantly discharge by transpiration; and coloured fluids manifest their presence in the vessels of the wood, as well after as before the developement of those organs. The leaves, therefore, must be regarded as the organs which, by their perspiration, draw off, as Dr Hales observes, the redundant sap; and hence in an experiment, where a notch was cut two or three feet above the lower end of a stem, though a great quantity of sap passed by the notch, yet was it perfectly dry; because, says he, "the attraction of the perspiring leaves was greater than the force of trusion from the column of water." (*Veg. Statics*, p. 111.)

passes through the Leaves to the Bark.

54. Not only, however, does the developement of the leaves render the sap no longer visible in the wood, but they also appear to be the organs by or through which it finds its way to the bark. In all the experiments just recited, the bark continued dry until the sap disappeared from the wood; in other words, until it was drawn off by the leaves; and then, and not till then, the bark became moist, and continued laden with sap through the rest of the summer. Now, as it has been before shewn that no sap enters the bark by the roots, nor gets into it directly from the wood, there is no other known channel by which it can be conveyed, except through the leaves; and these, therefore, necessarily appear to be the organs by which it is apparently carried off from the wood, and by or through which it, at the same time, finds its way to the bark.

This inference appears to follow, not only from the fact of the bark continuing dry until the leaves are developed, but from the circumstance that it is again rendered dry, after having become moist, if these same leaves be removed. If, says Du Hamel, we remove the leaves of a young tree, when in full sap, and whose bark is easily detached, in a few days after the same bark will adhere as closely to the wood as it commonly does during winter. This direct connection between the leaves and bark, is also well illustrated in an experiment of Hales, employed by him for a very different purpose. From two thriving shoots of a Pear-tree, he cut, in several places, half an inch of the bark off all round. All the ringlets of bark between these incisions had a leaf-bud upon them except one, and all but this

Elementary Organs.

one ringlet grew and swelled at their bottoms till August; and the larger and more thriving the leaf-bud was, so much the more did the adjoining bark swell. (*Veg. Statics*, p. 149.) Mr Knight also found the bark of the Vine to become shrivelled and dry when the leaves were stripped off; but in those parts in which it communicated directly with the leaves, it continued moist and flourishing. (*Phil. Trans.* 1801, p. 335.)

55. By connecting, therefore, the circumstances attending the flow of sap with the developement of the leaves, we gain satisfactory reasons for all the apparent anomalies observed to attend its course. In spring, before the appearance of the leaves, no natural outlet for the escape of the rising sap exists, and therefore, when the vessels are cut or perforated, they readily pour out their sap, or bleed; but late in spring, and in summer, when the leaves are developed, the more watery parts of the sap are thrown off by transpiration; and, while this process proceeds, the fluids do not then accumulate in such quantity in the minute vessels of the trunk, as to be effused, or bleed through their cut or perforated sides. A cold day, however, or a moist and still atmosphere, by checking transpiration from the leaves, restores more or less the propensity to bleeding from the trunk; and in autumn, when fructification begins, and vegetation makes a pause, the same disposition to bleeding recurs in the trunk, from the check imposed on the more active powers of growth.

Qualities of Sap in the Bark,

56. It is farther evident, that, when the vessels of the bark become supplied with fluid, they could not have derived it immediately from those of the wood, since, in these different parts, the fluids have frequently no sort of agreement in properties. Thus, Grew remarks, that almost all plants, late in spring and in summer, bleed from their bark; and the sap has either a sour, sweet, hot, bitter, or other taste. At this period, the bark of the Vine yields a sour sap; but, "what is vulgarly called bleeding in the Vine, is," he adds, "quite another thing, both as to the liquor which issueth, and the place whence it issues—that is—it is neither a sweet nor a sour, but a tasteless sap, issuing, not from any vessels in the bark, but from the air-vessels of the wood." (*Anatomy of Plants*, p. 125.) Malpighi also was well aware of the difference in the qualities of the sap, and thought every plant possessed its peculiar sap; but he has not so accurately defined the situation of the vessels that contain it. Du Hamel, however, points out distinctly the difference of quality in the sap of the bark and wood. In the bark of some plants it is white; in others red; and in others yellow: It is in some instances milky; in others resinous; and in others gummy. In many plants it has a sweet taste; in some it is caustic; and in others insipid. It has sometimes much odour as well as flavour, and frequently it is destitute of both. (*Phys. des Arbres*, Tom. I. p. 68.)

acquired in the Leaves.

57. But, if the qualities of the sap in the bark be thus different from those of the sap in the wood; if these peculiar qualities are detected in it, only after the developement of the leaves, and the leaves be the organs by which alone the sap can be conveyed from the one part to the other—then it seems to follow, that the sap must acquire these new properties in the leaves, during its transmission through them. Malpighi remarked the existence of this altered sap in the leaves, and held them to be the organs which prepared nutrient matter for the plant; and Dr Darwin, by immersing plants of Spurge in coloured liquors, not only saw, as others had previously done, the red fluid ascend through the leaf; but another fluid, of a white colour, returning, at the same time, from the extremities of the leaf, and descending into the petiole. (*Botanic Garden*, Vol. I. Notes, p. 450—453.) This same returning fluid, Mr Knight observed, in similar experiments, on branches of the Apple and Horse-Chesnut trees, and even traced it through the petiole into the inner bark, by the vessels of which, it seemed to be conveyed to the extremities of the roots. (*Phil. Trans.* 1801.) The motion, therefore, of the sap in the bark, is not that of *ascent*, as Grew and Malpighi and many others have believed; but of *descent*, as the observations and experiments of De la Baisse, Du Hamel, Knight, and others, abundantly prove. To these vessels of the bark, Grew assigned particular names, according to the apparent quality of the fluid they conveyed. Malpighi gave them the general appellation of *vasa peculiaria*, from their containing a fluid different from the common sap. By others they have been called *cortical vessels*, a term, however, not applicable to many tribes of vegetables which are entirely destitute of bark. Lastly, Du Hamel and others denominated them *proper vessels*, which term differs but slightly from the appellation of Malpighi, and, though not very precise, is that we shall continue to employ.*

58. From regarding the newly formed vessels of

* The view thus presented of the course of the sap, and the modifications which its movements and qualities experience from the developement of the leaves, may assist in the determination of the important and long-agitated question regarding the proper period of *felling* timber, as it relates both to the bark and wood. The most proper period for the timber, is doubtless that in which it is most dry or destitute of sap; and the properest period for the bark, both as regards its chemical condition, and the facility of stripping it, is, when it is most succulent, and filled with its "proper juices." But these respective periods and conditions do not happen to coincide, and therefore, the time at which the wood is in best condition, is that in which the bark is in its worst; and *vice versa*. If, therefore, the qualities of the bark dictate the period of felling, it will be late in spring or in autumn, when it is most abundantly filled with its proper juices, and of course, when the wood also is necessarily filled with fluid, and in an active state of vegetation; if, on the other hand, the condition of the wood regulate the period, then it will be late in winter, or before the sap rises in spring, when the wood is destitute of sap, and the bark, of course, is necessarily dry and adherent. To reconcile these opposing conditions, it seems desirable, as far as it may be practicable, to strip the

Elementary Organs.

Description of the Proper Vessels;

the wood as part of the bark, Grew uniformly represents the bark as possessing two distinct species of vessels, in which he has been since followed by several other writers; but the vessels which he calls *lymphæducts*, belong rather to the wood, so that we may regard him as describing only one species of *proper vessels*. In herbs, these vessels stand sometimes in distinct parcels or columns; sometimes they are disposed in a ring; sometimes they have a radiated position; and sometimes they are more intermixed with the sap-vessels, and seem to alternate with them. In trees, the vessels of the bark are more distinct, and have a much more regular appearance. They are commonly postured near the inner margin of the bark, and, when viewed in a longitudinal direction, seem collected into fasciculi which are more or less numerous, and the component vessels of which continually diverge and join with others, so as to form a reticulated appearance; as in fig. 18. Plate XV. Of these reticulated fasciculi, many layers exist in an old tree; and to these layers the thickness of the bark is chiefly owing. As they proceed inward, the direction of the fasciculi is less oblique, so that near to the wood they are almost straight: Hence, the spaces formed by the reticulations are very unequal, often large in the exterior part of the bark, and diminishing in size towards the wood; they are everywhere filled with cellular tissue. Such is a general description of the *proper vessels* of the bark as given by Grew, Malpighi, and Du Hamel. The organs here described, we regard as truly vessels; but some writers have also described, as vessels, various collections of the proper juices which occur in different parts of the cellular tissue of the bark, and have thus lost sight altogether of the anatomical characters which distinguish vessels from cells.

their Structure;

59. The vessels which thus form the vascular portion of the bark appear to differ but little in structure from the more simple vessels of the wood. Grew considered them to possess a similar structure, from believing them to be formed by the inner bark, at the same time with the vessels of the wood; and, therefore, he adds, "they may be reasonably thought similar in the bark and wood." (*Anat. of Plants*, p. 112.) Malpighi regarded them as simple tubes, containing sometimes peculiar juices, but advances nothing particular respecting their structure. (*Anat. Plantar.* p. 3.) M. Mirbel's opinion deserves some notice, inasmuch as he declares the structure of these vessels to differ entirely from all those of the wood. Their sides, says he, are perfectly entire; they have neither pores nor clefts, and may therefore be deemed simple tubes. (*Exposit. de la Théorie de l'Organisat. Végét.* p. 109). A single vessel of this kind is represented in Plate XV. fig. 16.; and in fig. 17. a fasciculus of the same vessels magnified, is given, as delineated by M. Mirbel. A remark also of Hill, if it be deemed to rest on correct observation, is entitled to great attention. "The vessels of the bark that form the fasciculi are not," says he, "united to each other, but are connected with the cellular tissue at numerous places, and, when separated from it, there appear on the sides of the vessels small oval depressions, dotted as it were with pinholes." (*On the Construction of Timber*, p. 28.) These appearances he regards as of a glandular nature, but their description corresponds better with that of Leuwenhoeck respecting the lateral ramifications from the vessels of the wood; and they may probably be the points at which communication is effected betwixt the vessels and cells.

their Reticulation;

60. The cause of the reticulated appearance which the vessels of the bark exhibit in trees, is doubtless to be attributed, as we think Du Hamel somewhere remarks, to their peculiar mode of growth. A new layer of cortical vessels is every year added to the inner surface of the bark, as well as a new layer of ligneous vessels to the outer surface of the wood; so that, as Grew observes, the new matter of the tree is every year distributed two contrary ways; one part falling outward towards the bark, and the other part retaining its situation inward to constitute the wood. At first, the newly formed cortical vessels are straight, and stand parallel, like those of the wood; but, by the continual growth of the new parts, formed between the bark and the wood, the older vessels of the bark are gradually forced outward, and being thus every year disposed around a larger cylinder, are necessarily more and more separated from each other, and produce at length that net-like form which we observe them to possess. The newly formed vessels of the wood, on the other hand, retain their original position, and, therefore, preserve their parallelium, seldom or never exhibiting those flexures and reticulations so common to the vessels of the bark.

their Size;

61. In the bark, as well as in the wood, the vessels are found to possess different sizes. In the Pine, vessels containing turpentine are represented by Grew, which are very much larger than the common sap-vessels, and are surrounded by smaller ones, exactly as the large spiral tubes of the wood are said to be ensheathed by the common sap-vessels. The milky juice of a species of Sumach is contained in very large vessels, disposed so as to form a ring, and each large vessel is surrounded by many smaller ones. (*Anat. of Plants*, Tab. 20.) The appearance of these large vessels in one species of Pine, is well represented by Hill, and the account he gives of their formation is probably correct. In this tree (*Pinus orientalis*), some of these vessels form oval openings, large enough to admit a straw; these openings occupy the centre of the bark, and are surrounded by a ring of smaller vessels; as their contents are soluble in alcohol, it is easy to obtain them empty. In fig. 19. Plate XV. the vessels of this tree, as they appear in the bark, are displayed; the woody portion of the tree has been scooped away, so that the longitudinal aspect, as well as the transverse sections of them, is exhibited. From a strict inquiry into

---

tree of its bark while standing, in autumn, at or a little before the period of fructification, when the bark must possess its richest qualities, and be in the best condition to separate; and to fell the tree late in winter, when the wood is destitute of sap, and its vegetative powers are most completely suspended.

Elementary Organs.

their nature, Dr Hill concluded that these larger vessels were originally the same as those of the smaller fasciculi in the bark of the same tree; "so that, if we conceive one of these smaller fasciculi opened in its centre, and the vessels driven every way outward, till they are stopped by the substance of the bark, we shall have an idea of the structure of this large vessel, which is nothing more than a great cylindrical hollow formed in the centre of such a fasciculus." (*Hill on the Construction of Timber*, p. 29.) It is in trees that have copious and viscid juices, that these enlarged vessels are formed; and where the juices do not concrete, it is probable, that, as the vessels annually recede from the centre, they suffer a reduction in size, from the continued effects of desiccation and compression to which they are exposed.

their Position.

62. The foregoing varieties appear alone entitled to the appellation of the *proper vessels* of the bark. In many tribes of vegetables, however, as will afterwards be shown, no distinction of bark and wood exists; but one uniform distribution of vessels extends from the centre to the circumference of the plant. Such plants have also their *proper vessels*, but the place and disposition of these vessels are not so precisely ascertained. From the mode in which their growth is accomplished, as well as from observation of their structure, it may be inferred, that their *proper vessels* are distributed through the whole substance of the plant, accompanying, in every part, the sap-vessels. In some plants, possessing this arrangement of parts, such as different species of wheat, Malpighi describes and delineates a *vas proprium* as forming a part of each fasciculus of vessels; and a similar intermixture of the two kinds must, we conceive, exist in all similar structures.

63. Even in many plants, possessing a distinct bark, vessels containing proper juices are found in the wood. In every circle of wood, from the inmost that surrounds the pith, to the outmost in contact with the bark, vessels containing a gum, turpentine, or some other concrete or coloured juice, may frequently be found. Malpighi conceived them to exist in all plants, though, from the nature of their fluids, they could not always be distinguished; and he believed them to afford a highly perfect juice for the nutrition of the plant. According to Grew, "the turpentine vessels that are scattered up and down the wood of the Pine and Fir are the self same which did once appertain to the bark; but being pinched up by the wood, they are become much smaller pipes." (*Anat. of Plants*, p. 115.) Du Hamel also regarded them as similar to those of the bark, but rendered much smaller by compression. In the Pine and Fir, they are disposed circularly around the axis, much like the sap-vessels, and alternate with them. (*Phys. des Arbres*, Tom. I. p. 41.)

In *Piscidia erythrina*, the proper juices are of a scarlet colour, and the vessels that contain them are therefore readily discerned wherever they exist. This plant has been selected by Hill to demonstrate the position of these vessels. In the bark, they are collected into fasciculi, all the vessels of which contain coloured juices, and are disposed in a ring on the inner margin of the bark. Within this ring stands the alburnum, through the substance of which many smaller red vessels are distributed, and similar red vessels are more sparingly seen in every layer of wood, particularly in that which envelopes the pith. (*Constr. of Timber.*)

Elementary Organs.

64. Now, the red vessels thus observed in the wood of the above mentioned plant, must either have been formed in the situations they occupy, or transported from some other place. The latter supposition is inadmissible, inasmuch as the wood of trees is formed by layers of new vessels superimposed on one another; and no removal of the old vessels, nor reproduction of new vessels within the old layers, ever takes place; consequently, no actual transposition of vessels could occur; nor could new vessels be developed in the wood after it had been completely formed. If, however, an alternate deposition and absorption of matter go on into, and from the cells, it is possible that the vessels might, in this way, become filled with a matter different from that which they originally possessed; but in the case before us, a readier explanation presents itself. The new matter of the wood is formed at the same time, and in the same place, as that of the bark; and through this new woody matter the red vessels were dispersed as well as in the bark. Consequently, every addition made to the ligneous layers would furnish some vessels that contained these proper juices; and this being annually repeated, would exhibit that intermixture of proper vessels with sap-vessels, which is observed in all the ligneous layers of this and many other trees. Hence these *proper vessels* of the wood must be held to retain the position in which they were originally produced; and cannot be said to have approached nearer to the centre, but only, by the addition of new layers exterior to them, to be placed farther from the circumference of the tree. As Grew, therefore, held the alburnum to be a part of the bark, he might correctly say that these vessels "did once appertain to it."

### Article VII.

*Of Collections of the Proper Juices in the Cellular Tissue.*

In single Cells.

65. Beside this accumulation of the proper juices in certain vessels of the wood, it frequently happens that depositions of similar matter occur in all parts of the cellular tissue of plants. In the bark of the Oak and Poplar, and of other trees, resinous concretions are often found in the cells; they are situated irregularly, and, according to Malpighi, are observed even in very young bark. Sometimes the cells containing milky and resinous juices are so postured in the bark, says Grew, as to form cylindrical channels, which are neither parallel nor anywhere inosculated, but run, with some little obliquities, distinct from one another. They appear to be formed out of the cells, and are not bounded by any walls or sides proper to themselves, but only by those of the cells. (*Anat. of Plants*, p. 112.) They are often short and tortuous, always isolated, and are sometimes placed irregularly; at others, disposed in a circular form. They occur sometimes in the pith, and possess very different sizes and figures. They have fre-

Elementary Organs.

quently been deemed a species of *proper vessels*, from the mere circumstance of their containing similar juices, and from possessing sometimes an elongated form; but they are organs which, neither in form nor in function, bear any resemblance to vessels. Mirbel proposes to name them *secretory canals*, and M. Link *cellular reservoirs*; the term certainly most generally applicable, and involving no hypothesis respecting either their formation or functions.

In Cellular Reservoirs.

66. The manner in which these cellular reservoirs may be produced in the bark or pith, is readily explained, on the supposition that a communication everywhere subsists between vessels and the cells. One set of vessels has been shown to receive and carry out sap to the leaves, and another to bring it back from them to the bark; and these latter vessels are everywhere, in their course, surrounded by cellular tissue. Hence the cells, in every part, may receive a portion of the fluid which the vessels are employed to convey. Thus in herbs, the cells both of the bark and pith are filled with fluid, which led Grew to believe that the sap was actually transmitted through those organs; but at the same time he delivers facts which, even in his own opinion, prove that it is derived directly from the vessels. Not only in herbs, but "in every annual growth, whether of a sprout from a seed, of a sucker from a root, or of a scyon from a branch, the pith is always found the first year full of sap; but in the second year, the same individual pith always becomes dry, and so it continues ever after. One cause whereof is, that the lymphæducts of the bark being, the first year, adjacent to the pith, they do all that time transfuse part of their sap into it, and so keep it always succulent. But the same lymphæducts, the following year, are turned into wood, and the vessels which are then generated and carry the sap, stand beyond them in the bark; so that the sap, being now more remote from the pith, and intercepted by the new wood, cannot be transfused with that sufficient force and plenty as before, into the pith; which, therefore, from the first year, always continues dry." (*Anat. of Plants*, p. 124.)

All that is here said respecting the transfusion of the common sap from the vessels to the cells, as it ascends through the wood, is equally applicable to the *proper juices* as they descend through the bark. During the first year of growth, both the sap and proper vessels are adjacent to the pith, as well as to the bark, and each order may therefore transfuse its fluids into the cells of either. The common sap, from retaining its fluidity, is frequently removed by absorption, and the cells that contained it appear empty and dry; but where the proper juices are transfused, and become viscid or concrete, they are retained, and appear in different quantities and forms both in the bark and pith, according to the nature and properties of the juices from which they are derived, and the texture and situation of the tissue into which they are poured.

In Intercellular Canals.

67. To these collections of the *proper juices* in the cells of the cellular tissue may be referred the opinions of those who describe them as existing sometimes in vacuities betwixt the cells. M. Treviranus professes to have discovered certain interstices between the cells, formed in a mode hereafter to be explained, to which he has given the name of *intercellular canals*. According to him, these canals contain the proper juices, and convey them to all the cellular parts of plants; and are the true *proper vessels* of the bark. We before saw that M. Kieser, after making the wood to consist almost entirely of spiral vessels, and then converting these vessels into tubes destined only to convey air, supposed the sap to be carried by these same intercellular canals. (*Kieser's Mém. sur l'Organisat. des Plantes*, p. 36.) With M. Treviranus he also considers them as the real *proper vessels* of the bark, by which alone the juices are conveyed to all parts of the cellular tissue. (*Ibid.* p. 216.) If such canals really exist betwixt the cells, it is probable, that, like the cells themselves, they may sometimes become reservoirs of the *proper juices*; but simply on that account, to pronounce them vessels, is, in an anatomical sense, exceedingly incorrect; and to make them afterwards supersede the existence of the real vessels themselves, seems nothing less than downright extravagance and absurdity. Were there any truth in such statements, we might at once banish from the organization of plants all the varieties of vessels, whose situation, structure, and characters we have been labouring to describe and define. But the opinions of these writers have not at all shaken our faith in the facts observed by their predecessors; and as long as the vegetable functions shall continue to be exercised as they have hithero been, so long, we believe, will a vascular system, such nearly as we have attempted to demonstrate, be employed as the chief instrument in their execution.

## Section II.

### *Of the Absorbent and Exhalent Systems.*

#### Article I.

#### *Of the Absorbent System.*

68. Connected with the vessels that distribute the fluids through organized bodies, is another system of vessels by which extraneous matter is taken up to support the growth of parts, and supply the waste occasioned by the exercise of the various functions. To these vessels Anatomists have given the name of *Absorbents*. The function which they perform is carried on either from the external surface, or from some internal part of the body: and its exercise, in animal bodies, may be distinguished into three kinds or stages. The first is that in which new or extraneous matter is taken up and added to the system, as in the absorption of substances from the skin, or of chyle from the intestines: the second is that in which substances previously separated from the fluids by secretion, but without becoming organized, are again taken up by the absorbents, and reconveyed into the blood-vessels, as in the absorption of milk, bile, and fat: the third kind is that in which the secreting organs themselves, and successively all the solid parts of the body, are removed by the action of the absorbent vessels. By plants, this function is exercised to less extent, and seems to comprise only the two first kinds or degrees of it, viz. the primary absorption of extraneous matter, and the reabsorption of certain

Elementary Organs.

Absorbent Function in Plants,

secreted matters; but in them there does not appear any power of reabsorbing what has once formed an organized part of the system. Hence the formation of organized parts in plants is not accompanied, as in animals, by the unceasing removal of old particles: but the particles, which have once become organized, continue permanent, until removed by some cause or process foreign to the living powers of the plant. When once, therefore, the organs of plants have become mature, they are exposed to decay only from the operation of foreign causes, and cannot be mined from within by that gradual loss of balance between the secreting and absorbing functions, which the advances of age bring on the animal system. Neither in the vegetable system can the removal of organized parts under disease, any more than in health, have place; and consequently, the several modes or stages of ulcerative absorption, so finely illustrated by the researches of Mr Hunter, belong not to the economy of plants.

...s very ...imple.

69. As the function of absorption is thus of more limited extent in plants than in animals, so may we expect to find the arrangement of organs destined to its exercise. In animals, the absorbent vessels are quite distinct from those which carry blood, are provided everywhere with glands, and, like the veins, are furnished with valves. From their beginnings, in all parts of the body, to their termination, they continually unite with one another into vessels successively increasing in size, until, after a long course, they form at length two trunks, which deliver their contents into the large veins near the heart. As no common reservoir exists in plants, there is no such single point to which their absorbed fluids require to be carried. Hence their absorbents seem everywhere to have a very short course, to form no union with one another, but to deliver their contents at once into the sap-vessels adjacent to them. They appear to be destitute alike of glands and valves, and indeed, in an anatomical view, they can scarcely be considered distinct from the sap-vessels, but may rather be deemed ramifications from them; so that although we grant, with Grew, that the ordinary sap-vessels do not ramify one out of another, yet they certainly send off those fine ramifications which, from their office, we denominate the absorbents of plants.

...sorbents ...he Root;

70. In the root, the absorbents are capable of being demonstrated: when a plant is immersed in coloured fluids, many of its capillary absorbents become tinged through their whole course to their termination in the sap-vessels, proving them to be simple ramifications from these vessels themselves. A farther proof of the identity of these two systems is derived from the fact, that any part of a sap-vessel is not only capable of emitting capillary absorbents from its sides, but of exercising itself an absorbent function, whenever its cut extremity is brought into contact with a fluid. These absorbents are formed very speedily, and in great multitudes on the roots of annual plants; and even in perennial plants, they appear, like the leaves, to suffer an annual decay, and be reproduced with the return of vegetation.

...in Leaves.

71. But plants absorb fluids by other parts of their surface as well as by the roots. This absorbing power extends, in some of the lower tribes, over the entire surface of the vegetable, which is destitute of any organ analogous to a root; in other instances, where the roots are small and the soil arid, the plant derives almost all its moisture by the absorption of dews through the leaves. The experiments of Bonnet show that all leaves, both those of herbs and of trees, when brought into contact with water, are capable of absorbing it, and that the moisture thus absorbed is communicated through the vascular system of the leaf. The leaves of herbs he found to absorb nearly alike from either surface; but those of trees absorbed best by the lower surface. The petiole and larger riblets appeared to absorb much less than the other parts of the leaf. So great and general is this absorbing power, that vegetables, says he, may be said to be planted in the air, nearly as they are in the earth, the leaves being to the branches what the capillary rootlets are to the roots. (*Recherches sur l'Usage des Feuilles*, p. 22, 47.)

External Absorption by Pores.

72. What then are the organs by which this function is carried on in the leaf? M. Bonnet imagined the vessels of the leaves to receive their fluids through the pores adjacent to them; and that the leaves, which had only few pores, possessed but little absorbent power. (*Ibid.* p. 20, 22.) He thought, also, that the hairs frequently distributed over the leaf, attracted moisture, and might even act as absorbents; though he admits that many leaves which have only slight inequalities on their surface, without hairs, exercise an absorbent function. (*Ibid.* p. 47.)

This subject has been since investigated by M. Decandolle, whose researches appear to confirm the account of Bonnet, as to the absorbing power of the pores. According to him, these pores are found on all parts of the leaf except the riblets, which have none, but are covered with hairs. At the mouth of the pore, a vascular net-work is always to be found, which he regards as a production from the larger vessels of the leaf. He asserts that pores are found only in those parts where vessels go to terminate, and not in others; and that in trees, this structure occurs chiefly on the lower surface of the leaf, while in herbs it is equally seen on both surfaces. The stem, in general, has few or no pores, except where it is soft and herbaceous; and even then, the pores occur only in the deeper green furrows, not on the prominent lines which bound them, and are usually covered with hairs. No pores are to be found on roots or bulbs or fleshy fruits, but most of the organs above ground are more or less furnished with them. Exposure to the air seems necessary to their formation; for plants, or parts of plants, that live beneath water or earth, are destitute of pores, but acquire them if brought into the free air. Exclusion of light prevents also the formation of pores; and hence etiolated plants are not furnished with them. (*Mém. de l'Instit. Nat.* Tom. I. p. 351.) In general, his anatomical researches, respecting the existence of pores in leaves, agreed with the results of Bonnet's experiments on the absorbing power of their surfaces; and when we consider that all plants, and parts of plants, secluded from the air, are at the same time destitute of pores, and of the power of absorbing by their surfaces, it may be inferred that the organs of absorption, on the external surfaces of

Elementary Organs.

plants, are the minute vascular productions, which in tender and succulent parts exposed to the air and light, everywhere perforate the cuticle, and form in it those innumerable orifices which we denominate pores.

Internal Absorption,

73. But the function of absorption in plants, is not confined to the taking up of extraneous matters. Many facts prove that, in every part where active vegetation exists, *internal absorption* is continually going on. The organs by which it is immediately performed cannot, perhaps, from their extreme delicacy and minuteness, be rendered capable of anatomical demonstration; but certain facts which occur in plants, coupled with certain analogies derived from other organized textures, must, we think, carry complete conviction of their existence. In almost every part, and on every surface of animal bodies, the vessels which exercise absorption may be traced; but the mouths or orifices by which they actually absorb, are scarcely ever to be seen. In one instance only, viz. in the intestines, have they been followed to their beginnings, and discovered in the act of exercising their appropriate function. (*Gordon's System of Human Anat.* Vol. I. p. 70.) But though their orifices remain, in other parts, undiscovered, no anatomist hesitates to admit their existence when he sees the canals of the vessels themselves laden with blood, or milk, or bile; and seeing them thus to convey fluids, whose colour manifests their presence, he equally believes them capable of absorbing and conveying other substances, though they may not be visible to the eye. Believing farther, that no solid part of the body, nor even fluid part that has been deposited in closed cavities, can be removed in a natural manner from its place, but by the agency of these vessels, he comes to regard the simple fact of the disappearance of such part, as sufficient evidence of its absorption.

in Seeds;

74. Now the facts and analogies on which internal absorption rests in the vegetable system, are precisely of the same nature, and the evidence of its existence is scarcely less complete. In every part of the cellular tissue of plants, various substances have been found, which must have been primarily derived from the vessels, the only organs which furnish new materials to the plant. These substances, however, often disappear from the cells, and are again to be detected in the vascular system. Thus, in the seed, as will afterwards be shown, the cells of the cotyledon contain a solid unorganized matter, which could have been originally deposited in them only by means of the vessels. During germination, this solid matter is rendered fluid, disappears from the cells, and is again to be traced in the vessels on its way to afford nutriment to the radicle and plume. We say then that this unorganized matter must have been taken up from the cells of the cotyledon, and conveyed into the vascular system, by the agency of absorbent vessels, which, it is probable, are distributed everywhere on the inner surface of these cells; just as, in the animal system, absorbent vessels are considered to take up the fat from the surface of the cells in which it is deposited, and convey it into the vessels of the animal.

in Bulbs;

75. This alternate absorption and deposition of the nutrient matter of seeds, is sometimes strikingly displayed in the growth of potatoes. It frequently happens that potatoes, lying in a damp cellar, put forth shoots which grow to a considerable size without the access of any foreign agents, except heat, water, and air. On these shoots, young potatoes, as large as the eggs of pigeons, are sometimes to be found, and the substance of the old potatoe has in great part disappeared. In such cases, the matter from the cells of the old potatoe, must be considered as removed by absorption, and conveyed into the vessels of the shoot, where it was in part employed in forming the new organs of the young potatoe, and in part deposited, to experience, perhaps, in some future growth, similar successions of removal and deposition. In the living parts of perennial plants also, nutrient matter appears to be alternately deposited and absorbed from the cells during the active periods of vegetation; and in the cellular tissue of herbaceous plants, a similar deposition and absorption of fluids seems to be frequently taking place; so that in all the vegetating parts of plants, these alternate functions of secretion and absorption are more or less constantly exercised.

76. A good illustration of the manner in which these functions are alternately exercised, is afforded by an experiment of M. Decandolle. The parasitic plant called Misletoe draws its nourishment, as is well known, from the tree on which it grows. M. Decandolle placed a branch of an Apple-tree, bearing a stalk of misletoe, in an infusion of cochineal for five days. He then dissected it, and observed the coloured liquor to have risen through the wood and alburnum of the apple-branch, and reached the place of junction between it and the misletoe, which it strongly reddened; and from thence it penetrated into the woody part of the misletoe. There did not, however, appear to be a true anastomosis between the vessels of these different plants; but, at the base of the misletoe, where the parts were so deeply reddened, a minute cellular structure was observed. Into these cells the vascular system of the apple appeared to deposit its sap, and from them the capillary absorbents of the misletoe, distributed upon the cells, seemed, like the ordinary absorbents of roots, to take it up. (*Mém. de l'Instit. Nat.* Tom. I. p. 370.) From these and many similar facts it may be inferred, that absorbents, communicating with the vessels of the plant, exist in every part, and that the removal of all secreted matters from the cells and other closed cavities of the vegetable, when effected by the living powers of the plant, is accomplished, as in animal bodies, by the exercise of an absorbent function. in Trunks.

### Article II.

#### *Of the Exhalent System.*

Organs of Exhalation,

77. But from their external surface, and from the same parts as we have seen to exercise an *absorbent* function, plants, in certain circumstances, give off a large quantity of fluid by *transpiration;* and the organs by which this function is performed, seem, from many considerations, to be the same as those by which, under other circumstances, absorption is accomplish-

Elementary Organs.

ed. This function of transpiration is common to all terrestrial plants, and all are more or less furnished with pores; but it does not occur in aquatic plants, according to Decandolle, which are destitute of pores. Fleshy plants and the petals of flowers, which have but few pores, transpire little, and etiolated plants, which are destitute of pores, do not transpire at all. On the contrary, herbaceous stems and plants, which have numerous pores, throw off most fluid by transpiration. This general agreement between the existence of pores, and the exercise of the transpiratory function, leads to the presumption that they are the orifices through which the fluids are discharged; and if it be admitted that these pores are situated at the extremity of the fine ramifications that come off from the vessels, their fitness for such an office cannot be denied. Comparing these facts, regarding transpiration, with those previously stated concerning absorption, M. Decandolle is led to conclude that the pores on the surfaces of plants are the organs by which these functions are alternately carried on, according to the existing condition of dryness or humidity in the surrounding atmosphere.

...e same as ...ose of ...bsorption.

78. Repulsive as this conclusion may at first seem to our ordinary conceptions of organized bodies, yet there are many circumstances in the structure and habits of plants that give to it great probability; so much so, that we ourselves had long since reached the same point by a route different from that pursued by M. Decandolle. It is highly probable, that the exhalents of the leaves are simple ramifications from the larger vessels, like the capillary rootlets; and as they have no valves in their canal, there is no mechanical impediment to their exercising an inverted action. The sap-vessels themselves readily absorb, even coloured fluids, when inverted; and though their exhalent terminations are too fine to receive such fluids, yet why may they not, like the trunks from which they spring, be capable of taking up ordinary fluids in that manner? The fluids absorbed through the leaves must at once enter the sap-vessels, for there is no common reservoir to which they can first be carried; and it is extremely improbable, that, from the same parts of the same vessels, exhalents and absorbents, capable of exercising only opposite functions, should at the same time arise. In the animal system, the exhalents spring from arteries, and the absorbents terminate in veins; but in the less complex structure of plants, it seems demonstrable, that both orders of vessels must at once communicate with the same sap-vessels. It is, therefore, more probable to suppose, that, instead of two distinct orders of vessels, as in animals, one only should be provided, capable, under different circumstances, of exercising different functions. This vicarious office of the organs, under consideration, leads to no confusion in its exercise; for the condition of the atmosphere, which favours transpiration, is that which removes from the leaves the power of absorption; and, on the contrary, absorption occurs only in a humid atmosphere, when, as Hales has shown, little or no transpiration takes place.

I...rnal S...creting

79. The view thus presented of the *external* absorbent and exhalent vessels, may probably be extended to the minute vascular productions which seem everywhere to spring from the vessels *internally*. If secreting and absorbing vessels be held to exist in every part of the plant, they must everywhere communicate with the vascular system; for it is from the vessels of this system that the matter of their secretions is primarily derived, and it is into the same vessels, that, in many cases, these secretions are subsequently returned. Nor does the exercise of the two functions of secretion and absorption in plants present any apparent obstacle to the supposition of their being performed, at different times, by the same organs. Thus, when nutrient matter is deposited in the cellular tissue of the seed, it is destined only for a future use, and the purpose of nature would be defeated, were an absorbent function to be, at the same time, employed for its removal. On the other hand, when this matter is again taken up, during the germination of the seed, no secreting function seems then to be exercised in that part; for the organ itself, in many seeds, gradually wastes, and no fresh matter is deposited in it. Even when the cotyledon, to a certain extent, augments in size, its nutrient matter is continually drawn off for the support of the radicle and plume, and no fresh matter of the same kind seems to be then deposited; so that the same vessels, which formerly exercised the function of secretion, may, without disturbing the economy of the plant, be now employed in the exercise of absorption. As thus the two functions do not require to be performed, in the same part, at the same time, they may, if nothing else forbid, be exercised at different times by the same organs. In the animal system, where the organs themselves are removed, secreting and absorbing vessels must necessarily co-exist; and to maintain the integrity of parts, their functions must proceed at the same time, and, to a certain extent, balance each other; but, as no similar operations appear to be carried on in the vegetable system, no such complex organization is required to sustain them.

Elementary Organs. and Absorbing Organs.

## Section III.

### *Of the Cellular Tissue.*

#### Article I.

#### *General Description and Character of the Cells.*

Definition.

80. The elementary organ, denominated *cellular tissue*, may be said to consist of a membranous substance, disposed into a great number of small circumscribed cavities, connected with each other, and arranged in rows or suites, generally in a direction that cuts at right angles, the perpendicular tubes which represent the vascular system. From Grew, it received the appellation of *parenchyme*, a term still often used in describing different parts of this tissue; by Malpighi, it was called the *utricular substance*; and it owes, we believe, its present name to M. Du Hamel.

Description.

81. The cavities which distinguish its construction were called indifferently bags or bladders, pores and cells, by Grew; by Malpighi, utricles; by others,

Elementary Organs.

vesicles; and more commonly cells. The form of these cells varies so much, not only in different plants, but in different parts of the same plant, as to have authorized, in some degree, these different appellations. The tissue which they constitute, enters into the composition of every organ in the more perfect plants. Of many herbaceous plants it forms the chief portion, and some of the lower tribes of vegetables are said to be wholly composed of it; in other words, no vessels can be actually demonstrated in them. In most cases, it contributes greatly to modify the form of organs, and adds always to their bulk and strength. Nothing can exceed the diversity of appearance in figure, bulk, and texture, which it exhibits in the several parts, circumstances, and conditions in which it is placed. It represents sometimes a lax cellular substance, all the parts of which are succulent and transparent; in other instances, it is compressed into a solid opaque body, retaining but faint traces of its former cellularity; and in others again it is spread out into a most thin and delicate membrane, in which the cellular character is wholly lost. It everywhere envelopes and holds together the vascular system, and seems to be the general receptacle of almost all the vegetable secretions.

Figure of the Cells;

82. The figure of the component cells of this tissue is exceedingly various. Sometimes they have nearly a globular or spheroidal shape; in other instances, they are angular, and exhibit, in their section, a greater or lesser number of sides and angles, being in a few examples triangular; in others, square, but more commonly hexagonal; the figure which collections of soft cells, mutually impressing each other, seem naturally disposed to assume. This form is represented in the transverse section of cells, fig. 20. A. Plate XV.; they seem, in this figure, and in most of those given in different works, to possess double sides; but as M. Kieser has remarked (*Mém. sur l'Organisat. des Plantes*, p. 91.), this appearance is produced by the borders of the subjacent cells being seen through the transparent sides of the superior layer. In Plate XVI. fig. 22. is a representation of a transverse slice of the cellular part of Sugar-cane, drawn from nature, and so thin as to exhibit only one layer of cells, in which the sides appear distinctly single; but, in a thicker slice of the same plant, fig. 23. comprehending more than one layer, the double appearance becomes very evident.

their Size;

83. The size of the cells varies not less than their figure in different plants, and in different parts of the same plant. In one of the plates of Grew, they are represented as possessing twenty different sizes, from that of a minute pore, to the size of a common pea. Hooke examined them in Cork, and in the pith of many plants. In Cork, he reckoned several lines of these cells, or pores, as he calls them, and found there were about sixty placed endwise in one-eighteenth part of an inch, or somewhat more than a thousand in the length of an inch; and, therefore, in a square inch above a million, and in a cubic inch above 1200 millions. (*Micrographia*, p. 114.) In this substance, the cells are not visible by the naked eye, but become very distinct when highly magnified. In most plants, however, they are readily visible, and their appearance is familiar to every one.

84. When viewed in a longitudinal section, their hexagonal form is much less distinct, and is sometimes wholly lost. In fig. 24. Plate XVI. is a series of single columns of the cells of sugar-cane, in which each cell is, to appearance, bounded only by four sides. Similar representations are given by Hooke of the cells in Cork, and by Kieser, in most of the figures which exhibit longitudinal sections of the cellular tissue; but, in some instances, the hexagonal form is visible even in these sections. In fig. 25. of the same plate, we have given, in outline, the appearance of two series of columns of these transparent cells, in which one series is seen behind the other, and gives somewhat of the confused double appearance exhibited in the transverse section, fig. 23.

Contents;

85. The nature of the matter contained in the cells of this tissue, varies according to the part in which it exists, and the peculiar powers of the plant. Both Hooke and Grew remarked, that, in the pith and bark of succulent plants, the cells were often filled with aqueous juices, and in the same plants, at other periods, they appeared empty, or filled only with air. In the seed, the cells of the cotyledons contain minute unorganized particles which, at a future period, serve as nutriment for the young plantule. Other particles of still smaller size, of a resinous nature, and a green colour, exist in other parts of this tissue, and bestow on the plant its verdure. In every part of the plant, these cells are also the occasional receptacles of the peculiar fluids which both the sap-vessels and the proper vessels convey; and hence various gummy and resinous substances, corresponding in quality to the fluids previously existing in the vascular system, are frequently detected in them. In the pulp of fruits, the various acid, saccharine, and austere juices that we meet with, are contained in different modifications of this tissue; and it is into its cells that the osseous secretions, which constitute their shells and stones, are made. These facts prove not only the great importance of this tissue in the construction of the vegetable organs, but the active share it bears in the economy of their functions, and demonstrate likewise an universal communication betwixt the vessels and the cells.

Structure;

86. The sides of these cells, when emptied of their contents, and viewed through the microscope, appear to be formed by a very fine transparent membrane, which some maintain to be everywhere entire, and others to be perforated with pores. The same sources of error exist here as before noticed in similar microscopical observations on the vascular system; and, accordingly, the respective disputants maintain, with equal confidence, the same opinions with regard to the porosity or non-porosity of the cells, as they had previously held concerning the vessels. We must therefore call in the aid of other means besides those of the microscope, for determining the important fact, whether the cells have or have not any direct communication with each other.

are close Cavities.

87. Dr Hooke examined the films or sides of the cells of Cork, of the pith of Elder, and of many other plants, with the very purpose of discovering

6

Elementary Organs.

whether any direct communication existed between them; but "each cavern or cell," says he, "is distinctly separate from the rest, without any kind of hole in the encompassing films;" nor could he, with his microscope, nor by his breath, nor by any other way that he tried, "discover a passage out of one of those cavities into another." (*Micrographia*, p. 116.) Dr Grew describes the little cells or bladders that compose the bark of roots, as possessing a spheroidal shape in most plants. When viewed with the microscope, their sides are as transparent as water; and "none of them," he adds, "are visibly pervious from one into another, but each is bounded within itself." (*Anat. of Plants*, p. 64.) Both Hooke and Grew, however, believed a communication to exist between the cells, from the fact of their containing liquor; and Malpighi held the same opinion from similar considerations; but they nowhere describe the mode or structure by which they conceived it to be accomplished.

88. Later writers have not only adopted this opinion, but professed to demonstrate the structure by which the communication is maintained. M. Mirbel describes the sides of the cells as composed of an extremely thin, colourless, and transparent membrane, which is commonly perforated with pores, the diameter of whose aperture is not, perhaps, the 300th part of a millimetre. These pores are ranged generally in transverse series, and through them, it is said, the cellular tissue both receives fluids from the vessels, and transmits them very slowly through its cells. (*Exposit. de la Théorie*, &c. p. 105.) M. Sprengel, and some others, adopt this view of the porosity of the cells; but it is denied by Link, Treviranus, and Kieser. The latter author declares, that, "notwithstanding all that has been said concerning the pores in the sides of the cells, his observations, made with the greatest care and exactness, have not enabled him to discover the slightest trace of them." The sides of the cells, he adds, are always formed by a membrane extremely thin, but altogether smooth and uniform; and "the cells themselves have never an open communication with each other." (*Kieser sur l'Organisat. des Plantes*, p. 94.) In a critique on M. Mirbel's doctrine, he farther observes, that, although possessing eyes extremely piercing for microscopical objects, and employing the highest magnifying powers, he has never been able to discern, in the membrane of the cells, the existence of pores, though he sought for them with the greatest care and precaution." (*Ibid.* p. 29.)

Have no Pores.

89. From the results, therefore, of direct experiments employed to discover the porosity of the cells, as well as from the combined reports of the most accurate microscopical observers, we must pronounce against the opinions of M. Mirbel; and although he has delineated the form and position of the pores, computed their number, and even measured their apertures, it may, we think, be asserted, that he has either been deceived himself, or has exhibited, as real copies of nature, forms and structures which never had existence but in his own imagination. This charge seems accordingly to have been preferred by some of his opponents; and, in the preliminary observation to the explication of the figures in his last work, he comes forward with this reply to it: "Pour éviter désormais toute espèce d'équivoque, je dois prévenir que les parties que je nomme *organes élémentaires*, ne se présentent jamais isolément dans la Nature. Je fais donc ici ce que j'ai fait dans mes descriptions; je divise par une opération de la pensée, ce que la Nature n'offre que réuni; et je montre, non pas rigoureusement ce qu'on peut voir, mais ce que la reflexion, guidée par l'observation et l'expérience, présente à l'esprit. N'est-ce pas là le résultat de l'analyse philosophique?" (*Exposition*, p. 114.) he exclaims! We answer, that, in cases of this sort, we want the fair transcript of the object itself, and not the analytical result of the author's speculations about it; and we hold it not only unphilosophical, but something worse, knowingly to have given, as faithful copies of Nature, representations of the elementary organs, which, as M. Kieser remarks, are designed not from Nature, but from imagination. (*Mém. sur l'Organisat. des Plantes*, p. 77.)

Mode of Communication.

90. If, then, no pores exist in the sides of the cells for the reception and transmission of the fluids they contain, some other means must be provided for the accomplishment of these objects. M. Link, accordingly, supposes the juices to pass from one cell to another by *transudation* through *invisible pores* in their sides,—a supposition which will scarcely be admitted by physiologists as applicable to *living* organized textures. And M. Rudolphi suggests the still more extravagant opinion, that a *decomposition of the fluid* is effected by the cells themselves, during which it is transmitted through their sides. (*Mirbel's Exposition*, &c. p. 183.) To us there occur no other means of accomplishing these operations, consistently with the integrity of the cellular structure, than the exercise of those alternate functions of secretion and absorption, which, from so many other considerations, we have supposed to be carried on in every living part of the vegetable system.

Sides of the Cells.

91. Another question of less improtance in relation to the sides of the cells is, whether they are single or double; that is, whether each cell has a side of its own, or whether one side is in every position common to two cells. Mirbel asserts the former, and Kieser maintains the latter opinion. In fig. 20. B. Plate XV. is an outline representation of these double sides as given by Kieser. From the extreme thinness of the membrane, it is very difficult, he says, to distinguish this double structure; but where the cells are large, and a glass that magnifies highly is employed, each partition that separates two cells is distinctly seen to be composed of two membranes, which are sometimes separated about the middle of the partition, and united towards the angular points. (*Mém. sur l'Organisat. des Plantes*, p. 91.) The existence of this double structure receives some countenance from the fact lately observed in the construction of the honeycomb by Dr Barclay, who says that each side of every cell in the comb is composed of two plates, or is double. (*Wernerian Transactions*, Vol. II.) It may still, however, be more properly said, that each side of every cell is truly single, and is rendered double only by coming into contact with the corresponding side of an adjacent cell.

Elementary Organs.

Intercellular Canals.

92. When the cells have a regular hexagonal figure, and are equally distended with their appropriate juices, there is no reason to suppose that any vacuities are left between their sides or angles. Mathematicians have long since demonstrated a regular hexagon to be one of those figures that completely fills up a given space; and that no vacuities can exist either about its sides or its angles. Where, however, the cells deviate from this regular figure, and more or less approach to a spherical form, vacuities or interstices may readily be conceived to occur. These vacuities are said to have been first noticed by Leuwenhoeck, and afterwards by M. Treviranus, who describes them as interstices left between the cells in their mutual approximations towards each other: He gave them the name of *intercellular canals*, and considers them as the only passages by which the fluids can be conveyed through the cellular tissue. (*Kieser's Mém. sur l'Organisat. des Plantes*, p. 20.)

93. On the other hand, MM. Mirbel and Rudolphi, altogether deny their existence; but M. Kieser contends strenuously for it. He describes them as small interstices situated at the angles of the hexagonal cells, and formed not by any sides of their own, but by the mutual approach of three contiguous cells, and possessing, therefore, a prismatic form. These interstices, he conceives to exist at every angle, and thus every cell to be surrounded by them. In fig. 20. B. Plate XV. the black angular points denote their place. By their conjunction with each other, they form a canal, which, when the hexagonal figure is perfect, and the cells are ranged horizontally, extends both in a longitudinal and transverse direction; and when the cells are placed obliquely, then the canals have a similar direction. Their size varies according to that of the cells, by the sides of which they are constructed; they contain and convey the proper juices in the bark, but in the pith are often dry; and their course is said to terminate only with that of the cells themselves, at the surface of the plant. (*Mém. sur l'Organisat. des Plantes*, p. 104.) Such are the organs which, as we have seen, M. Kieser considers to convey both the sap and the proper juices in plants; and which he describes as produced universally by that form of cell, which, of all others, is most calculated to exclude their existence. That, in some circumstances they may exist, and become reservoirs of the sap, or other juices, seems highly probable; but of the absurdity of ascribing to such casual productions, the performance of the primary functions of the vegetable system, we have already spoken.

Changes of Form in the Cells.

94. The cellular tissue, as described above, is that form of it which must be regarded as the most perfect. From various causes, however, it is subject to great alterations. In herbs, and in the pith and succulent parts of trees, the cells preserve their original form and appearance for a considerable time; but, by the growth of the other parts, and consequent extension and compression they experience, they acquire in the bark and wood an elongated figure, and this both in a transverse and longitudinal direction. In the latter case, they surround and connect the layers of vessels with each other, constituting what has been named the *parenchyme* of the bark and wood. In this form, their size is often greatly reduced, their cavities sometimes obliterated, and their cellular character altogether effaced. In other instances, traces of a cellular structure are occasionally visible, appearing in detached portions among the perpendicular vessels. In plants of very rapid growth, the cells are said by Kieser to become elongated in a longitudinal direction, and yet preserve their capacity nearly unchanged; so that the tissue which they form appears as if composed of a number of small cylinders. It was probably this construction that led Malpighi to regard sometimes as vessels, what, in reality, appear to be only a collection of these elongated cells. His error appears, however, but slight, compared with that of M. Kieser, who considers the bark as altogether constructed of these elongated cells, somehow metamorphosed into cortical fibres, and interlaced by other similar cells extending in a transverse direction. The wood, too, he supposes to differ in construction from the bark only in possessing spiral vessels; its ligneous fibres he farther holds to be formed by the sides of the aforesaid elongated cells, where the intercellular canals have disappeared; and, as the spiral vessels, according to him, convey only air, no other organs remain for performing the office of sap-vessels but the intercellular canals. (*Mém. sur l'Organisat. des Plantes*, p. 99, 101.) But there is a wide difference between the observations and the opinions of M. Kieser;—the former we regard generally as laborious, minute, and faithful;—the latter often appear to us crude, inconsistent, and absurd.

95. From suffering compression in a transverse direction, the cells have frequently their longer diameter thrown into that position, and thus extend from the centre to the circumference of the plant. This disposition, as will afterwards be shown, was fully noticed by Grew and Malpighi. Leuwenhoeck also observed it, but mistook the cells, as Malpighi had done, in the opposite direction, for vessels, and considered their partitions as valves—errors which M. Kieser, as well as others, duly points out, and yet, as we have just shown, similar to that into which he himself has fallen. In this transverse direction, the tissue forms partitions more or less large between the vessels, as will afterwards be shown, and by the obliteration of its cells, it is frequently reduced to the condition of a solid membrane.

Ruptures of the Cells.

96. Beside these more constant and necessary changes in the figure and character of the cellular tissue, it often suffers others of a more casual and accidental nature. In the pith, as the plant grows up, divers ruptures, says Grew, occur, oftentimes very regularly, and observed constantly in the same species of plant: these ruptures are sometimes prolonged, so as to form a tube of considerable length. (*Grew's Anatomy of Plants*, p. 120.) Others have observed similar canals in the pith, formed not by sides of their own, but by those of the adjacent cells, and very various in size and form: they have been called *lacunæ* or reservoirs, contain a variety of substances, and sometimes, especially in aquatic plants, only air. As we have seen the cavities of the larger spiral vessels to be filled with vesicles, so the larger cells of the pith, according to Grew, frequently con-

Elementary Organs.

tain smaller ones, or are divided by cross membranes. A similar observation is made by Kieser, who likewise remarks, that, in the empty cells of *Calla Æthiopica*, he has sometimes seen small round-headed bodies, supported on little peduncles, which spring from the sides, and point towards the centre of the cells. Small crystallized bodies are also occasionally found in the cavities of the cells, and within the intercellular canals. (*Mém. sur l'Organisat. des Plantes*, p. 94.) Of those changes in the character of the cellular tissue, by which its cells are converted into receptacles and reservoirs of the proper juices of the plant, we before discoursed when treating of the proper vessels. To such an extent does this change sometimes proceed, that, in aged Oaks, and, according to Kieser, in Guiacum, and probably in many other plants, the whole cellular tissue becomes filled with these secreted matters, and the distinctive characters of the cells, and almost of the vessels themselves, are obliterated and lost.

Cells contain Vesicles.

### Article II.

*Of the Structure and Formation of the Cellular Tissue.*

Formation of the Cells.

97. But anatomists have not confined themselves solely to descriptions of the more obvious forms and characters of this tissue: they have attempted to penetrate into the secret of its ultimate structure, and, deserting thus the beaten path of observation and of sense, have wandered at large through the regions of imagination. It would be a waste of time to pursue, to any considerable extent, these vagaries of the fancy; but a brief notice of a few of them may afford some amusement, and perhaps instruction, to the reader.

98. It seems pretty generally admitted, that the tissue, of which the cells are constructed, partakes of a membranous nature; and the first question therefore is, of what materials is this membrane composed? Grew considered the cells, as well as the vessels, to be formed of exceedingly minute fibres, which were themselves tubulous, or rather smaller vessels. (*Anatomy of Plants*, p. 76, 77.) Malpighi deemed the thin membrane that forms the cell to be produced from an effused juice, that gradually acquired solidity, and was everywhere furnished with a reticulation of vessels. (*Anat. Plantar.* p. 29.) According to Du Hamel, the constituent part of this membranous structure is rather to be regarded as filamentous than vascular; though he admits, that, in fleshy fruits the vessels of the cellular tissue are so numerous that they seem to form the cells themselves. (*Phys. des Arbres*, Tom. I. p. 15, 24.) In the leaf, the elder De Saussure maintained, that what is called the cellular part is formed entirely of minute transparent vessels, which, between their junctions, swell out so as to give the appearance of cells or vesicles, though in reality they are a net-work of vessels. (*Encyclop. Méthod.* Tom. I. Art. Parenchyme.)

Opinion of Grew; of Malpighi; of Du Hamel; of De Saussure.

99. The manner in which these primitive vessels or filaments have been employed to form the membrane, has likewise been differently conceived by different writers. Grew imagined them to be disposed in opposite directions, like the warp and woof of the weaver's cloth, and everywhere knit together by the weftage of other fibres. Du Hamel could see no such regular structure, and therefore believed them to be united promiscuously, like the filaments in a piece of felt; and Malpighi and Saussure seem to have regarded them as joined together in the form of net-work.

100. Not less different have been the modes in which this membranous substance, during or after its formation, has been supposed to acquire its cellular figure. Grew seems to have thought that the figure of the cells was determined by the course which the vessels pursued in their formation; hence he remarks, that while the vessels proceed circularly, and keep within the compass of the cells, the cells are round; but where they wind out of one cell into another, then an angular form is produced. (*Anatomy of Plants*, p. 77.) Later observation, however, has rendered it probable that the angular form is the result rather of the mutual pressure which the cells subsequently exert on one another, than communicated during their formation. The general appearance which a mass of cells exhibited after their formation, he resembled to that of the froth of beer (*Ibid.* p. 67.); but never, as some seem to have supposed, imagined them to be produced by a similar operation. By all those who maintain the vascular nature of the cellular tissue, the cells must be considered as originating from the vessels—an opinion frequently advanced by Malpighi, who particularly describes the excrescence on the leaf of the Oak, called gall-nut, as composed of a cellular structure, which is derived immediately from the vessels of the leaf, and which opinion, as he justly remarks, the structure of the leaf itself, of the flower, and the fruit, hereafter to be described, will illustrate and confirm.

Opinion of Ludwig; of Mirbel.

101. A different view of the origin and formation of cells has been taken by others. Ludwig conceived the vessels, as well as the cells, to derive their origin from a common membrane, but does not describe the manner in which the cells and vessels could be produced out of it. (*Institut. Phys. Regni Végétab.*) This opinion has since been adopted by Mirbel, who considers it as perfectly original; and has gone more into detail regarding the mode in which cells and vessels are produced. According to him, the entire mass of the vegetable is a membranous tissue, the ultimate structure of which he does not pretend to explain, and out of this tissue the small cavities called cells, and the vessels are alike formed. He of course denies the independent existence of cells and vessels, and of the vascular productions or fibres by which these two organs have, by others, been supposed to be united: and maintains that the entire vegetable is constructed of one continuous membrane, between all the parts of which a communication is kept up by means of innumerable pores. (*Exposit. de la Théorie de l'Organisat. Végét.* p. 60, 62, 279.) How this membrane acquires the varied and regular forms which it exhibits in the cells and vessels of the plant, we are not distinctly told. All that we can discover on this point, is, that the cells are not distinct sacs or utricles, but produced out of a membrane which unfolds itself (se dédouble) in some inconceivable manner, so as to leave empty

Elementary Organs.

spaces contiguous to one another, which constitute the cells. (*Traité d'Anat. et Physiol. Vég.* Tom. I. p. 56.) The mass of cells thus formed, is considered very similar to the vesicles of the froth of beer, with which Grew had previously compared it: for the thin transparent plates of these vesicles are said to be everywhere continuous, and each side to be common to two vesicles, while all interstices or intercellular spaces, and all connecting vessels and fibres, are completely excluded. We are also told that the smaller vessels are only elongated cells, and the larger ones cavities formed in the cellular tissue; so that this tissue must be regarded as the essential organ of vegetables, and the other organs are but modifications of it; and in this way M. Mirbel passes off the assertion of an opinion for an explanation of the mode in which the vessels are constructed.

Opinion of Sprengel;

102. Instead of the continuous mass of cells which Mirbel professes to describe, M. Sprengel conceives the cells of this tissue to originate from elementary globules, such as are found in the cotyledon of the bean, which at first seem a chaotic mass of extremely minute vesicles, but are gradually developed, and acquire an angular form. This seems likewise to be the opinion of M. Treviranus, who regards the cells as originating from the aforesaid cotyledonous vesicles, which have at first a round form, but are changed afterward by the effect of pressure; these vesicles are supposed gradually to extend, to close towards each other, and in this way to construct the tissue. The elementary vesicles, however, out of which these writers construct their cells, are justly regarded by M. Link (*Kieser's Mém. sur l'Organisat. des Plantes*, p. 17, 19, 23.) as globules of starch deposited for the future nutriment of the embryo.

of Treviranus;

of Kieser.

103. M. Kieser also derives the origin of the cells from primitive globules, but looks for them in a different part of the vegetable system. In the proper juices of plants, certain minute particles or globules have been observed, which, according to this author, are the rudiments of future cells, or rather, says he, true cells themselves, though extremely minute. An infinite number of these globules exist in the proper juices, which juices are present in every primitive utricle. Gradually these globules dilate, approach, and are soldered to each other, receiving by their reciprocal pressure an hexagonal figure, and thus constructing the cellular tissue, which is nothing but a parenchyme of many small cells, enclosed in a great cell, or primitive utricle. Each cell, therefore, of the cellular tissue is, in its origin, only a transparent globule, which becomes filled with fluids, and soldered to the adjoining cells, so as to form an entire piece, the parenchyme of the plant. As this dilatation of these primitive globules is, in all cases, the first function of the plant, the cellular tissue is the first and primitive organization of the plant, from which proceed afterwards all the other elementary organs. (*Ibid.* p. 219.) Such is M. Kieser's account of the origin of the cellular tissue, which, as we think, surpasses in absurdity that of M. Mirbel, whose doctrine he so justly condemns;—but so much easier is it to "see the mote in our brother's eye," than to be conscious of the "beam in our own."

Common Textures.

## CHAP. II.

### THE ANATOMY IN GENERAL OF THE COMMON TEXTURES OF VEGETABLES.

*Preliminary Observations.*

Nature of the Common Textures.

104. The elementary organs, whose description has so long occupied our attention, form, either singly or by their combination, all the other parts of plants. Some of the lower tribes of vegetables consist entirely of cellular tissue, in which no vessels are at any period to be seen; and, even in the higher orders, many parts exhibit no appearance of a vascular structure. There can be little doubt, however, of the existence of such a structure, since, physiologically speaking, we can form no just conception of the growth of an organized body, without associating with it the existence of a vascular system. In all plants, the pith consists of cellular tissue alone. In herbaceous plants, this tissue forms their greater portion; but in trees, the number of vessels is so great, as to constitute the chief bulk of the plant. To certain forms of these elementary organs, whether existing singly or in combination, we have given the name of *common textures*, because they are very generally to be found in all plants, and in almost all parts of them, howsoever varied in quantity, proportion, and arrangement. These textures are familiarly known under the names of Cuticle or Skin, of Bark, of Wood, and of Pith; to which may be assigned the general appellations of the Cuticular, the Cortical, the Ligneous, and Medullary textures.

Their Position various.

105. All the several textures just enumerated, are readily distinguished, by their different places and characters, in the section of most arborescent plants, in which they commonly appear well defined, and perfectly distinct from each other. In many plants, however, both herbs and trees, this distinction of parts is not preserved; but, with the exception of the cuticle, all the other textures are blended together through the entire substance of the plant, as was long since noticed both by Malpighi and Grew. "In the stalk of maize or Indian wheat," says Grew, "the work of nature appears less diversified; in which, although there are the same parenchymous and ligneous parts, as in all other plants, yet is there neither bark nor pith, the vessels being dispersed and mixed with the parenchyma, from the circumference to the centre of the stalk." "The like structure," he adds, "may also be seen in the Sugar-cane, and some other plants." (*Anat. of Plants*, p. 104.) Similar observations were made by Malpighi, not only on different species of wheat and sugar-cane, but on ferns and palms. "In Ferns," says he, "the vascular fasciculi are numerous, but placed without order, and are everywhere sustained by the intervening cellular tissue, the cells of which are sometimes much smaller than the orifices of the vessels themselves." (*Anat. Plantar.* p. 24, 25.) This structure is represented in the transverse section of the sugar-cane, Plate XVI. fig. 26.; and in a similar section of the palm, fig. 28. of the same Plate.

Common Textures.

Theory of Desfontaines.

106. This variety of structure, thus clearly described, and distinctly delineated in the works of Malpighi and Grew, has lately been noticed by M. Desfontaines, who deems it common and peculiar to all plants, whose seeds have but one lobe or cotyledon; while all plants produced from seeds that have two cotyledons, are held to possess a very different arrangement of parts. Vegetables, according to him, may be distinguished into two divisions: 1*st*, Those which have no distinct concentric layers, whose solidity decreases from the circumference towards the centre, and whose pith is interposed among the vessels, and does not extend in divergent rays. 2*d*, Vegetables which have distinct concentric layers, whose solidity decreases from the centre towards the circumference, and whose pith is contained in a longitudinal canal, and extends in divergent rays. The former structure he considers as peculiar to plants, whose seeds are monocotyledonous, and the latter as belonging to those which have dicotyledonous seeds. (*Mém. de l'Institut. Nat.* Tom. I. p. 478.)

Not just.

107. There does not, however, appear any just ground for this supposed coincidence of structure betwixt the seed and the stem. That many plants which spring from monocotyledonous seeds, are destitute of concentric layers, and have no distinct bark or pith, is most certain; but it is not less certain that many herbaceous plants, which are produced from dicotyledonous seeds, are pretty much in the same condition, being equally destitute of concentric layers, and of divergent rays; and in which the bark and the pith must be regarded as one continuous structure. On the other hand, some monocotyledonous plants, as M. Desfontaines admits, may deviate a little from the prescribed conditions. In a paper on the organization of such plants, M. Mirbel, who regards this doctrine as the most important step made of late years in Vegetable Anatomy, says, nevertheless, it would be erroneous to assert that they have never a bark. In several species of plants, he produces examples to the contrary; and adds, that, in some instances, their diametral growth goes on at the circumference, which would seem to approximate them to dicotyledons. As, however, there is no appearance of divergent rays, or of concentric layers, these examples are considered by him rather to confirm than overturn the theory of M. Desfontaines. (*Annales du Mus. d'Hist. Nat.* Tom. XIII. p. 67.) But if, in this theory, its second division embrace only those plants in which the concentric layers are perfect, and divergent rays exist, then it excludes a great number of herbaceous plants, whose seeds have two cotyledons; and if the absence of these regular layers, and of divergent rays, serve as a passport to the first division, then many of these same plants must be admitted among those whose seeds have but one cotyledon. The theory of M. Desfontaines, therefore, rests on too partial an observation of the structure of plants. All that is true in it was previously known, and all that is new will not serve the purpose of its author. For the former part, he has omitted to do justice where it was due; for the latter, he has received extravagant praise where it has not been deserved. It has been our wish to render equal justice to all.

108. Instead, therefore, of seeking to found the structure of the stem on the form of the seed, it will be more correct to describe the several varieties of its appearance, as they actually present themselves on dissection; beginning, as Grew and Malpighi have done, with the more simple arrangement of the elementary organs, as they occur in certain plants, and following them, through their several gradations, to more precise and better defined forms. Although some of these plants do not, properly speaking, possess either distinct bark or pith, yet no misapprehension can arise from treating of these parts under the denomination of *common textures;* for though not universally, they are very generally, present; and even where they are not, the descriptions will, with little variation, apply to such structures. As of these common textures, the pith is the most simple, we shall commence our account of them with a brief description of it.

Common Textures.

## Section I.

### *Of the Pith or Medullary Texture.*

109. The pith (medulla) of plants when present, occupies the centre of the stem, where it is commonly surrounded by a circle of vessels which construct for it an appropriate canal. In the succulent shoots of trees, its proportion to the other parts is generally large; but it diminishes as the tree advances in age, and is frequently entirely obliterated. Where the vessels of the wood are few in number, as in herbs, only a few fasciculi are seen to surround the pith, and the intervening spaces are occupied by a boundary of thickened cellular tissue. In some plants again, no pith whatever exists, but the stem is hollow or tubular. In other instances, and especially in roots, the centre of the stem is occupied by vessels; and in others, both cells and vessels, promiscuously blended together, constitute the centre of the stem. The Pith.

110. In those plants where the pith is present, and possesses its most perfect form, it is seen to be composed entirely of cellular tissue, possessing often very different shades of colour, but, in its anatomical characters, resembling exactly the description already given of that tissue. Its bulk, in different plants, is exceedingly different, as are also the form and size of its cells. It is frequently entirely insulated by the surrounding vessels, but is often continuous with the cellular tissue of the bark. Its cells contain, especially in the early age of the plant, aqueous fluids which afterwards disappear, and then the cells become filled only with air. The proper juices of the plant may also be sometimes detected in the cells of the pith. Of the ruptures produced in it by desiccation and other causes, we have already spoken in discoursing of the cellular tissue; they occur particularly in succulent plants, where the cells are large, and their sides thin; so that, as the plant advances to maturity, the pith breaks and shrinks up, making the trunk a pipe. (*Grew's Anatomy of Plants*, p. 129.) We have also noticed the fact, that, within the cavities of the larger cells of the pith, new vesicular productions are sometimes found. Description.

Common Textures.

Vessels in the Pith.

111. Grew speaks of the existence of vessels in the pith of certain plants, as in that of the Fig and the Pine; but he adds, that they are usually so postured as to form a ring about its margin. (*Anatomy of Plants*, p. 119.) They are doubtless to be considered as enlarged *proper vessels*, which made a part of the first ligneous circle, and have retained therefore nearly the situation in which they were originally formed. Hence, as he observes, they are of divers kinds, answerable to those of the bark, containing, in the Fig, a milky juice, and in the Pine, a resinous substance. Similar vessels, containing a proper juice, were observed also in the pith of Elder by Malpighi, who seems to regard such appearances as common, where the contained juice concretes, or possesses a dark colour. (*Anat. Plantar*. p. 4.) It is probable, however, that the organs here considered to be vessels, may, in some cases, be cells, into which these juices have been poured; but where real vessels of this kind are found, they are not to be considered as a part of the original structure of the pith; but occurring only in consequence of the changes, which the vegetable body undergoes in the progress of its growth.

Its Nature.

112. The general nature of the pith is thus clearly announced by Grew. "Although," says he, "it have a different name from the *parenchyma* in the bark and the *insertions* in the wood, yet, as to its substance, it is the very same with them both; whereof there is a double evidence, viz. their continuity, and the sameness of their texture;" so that all these parts are "one entire piece of work, being only filled up, in divers manners, with the vessels." (*Anat. of Plants*, p. 119.) This continuity of the pith with the cellular tissue of the bark, by means of the insertions or transverse ranges of *utriculi*, as he calls them, is also adduced by Malpighi as evidence of the similarity of their nature, and of the pith being, as it were, an intercepted portion of the bark (*Anat. Plantar*. p. 4—30.); an opinion which seems abundantly confirmed by the intermixture of the medullary and cortical textures in many plants, in which, as already remarked, the distinctive characters of bark and pith are alike lost, and the entire stem exhibits only one uniform appearance of structure.

Errors concerning it.

113. The term *medulla*, employed by the ancients to denote this texture, derived its origin, no doubt, from the resemblance which the pith, in the centre of trees, bore to the marrow in the bones of animals; and as the same term, in Animal anatomy, was incorrectly employed to express alike the marrow in the bones, and the nervous substance in the vertebral column, so the same latitude of signification has been extended to the vegetable system. Hence, as Malpighi remarks, the medulla in vegetables was regarded as analogous, in its nature, to the brain of animals, a doctrine which even later writers have continued to espouse. It is not our present intention to describe the uses of the pith, but only to remove erroneous opinions concerning its nature, and restore to it that just anatomical character, long since assigned it by Malpighi and Grew; and which some writers have of late put forth as a considerable novelty.

### Section II.

#### *Of the Wood or Ligneous Texture.*

Common Textures.

The Wood

114. Immediately surrounding and enveloping the pith, is the part called the wood (*lignum vel lignea portio* of Malpighi.) It is essentially composed of vessels and of cellular tissue, but combined in such an infinite variety of proportions, and exhibiting such a boundless diversity of forms, that it is difficult to seize even its more general features, without the risk of extending our descriptions beyond the limits which our plan necessarily prescribes.

Description.

115. Except in those vegetables in which no vessels have been hitherto demonstrated, but in which they must nevertheless be presumed to exist, this texture may be considered to form a part not only of every plant, but of all its organs; for into whatever part fluids are conveyed, vessels must be supposed to extend; and wherever vessels are present, cellular tissue is to be found: hence, in its distribution, it may be considered the most universal of all the textures. In trees, the vessels, as we have frequently remarked, are very numerous, and, when viewed in a transverse section, are seen to be disposed in layers or concentric circles around the axis, and to stand also in lines or radii, diverging from the centre of the tree. See fig. 4. Plate XVII. Between each line or ray of vessels, a thin partition of cellular tissue is interposed, which extends in the direction of the ray, through the entire substance of the wood. At certain distances, varying in different trees, thicker transverse portions of the same substance are placed, and are readily distinguishable in almost every species of wood. Between each layer that is annually added to the wood, and each of the smaller layers that go to the formation of the larger one, cellular tissue seems also in some trees to be longitudinally interposed; so that it is probable, that, in both directions, each fasciculus of vessels is intercepted by cellular tissue, and that in such trees no two fasciculi are on any side in immediate contact with each other. It is even probable, that the individual vessels which contribute to form the fasciculi, are themselves connected by intervening cellular tissue, which acts like the *neurilema* that holds together the filaments of the fasciculi in the nerves, or the cellular substance that connects the primary filaments in the muscular fibres of animals. In this manner, the whole vascular system of the plant is everywhere connected and held together by cellular tissue. Of this tissue, and the different figures its cells acquire, from the different modes and degrees of compression to which they are exposed, we have already spoken.

In ordinary Trees.

In Palms.

116. In many trees, however, as Palms, the vascular fasciculi, though numerous, are much less abundant than in the examples just referred to. They are consequently placed at a greater distance from each other, and, not being disposed in regular lines, do not constitute that radiant appearance so common in ordinary trees, but are promiscuously dispersed through the cellular tissue. See fig. 28. Plate XVI. As this tissue itself is not, from the same causes, compressed either in the direction or to the extent before described, the smaller membranous partitions that divide the vascular radii from each

Common Textures. other are not produced; neither, for similar reasons, is there any distinct appearance of the larger partitions, that, at certain distances, intersect the diameter of other trees. The cellular tissue, therefore, in such plants, retains more of its primitive character, and appears everywhere to surround the vascular fasciculi, but nowhere to be so compressed as to form solid partitions between them. In some plants which possess this structure, as the Sugar-cane (fig. 26. Plate XVI.), the cells indeed retain their perfect forms, and even the fasciculi of vessels, though standing at considerable distances from each other, have towards the centre of the plant a symmetrical arrangement. This latter circumstance is observable in many other plants, which have even fewer vessels than the Sugar-cane; so that it is probable, that, in the first instance, it takes place in all; and that the irregular position of the vessels in the Palm and similar trees, particularly towards their circumference, proceeds from the peculiar modes of their growth, and are not a primary condition of their structure. This intermixture of the vessels and cells in the plants, now under consideration, extends from the circumference to the centre, so as to constitute their entire bulk, to the exclusion of bark and pith; unless we choose rather to say, that, in such plants, the medullary, ligneous, and cortical textures, are all blended together.

In Herbs. 117. In other examples, the vessels form a still smaller portion of the ligneous texture, consisting only of a few fasciculi which stand at considerable distances from each other, the intervening spaces being occupied by cellular tissue, which forms the chief bulk of the plant. See fig. 32. Plate XVI. Though few in number, the vessels, however, are symmetrically disposed, and, in the same species, preserve always the same position, the fasciculi being placed at the same relative distance from each other, and from the common centre of the pith. Sometimes, instead of a few solitary fasciculi, they consist of several ranges, forming an imperfect sort of concentric layers, and in such examples, the ligneous texture is commonly separated by distinct but irregular marks from the two other textures. In these plants, the cellular tissue preserves its characters, and exhibits no appearance of divergent rays.

Causes of its Varieties. 118. The three modes of arrangement above described, appear to constitute the chief varieties of structure in the ligneous texture; but in each variety, and through every stage by which they graduate into one another, the greatest diversity of forms prevails. Each species of plant has its peculiar *internal structure*, as well as its *external* form; and this seems to be in a great measure determined by the number of vessels that enter into its composition, and their peculiar mode of arrangement. If the vessels are few, the cellular tissue is large in proportion, and its characters are distinct and well preserved;—if they are numerous, and disposed in rays, the tissue is compressed in various directions, loses more or less completely its cellular character, and forms alike those divergent rays, or transverse partitions already so often noticed, and those thin membranous expansions, or *fasciæ*, which, both in the bark and wood, are seen sometimes to cover the vessels in a longitudinal direction.

119. The manner, too, or rather the place, in which the vessels are developed, in perennial plants, will greatly contribute to vary the appearance of the ligneous texture. In those trees, whose diameter is annually increased by the formation of new vessels around the cylinder of older wood, the new parts must necessarily present in their longitudinal section the appearance of annular layers superimposed on one another, and, in their transverse section, that of concentric circles; but in Palms and similar trees, where the developement of new parts seems to be accomplished in a different manner, their appearance, under similar sections, may be expected to be different. Common Textures.

120. In a longitudinal section of the Palm, says M. Desfontaines, we discover an assemblage of large ligneous fibres (that is, vascular fasciculi), solid, smooth, and flexible; and these are composed of others still smaller, which are firmly united together; they mostly run parallel to the axis of the trunk, from the base to the summit, without interruption; but some proceed obliquely, and cross the others at angles more or less sharp. See fig. 29. Plate XVI. In a transverse section of the same stem, continues the author, we remark neither concentric circles, nor transverse partitions; but the fasciculi of vessels placed without order by the side of each other, are enveloped by the cellular tissue, which fills up all the intervals: they sensibly approach each other, harden and diminish in size in proceeding from the centre to the circumference. See fig. 28. Plate XVI. So that the stem has much more strength and solidity near the surface, than in the interior, an organization quite distinct from that of ordinary trees. Structure of Palms.

121. The cause of this diversity of structure seems to be amply accounted for by the different modes in which the growth of these trees is accomplished. When the seed of a Palm is sown, the leaves, says M. Desfontaines, successively develope and augment in number for four or five years; the neck of the root augments in the same proportion; the bulbous part, formed by the reunion of the petioles of the leaves, increases insensibly; its solidity augments, and at length the stem rises above the earth with all the size it ever acquires. Its figure is cylindrical from the base to the summit, and if the diameter be measured at different epochs, it will be seen, as Kæmpfer had already remarked, not to increase. The Palm, therefore, is a regular column, whose summit is crowned with leaves, disposed above each other circularly; those which grow in spring shoot always from the top; the older ones, placed below, dry, and when they fall, leave circular impressions, which furrow the surface of the stem, and mark its years until it has ceased to grow. Their Growth.

122. If next we examine the interior, we discover, as M. Desfontaines thinks, the true reason why the stem rises in a column, and does not, like other trees, yearly augment in size. This was done by M. Daubenton, who states, that every leaf of the Date-palm, in proceeding from the bud, is formed by a prolongation of the vascular fasciculi and cellular tissue which exist in the trunk of the tree, as is apparent in the petiole of the recent leaves, and of the dried

Common Textures.

ones that adhere to the trunk. The elongation of the trunk is produced, therefore, by the leaves which annually proceed from it; and as the parts which form these leaves, spring from the centre, they always, as they shoot, force the older leaves outwards. Hence, therefore, as the augmentation of these trees originates at the centre, all the parts capable of displacement must be pushed outwards, just as the new layers of bark and wood, formed annually in ordinary trees, force outward the older layers of bark exterior to them.

Effects of the Growth on the Structure.

123. In these latter trees, continues M. Daubenton, the recession of the bark has no limits, so long as new parts continue to be formed beneath it; because the new cortical layers are flexible, and the older ones readily break and give way: but in the Palm, the substance of the trunk has more compactness as we approach the circumference, and, at a certain point of density, it no longer yields to the central force of the interior parts; so that, when this point is reached, no farther enlargement takes place; and hence, the Date-palm scarcely exceeds ten inches in diameter. It is for similar reasons that the trunk of the Date-palm is of the same size through its entire length; for, in proportion as the tree rises, the exterior parts of the trunk lose successively their flexibility, and when they have reached a certain degree of density, they no longer yield to the force from within; and as this is equally the case in all parts, the trunk is necessarily of the same size throughout. (*Mém. de l'Instit. Nat.* Tom. I. p. 482, &c.)

124. It is farther evident, that, in this mode of growth, no appearance of concentric circles, similar to those of ordinary trees, can have place; for, by the growth at the centre, the exterior vessels are continually displaced from their original positions, are more and more compressed as they are forced towards the circumference, and present, in their transverse section, that irregular distribution which they have been described to possess. Hence, the cylindrical figure and the absence of concentric layers are as necessary consequences of the mode of growth in these trees, as the presence of those layers and the conical figure are of the mode of growth in ordinary trees. The greater solidity of the parts at the circumference is clearly to be ascribed to the same cause; and even the want of regular transverse partitions must in part also have a similar origin, and be ascribed, perhaps, in part to the smaller number of vessels which these plants possess, as well as to their irregular distribution.

## Section III.

### *Of the Bark or Cortical Texture.*

The Bark.

125. This texture, in its component parts, resembles that of the wood, being made up, like it, of vessels and cellular tissue intimately connected with each other. Its structure, as a distinct texture, is best characterized in the bark of ordinary trees, as it is there separated, in a great measure, from the ligneous texture. As, in these plants, a new layer of vessels is annually made to the wood, so a similar, but much thinner layer, is yearly added to the bark, to which the name of *liber* has commonly been applied. These vessels are at first strait, and run parallel to the axis of the trunk; but, by the successive formation of new layers beneath them, they are gradually forced outward, become separated more and more from each other, and, touching in a few points only, exhibit at length a reticulated figure (See fig. 18. Plate XV.); the meshes of which yearly augment in size, from the greater space over which they are continually spread.

In Trees.

Is united to the Wood.

126. Between the vessels thus annually formed, a considerable portion of cellular tissue is interposed, which, in the young and succulent state of parts, contributes chiefly to the thickness of the bark. This tissue is variously compressed by the vessels, so as to form *transverse* partitions betwixt them, which, in the Vine, the Oak, and many other trees, as both Grew and Malpighi remarked, are seen to be continuous with those of the wood; and in this way the two textures are united together. In the expressive language of Grew, the bark, therefore, does not "merely surround the wood as a scabbard does a sword, or a glove the hand, but is truly continuous with it, as the skin of the body is with the flesh." In the Willow and other trees, when full of sap, the bark is so easily separated that it seems to have no connection with the wood; but this is supposed by Grew to arise merely from the extreme fineness and tenderness of the vessels that are annually formed in that part, and which, on that account, oppose no obstacle to the separation. (*Anat. of Plants*, p. 129.) It is probable, however, that the cellular tissue forms the only direct connection betwixt the cortical and ligneous textures, and that, if a vascular communication exist, it is only, as in all other cases, through the medium of that tissue.

Altered by Pressure.

127. Beside the transverse compression which the cellular tissue experiences from the vessels, it is compressed, in the opposite direction, by the formation of the new layers of bark and wood beneath the older bark. These, in the progress of their growth, exert an expansive force outwards, so that the cells of the tissue are made to assume an oblong or flattened form in the direction of the vessels of the trunk, or sometimes to form a thin *fascia* upon the vessels, in which the cellular character is nearly or entirely obliterated. It is by the continued exertion of this force, acting on the exterior and desiccated layers, that these latter ultimately crack; producing figures of different sizes, which have frequently the shape of rhombs, the fissures of which represent, according to Grew, the position and track of the vessels in their reticulations. (*Anat. of Plants*, p. 129.) The spaces or meshes formed by these reticulations, are always filled up by cellular tissue, which, in the opinion of Malpighi, originates from the vessels themselves.

Contains proper Juices.

128. Both in the vessels and cells of this texture, collections of the proper juices frequently occur; especially in plants in which these juices are of a viscid nature, and disposed to concrete; as was before remarked, when treating of the proper vessels. Similar collections of matter, originally existing in the bark, are likewise met with in every layer of wood, and even in the pith of certain trees. It is only in plants in which the proper juices are coloured, or

Common Textures.

disposed to concrete, that this intermixture of the cortical and ligneous textures has been traced through the whole substance of the tree; but it is probable, from the conjunction of the vessels of the bark and wood at the period of their formation, that it is common to other plants, the nature and properties of whose juices afford no clew to its detection.

The Bark in Herbs.

129. In most herbaceous plants, the cortical texture is not so clearly distinguished from that of the wood, since in them the greatest variety obtains both in regard to the number and relative position of the sap and proper vessels; and very frequently the cellular tissue is quite continuous, and of uniform appearance through the entire substance of the plant. In general, however, the sap-vessels occupy the inner place, and are surrounded by the proper vessels, disposed either in rings, or distinct fasciculi, more or fewer in number. Sometimes the sap-vessels seem to be placed exterior to the others, and hence it is difficult to discover the true place of the proper vessels in such plants, unless the nature of their juices conduct to it. From the position of the vessels, therefore, it is often difficult to define the boundaries of the cortical and ligneous textures, and for the reason already assigned, the cellular tissue rarely affords much assistance. According, however, to the number and disposition of the vessels, this tissue, even in these plants, suffers a certain degree of compression, so as to form thickened boundaries around the fasciculi, or sometimes large transverse partitions which communicate with those of the wood, in which, though the figure of the cells is more or less altered, the cellular character is usually preserved.

In Palms.

130. In other plants, the intermixture of proper vessels with those that carry sap, seems to be general through the whole plant; and consequently no distinction can be made between the ligneous and cortical textures. In such plants, the proper juices must be considered to exist in every part; and accordingly Malpighi, as we before remarked, points out a *vas proprium*, or proper vessel, as accompanying every fasciculus of vessels in different species of wheat. (*Anat. Plantar.* p. 24.) From the similarity of structure in Palms, and especially from their mode of growth, there can be little doubt that a similar intermixture of the two kinds of vessels prevails everywhere in them; and with respect to these plants, what has already been said of the construction of the ligneous texture, is equally applicable to that of the bark.

131. We have thus given a very brief and general view of the principal textures that enter into the construction of plants. and pointed out the more prominent diversities of character and appearance which they exhibit, as well in their simple as in their more complex forms; and as they exist either separately or variously intermingled together. Our descriptions have been confined entirely to the trunk or stem, but, with slight variation, they are applicable equally to the root and branch, in which a similar combination of the elementary organs obtains. In the root, however, they commonly exist in a more compressed and compacted form, so that the ligneous texture is seen chiefly to predominate, frequently to the entire exclusion of the pith; and often, in great part also, to that of the cellular portion of the bark. This is not however universal, especially in annual plants, some of which, as the carrot and others, particularly in a cultivated state, are distinguished by the very large portion of cellular tissue which enters into the construction of the cortical texture. Of the modifications of these several textures, as they exist in leaves and other organs, we shall have occasion to speak when we come to treat of them individually. We may now observe, that, how varied soever they may appear, when viewed only in their extreme results, yet all these variations seem to spring from a few original differences in character; which differences, modified by circumstances of subsequent duration and growth, produce, by gradations almost insensible, the manifold diversities of form and structure, which hereafter we shall attempt to describe.

In Roots and Branches.

In Leaves.

Mode of Connection of Vessels and Cells.

132. In our discussion of these several textures, we have noticed only in a general way, the direct means by which the vessels and cells that construct them are connected with each other; but, when treating of the sap-vessels of the absorbent vessels, and of the cellular tissue, we endeavoured to show, that an universal communication obtains between these elementary organs, and consequently inferred, that some mode of connection, by which it can be accomplished, must have place. Grew considered the vascular and cellular parts to be connected with each other, not only by the transverse partitions of cellular substance that intercept the vessels—but "*per minimas partes organicas;* that is to say, the parenchymous fibres are wrapped round about the vessels, or at least interwoven with them, and with every fibre of every vessel, as in very white ash or fir wood may be observed." (*Anat. of Plants*, p. 121.) These fibres, Grew elsewhere considers as vessels, and consequently must be regarded as maintaining, with Malpighi, a vascular connection between these organs. In a description of the young branches of Chesnut and Oak, Malpighi delineates minute filaments, springing on every side from the vessels of the wood, and continued into the adjacent cellular tissue (*Anat. Plantar.* p. 27.); but he does not state whether they are to be regarded as vessels or simple fibres. We have before shown, however, that he considered the cells to be everywhere furnished with minute ramifications derived from the perpendicular vessels; and, indeed, he held it probable, that the nutrient fluids, moving through the vessels, were, in in all parts, poured into the cells, and there undergoing a certain preparation, were afterwards mixed with more recent juices, and with them taken up and applied to the support of the young buds and leaves. (*Anat. Plantar.* p. 30.) This doctrine has since been held by Darwin and Knight, and it necessarily supposes a vascular connection between the vessels and the cells, by which the functions both of secretion and absorption can be performed. The microscopical observations of Leuwenhoeck, already noticed, supply farther evidence in support of this opinion.

Opinion of Grew;

of Malpighi;

133. In the hypothesis of Mirbel, both cells and vessels are considered as one and the same membrane. He rejects, therefore, the aid of all intermediate organs, as necessary to connect them together;

of Mirbel;

Common Textures.

and supposes a communication to be everywhere maintained between the vessels and cells, by the medium of pores in their sides. As, however, these pores are nowhere proved to have existence but in the imagination of the author, we may altogether reject their agency in maintaining a communication betwixt the vessels and cells of plants. In the opinion of M. Kieser, the conjunction of the cells with the vessels is extremely simple, the sides of the cells, says he, being contiguous to the sides of the vessels. (*Mém. sur l'Organisat. des Plantes*, p. 94.) But mere contiguity of parts does not amount to connection, much less does it afford any information concerning the actual communication that exists between these organs. In addition, therefore, to connection by cellular substance, it seems absolutely necessary to suppose also the existence of a vascular structure, which shall at once serve as a medium both of connection and communication.

of Kieser.

Resemblance of Vegetable to Animal Textures.

134. Before concluding this branch of the subject, we may observe that the structure of the cellular tissue, and its relation to the vascular system in plants, appears, in many points, to resemble that of the adipose cells, and their relation to the vascular system of animals. These cells are described as minute close cavities, possessing no apparent communication with each other; and within them adipose matter is alternately deposited and removed. Now, the deposition of this matter could only be accomplished by secreting vessels, which terminated in the cells, and its removal be effected by absorbents, which originated from them; and accordingly, both blood-vessels and absorbents are found to be present in this texture; but neither the secreting nor absorbing orifices have ever been actually observed. Within the cells of the cellular tissue of plants, the alternate deposition and removal of various matters are not less certain; and in the germinating seed, the matter that actually existed in the cells is found afterwards in the vessels. We are led, therefore, or rather we are driven, not only by the direct exclusion of all other alleged means of communication, but by a close analogy in the exercise of these animal and vegetable functions, to conclude, that secreting and absorbing vessels must be employed to deposit and remove the secreted matter from the cells of plants, in the same way as they are considered to effect similar depositions and removals of adipose matter from the cells of animals; and as this alternate function seems to go on in every part of the plant, capable of active vegetation, it may farther be inferred, that a vascular connection and communication exists between the vessels and cells in all parts of the vegetable system.

Irregular Movements of the Sap.

135. By means of this general communication between the vessels and the cells, we are enabled to assign satisfactory reasons for some puzzling phenomena, which have occurred in relation to the movements of the sap. It is by this alternate action of secretion and absorption, that, in young plants, we must suppose the cells of the pith, during the first year, to be filled with fluid; and to be rendered dry for the most part ever after. In like manner, the surface of the bark, in contact with the wood, appears, in some trees, as the Birch, to be rendered moist during the rise of the sap in spring; which led Dr Walker and others to suppose, that the sap rose in part betwixt the bark and the wood; an opinion not at all probable in itself, and certainly not supported by what is observed in most other trees. The fact, however, is easily explicable, on the supposition that the sap was transfused from the alburnous vessels of the wood, in the same manner as, at a later period, it is secreted in the same part, but in a different form, by the vessels of the bark, to form the new matter that is annually added to the tree.

Lateral Motion of Sap.

136. That the sap of plants was capable of moving in a *lateral* direction, was inferred by Malpighi from the fact that parts lived and grew, when the perpendicular vessels that supplied them with nutriment had been destroyed. (*Anat. Plantar.* p. 13.) The experiments of Hales afford more decisive evidence regarding this lateral movement of the sap. He cut two large gaps in the opposite sides of an Oak branch, at four inches distance from each other, carrying the incisions down to the pith: the branch nevertheless absorbed and perspired water, but only in half the quantity that another similar, but uncut, branch did. In branch of Cherry-tree, he made four similar cuts down to the pith, at four inches distance from each other, and opposed to the four points of the compass; the branch notwithstanding absorbed, in forty-eight hours, twenty-four ounces of water. (*Veg. Statics*, p. 128. 3d Edit.) And when similar incisions were made on branches, while still attached to the tree, their leaves continued green, nearly as long as those of other branches in a natural state; whence he justly inferred, that, at these gaps made in the branch, a lateral movement of the sap must have taken place. Experiments of a similar nature have been made, and like results obtained, by Mr Knight (*Phil. Trans.* 1808.); so that it seems clear, that, in certain circumstances, a lateral movement of the sap must have place.

How effected.

137. In what manner, then, must we suppose this movement to be accomplished? Grew supposed the cellular tissue, that stretches from the circumference to the centre of the plant, to be the instrument by which such a communication could be maintained; but the impermeability of this tissue to fluids opposes such an opinion. Malpighi thought the lateral communication to be made by an *anastomosis* of vessels; but in the vessels of plants no such mode of communication appears to exist. From the ascent of the sap in branches in which the vessels had been thus previously cut through, Mr Knight infers, that this fluid does not rise in the vessels at all, but is conveyed through the cellular tissue. This opinion necessarily implies the permeability of this tissue by fluids, which, as we have shown, is contradicted by direct experiment, as well as by microscopical observation. Since, therefore, this lateral movement of the sap cannot be accomplished, either by simple percolation through the cells or vessels, or by direct anastomosis of the vessels with one another, no other known means of effecting it remain, but those of alternate deposition and absorption by the vessels into and from the cells. And if, as we have seen, the sap-vessels of plants deposit coloured fluids in the cells which the capillary absorbents of parasitic plants are able to take up, there seems no reason for deny-

Common Textures. ing to the vascular productions, which have been supposed everywhere to spring from the perpendicular vessels, a like capacity of absorbing fluids from the adjacent cells. These fluids must, however, in all cases, have been deposited before they could be absorbed; and by the alternate exercise of these functions, there is no difficulty in conceiving how a lateral movement of the sap might be accomplished, in parts, where, by the incision of the vessels, a stop was necessarily put to its perpendicular ascent.

### Section IV.

*Of the Skin or Cuticular Texture, and its Appendages.*

#### Article I.

*Description and Structure of the Skin.*

[T]he Skin. 138. The skin, rind, cuticle, or epidermis, as it has been variously named, is the last of the common textures that remains to be described. It is the general envelope which invests all parts of the plant and all its productions, being equally common to the trunk and branches, the root, the leaves, the flowers, and the fruit; but in these different parts, and even in similar parts of different plants, it exhibits the greatest diversity of appearance, form, and texture.

[D]escrip[ti]on. 139. In herbaceous plants, and in the young shoots of those which are arborescent, it resembles a thin membrane, but is generally thicker on the stem than on the roots or leaves, and is of still more delicate texture where it is extended on the flowers. In some leaves, however, it is thick and dense, as is the case also in several fruits, and is thereby fitted to resist the effects of too rapid desiccation. On the upper surface of some leaves, on many fruits, and on roots, it is an entire membrane, destitute of any apertures or pores; but on many stems, on the under surfaces of leaves, and sometimes on the upper, it is frequently furnished with numerous pores, often visible to the naked eye, and with other luminous points of smaller dimensions, which Du Hamel also regards as apertures. It is readily separable from the bark in recent and succulent parts, or after maceration in water; and, in certain leaves, it is very completely separated by a species of caterpillar, named by Reaumur, the *miner*. It appears then to be a thin transparent membrane, often destitute of colour, and deriving, therefore, its appearance from the colour of the parts beneath; but both in leaves and flowers it is often itself coloured. It is frequently seen to extend in all its dimensions, in common with the parts it covers. Very often too, as will be noticed hereafter, its surface is covered with hairs, and sometimes small follicles or utricles are met with, which exercise a glandular function.

[In] Young [Tr]ees.

[In] Old [Tr]ees. 140. The characters above enumerated belong chiefly to the cuticle in its young and succulent state: In perennial plants, it commonly possesses others that are quite dissimilar. It is of a different colour not only on different trees, but on different parts of the same tree. It is white and shining on the trunk of the Birch, and browner on the branches; greyish on the Plum-tree; red and silvery on the Cherry; green on the young branches of the Peach, and ash-coloured on the larger branches. In these and many other instances, it does not, says Du Hamel, merely participate in the colour of the body it covers, but contributes itself to give colour to the exterior bark; for when it is stripped off, the substance below has frequently a different colour. (*Phys. des Arbres*, Tom. I. p. 10.) By the gradual enlargement of the trunk it is stretched and dried, and at length loses its vitality, and, as well as the bark beneath, is variously cracked and broken. Before this happens, however, it often undergoes considerable extension in all it dimensions, enlarging in breadth, and stretching longitudinally over the young shoots. This expanded state is particularly remarkable in certain fruits, in which, when they enlarge slowly, the cuticle is extended without rupture, to a very large size; but if the expansion be very rapid, as after considerable rains, the cuticle then gives way. In certain trees, the cuticle is more susceptible of expansion than in others; and in very vigorous trees, it breaks more slowly than in those whose growth is languishing, although these latter push forward more slowly than the former. (*Ibid.* p. 11.) In some vigorous trees of this description, it altogether resists rupture, and in this state the tree is often said to be hide-bound, or bark-bound.

141. In most instances, the cuticle, when taken from young branches, appears to consist of a single layer; but on the branches of many species, says Du Hamel, after one plate or layer has been removed, another may be seen beneath, which resembles the former in its texture, but is much thinner and more green and succulent. From the Birch-tree, he has removed more than six layers, very thin and very distinct from each other, and is of opinion that more might still be separated. Sometimes the original cuticle seems to be entirely thrown off, and the exterior covering is formed by a portion of the cellular tissue of the bark. Grew thinks that this substitution takes place annually, the older skin being cast off like the skin of an adder, by the generation of a new one beneath. (*Anat. of Plants*, p. 114.) Du Hamel describes also the existence of small leaflets or scales, which are continually detached from the cuticle of some trees; and these he considers to be as constantly replaced, by the formation of new ones beneath them. Composed of Layers.

142. Concerning the regeneration of the cuticle on parts from which it has been removed, Du Hamel observes, that when the wound is covered with waxed-cloth, a new cuticle is promptly formed without any separation of a portion of the bark beneath. When the exterior portion of the bark is removed with the skin, the inner part of it is equally capable of regenerating a cuticle; but if the wound be not protected from the air, a certain degree of exfoliation first occurs, and, under the decayed parts, a new skin forms. Even where the bark of a Cherry-tree was entirely removed from the trunk, he found that the wood was capable of regenerating a new bark and cuticle, if the parts were properly protected from the air. This cuticle did not originate from that which remained on the roots and branches; but was reproduced in isolated portions on different parts of the trunk; it continued, however, after the Is Regenerated.

Common Textures.

lapse of fifteen years, always different from that of the natural growth. In other instances, he adds, the cuticle does not seem to be regenerated at all. He remarks certain analogies to exist between the cuticle in some plants and in animals. Both, he adds, seem, in certain circumstances, capable of great extension; both are easily regenerated, and that in isolated portions, and not by continuity of organs, as is common in other instances; and both, lastly, are perpetually obliterated, and continually and imperceptibly renewed. (*Phys. des Arbres*, Tom. I. p. 11.)

Its Nature.

143. With respect to the nature of the cuticle, very different opinions have been advanced, and still continue to prevail. Are we to regard it as a peculiar organ, formed immediately by the proper exercise of the vegetative functions, or is it produced in a sort of secondary manner, by some changes induced on some previously constructed organ? Grew asserted it to be sometimes original, and in some instances produced out of the exterior layer of the cortical texture beneath it; and this view of its origin seems to be generally supported by the descriptive character which has been assigned to it. Its coexistence with the first traces of vegetable organization, its continued growth and expansion, and its subsequent regeneration, after removal, all seem to favour its primary and independent origin; and this view is also supported by investigations into its minute structure. Mirbel, however, and some other writers after Hill, have regarded it, in all cases, not as an original membrane, but formed by the exterior sides of the common tissue of the plant; and where there is no separation of these sides in the form of a membrane, such plants are held to be destitute of a cuticle. (*Exposit. de l'Organisat. Vég.* p. 103.) This may assimilate very well with the mechanical views that pervade all this author's speculations concerning vegetable organization; but will, we suspect, make few converts among those accustomed to contemplate the powers and properties of living textures.

Its Structure.

144. Another question relating to this organ is, Whether it must be considered a simple membrane of uniform structure, or a compound of two distinct parts, like the true skin and the cuticle in animals? Grew seems to have regarded it as a simple body, but constructed both of vessels and cells, the cells being continuous with those of the bark. (*Anat. of Plants*, p. 62.)

Opinion of Grew;

Such too seems to have been nearly the opinion of Malpighi, who describes it as constructed of horizontal ranges of cells, but often delineates reticulations of vessels as constituting a part of its structure. (*Anat. Plantar.* p. 2—19.)

of Malpighi;

In the Birch, the Plum, the Cherry-tree, and others, Du Hamel declares the component fibres of the cuticle to possess a direction transverse to that of the trunk; but this is not general. In the Birch-tree, the fibres seemed to be placed parallel to each other, and to be connected together by lateral fibres; but he could see nothing of the vesicular structure of Malpighi and Grew, and regards, therefore, the structure of this texture to be altogether fibrous. (*Phys. des Arbres*, Tom. I. p. 8 and 9.)

of Du Hamel;

M. Desfontaines, on the other hand, describes it as a membrane, resembling in appearance a thin plate of parchment, and perforated by imperceptible pores, which give issue to the insensible transpiration. Its structure he regards as unknown, but considers it capable of regeneration. (*Mém. de l'Instit. Nat.* Tom. I. p. 481.)

of Desfontaines;

of Kieser;

145. M. Kieser, who professes to have studied this texture with great attention, adopts nearly the opinion of Grew; pronouncing the cuticle to be constructed of a very fine cellular tissue, and of extremely minute vessels, which run through its whole extent. These vessels form an exceedingly delicate and subtile net-work, the meshes of which possess very different forms, and their vessels terminate at the orifice of a pore. His observations were made on the cuticle of leaves. On the inferior surface of the leaf of *Amaryllis formosissima*, (fig. 14. A. Plate XVIII.) magnified 260 times, these vascular meshes of the cuticle have an elongated hexagonal form; and four of their vessels proceed always to terminate at the orifice of the little oblong aperture or pore situated at their junction. In *Canna Indica*, the vessels of the meshes on the lower part of the leaf, which thus terminate in the pores, are said to originate from a fasciculus of the spiral vessels that ramify through the leaf; as is represented at *a'* in fig. 14. B. Plate XVIII.; and within the areas of the larger meshes, a still finer net-work of vessels is seen. On the inferior surface of the leaf of a species of Fern, the vessels of the cuticle, instead of forming meshes of different figures, exhibit the appearance of sinuous lines, which run in every direction through the cuticle. See fig. 15. Plate XVIII. which represents the central part of the little adjoining leaf, magnified 130 times. These sinuous vessels often join, and, after making a half circle, terminate by one extremity in the minute pores everywhere spread over the leaf, and by the other in the larger vascular fasciculi that ramify through it. At the letter *b'*, in this figure, the hexagonal cells that construct the parenchyme of the leaf, are distinctly visible through the vascular sinuosities of the cuticle. It was by the examination of this leaf that M. Kieser was first enabled to discover the origin and termination of the vessels that construct the cuticle; having in all his previous investigations examined the cuticle in its separated state, after it was detached from its connection with the other organs; but the researches made on this leaf rendered everything clear. (*Mém. sur l'Organisat. des Plantes*, p. 141-2.)

of Krocker and others.

146. The vascular net-work of the cuticle, thus described by M. Kieser and others, had been regarded as a deception by M. Krocker, who considered these reticulated figures as no part of the real structure of the cuticle, but merely as the sides of the subjacent cells; in which opinion, Sprengel, Link, Jurine, and Mirbel, concurred: but M. Kieser, in opposition to this opinion, maintains that, in the Fern and other leaves, the real cellular structure of the parenchyme is seen entire through the vascular reticulations of the cuticle, with the meshes of which the sides of the subjacent cells do not anywhere coincide. He observes that these cells are commonly much smaller than the vascular meshes which cover them; and that the vessels of these meshes may be traced, as before remarked, to the larger fasciculi that construct the leaf. In the Fern, the vascular structure of the cuti-

Common Textures.

cle is the same on both sides of the leaf, but the superior side does not possess pores.

Opinion of De Saussure:

147. A very different view of the structure of the cuticle was taken by the late celebrated M. De Saussure. He regarded it not as a simple, but a compound texture, consisting of a very delicate external pellicle or membrane, beneath which was placed a net-work of very fine vessels. The external membrane he describes as perforated by pores of unequal figure, between which he observed some opaque and tortuous filaments, disposed in a reticulated manner, each mesh being formed by six filaments, four of which terminated at each pore. To this arrangement of filaments, he gave the name of cortical network, and regarded it as quite distinct from the cuticle that covered it. The meshes of this net-work differ much in size and figure in different leaves; and, when minutely examined, they are often seen to form junctions, but never to cross each other; whence he was led to regard them as vessels derived from those of the expanded petiole, and thus constituting a very fine vascular net-work. A similar structure was observed in the petals of the flower. (*Encyclop. Méthod.* Tom. I. p. 67.)

of Decandolle.

148. M. Decandolle, to whose researches we before alluded when treating of the absorbent system, adopts a similar view of the compound nature of this texture. He describes it as consisting of a proper cuticle, and of a cortical net-work, the vessels of which terminate at oval pores, more or less elongated. Around these pores, the vessels (or fibres, as he calls them) form an oval ring, which is connected to the rest of the net-work, by two, three, or four radiating vessels, derived from the vessels of the petiole. These vessels of the petiole he considers to form, first, the larger vascular fasciculi; then, by their subdivision, the parenchyme of the leaf, and afterwards to construct the net-work that terminates at the pores. The form of the meshes of the vascular rings, and of the pores, is the same always in the same species, and on the same faces of the stem, the leaves, and the flowers. (*Mém. de l'Institut. Nat.* Tom. I. p. 351.)

149. Such are the very different opinions held by enlightened observers concerning this texture. Each professes to have given descriptions from accurate microscopical observation, and it would therefore be presumptuous, on mere reasoning alone, to decide on their respective merits. Granting to each party similar credit, as far as regards accuracy of observation, we confess that the latter opinion seems to us, on other grounds, best entitled to preference. In both views, the direct connection of the vascular system with the external pores of the leaf is admitted, which is perhaps the most important point in the inquiry; and the only difference is, whether these vessels shall be regarded as a constituent part of the cuticle itself, or as forming a fine vascular net-work, connected with, but still distinct from it.

### Article II.

#### *Of the Pores of the Skin.*

Description of Pores

150. The pores of the cuticle, called sometimes cortical or miliary glands, so often mentioned already, deserve a more detailed description. They were first noticed by Grew, who describes many orifices as existing on the leaves of different plants, which vary in size, number, shape, and position. In the white lily, they are of an oval shape, of a white colour, and each is surrounded by a slender border. When viewed through a good glass, they appear as if standing about $\frac{1}{6}$th or $\frac{1}{8}$th of an inch apart all over the leaf, but not arranged in any regular order. In the Pine also, they have an oval shape, but have no rising border; and are arranged in lines from one end of the leaf to the other. (*Anat. of Plants*, p. 153.) Hedwig considered the borders mentioned by Grew, as produced by a ring of one or more vessels which terminated in the pore. The number of pores he represents as exceedingly great. In the square of a line of the cuticle of a bulbous lily, he reckoned 577 pores.

by Grew:

by Decandolle.

151. The characters and position of these pores have been farther examined by M. Decandolle, on more than 600 plants. They occur most frequently on the leaves, occupying both surfaces in herbs, and in trees chiefly the inferior surface. Stems, in general, have no pores, except, as in the *Gramineæ*, where they are succulent, and have the character of leaves, or where the plant is altogether destitute of leaves, as the Cactus. On the prominent lines of the leaves and stems, no pores are to be seen, but only in the grooves or depressed surfaces. They are never observed on the root, not even on bulbous roots, where the scales of the bulb are true leaves. The small leaflets called *stipulæ* and *bracteæ*, sometimes have, and sometimes have not, pores. The *calices* of the flower, in general, have pores, but the petals have not. Pericarps exhibit great variety in regard to pores; fleshy fruits are generally destitute of them. The envelopes of the seed are destitute of pores, but they are found on all seminal leaves that rise above the ground. The lower tribes of vegetables, as the *fuci, musci, hepaticæ, fungi,* &c. are destitute of pores.

Influence of Air on the Pores.

152. The occurrence of pores in those plants where they are found, seems to be much influenced by external circumstances. They are never met with but on vegetables, and those parts of vegetables that are exposed to the air; and, therefore, the internal surfaces of many leaves that embrace the stem are without pores, though, on the external surfaces of the same leaves, they are abundant. No plant that is completely aquatic, nor any part of it that is habitually under water, is provided with these organs, but the parts which rise above the water, are furnished with them. In *Ranunculus aquaticus*, the leaves that are constantly under water, are destitute of pores, while those that float on the surface are provided with them, but only on their superior face. Even leaves, which do not naturally possess pores when under water, acquire them if they are made to grow in air; and land plants, on the contrary, when made to grow under water, may, by such treatment, be deprived of their pores. Thus, the leaf of green mint, when growing in air, possesses not fewer than 1800 pores on its lower surface; but if kept for a month under water, its leaves fall, and the new ones that succeed are destitute of pores,

Common Textures.

Of Light on Pores.

153. Light seems to be necessary also to the production of pores, for etiolated plants do not possess them. When grown by the light of lamps, the leaves possess a few pores; and in all cases, the parts secluded from light and air are destitute of these organs, but acquire them if they are duly exposed. These pores, M. Decandolle, as we had before occasion to remark, considers to perform alternately the functions both of transpiration and absorption. (*Mém. de l'Instit. Nat.* Tom. I. p. 351.)

Researches of Rudolphi.

154. This general account of the pores of plants is confirmed by the researches of M. Rudolphi. In most herbaceous plants, he found the pores to occupy both sides of the leaf, but in trees, only the inferior surface. They were not often met with on the parts of the flowers, or on fruits; they were never seen on roots, nor on the trunks of trees; nor ever on aquatic plants, except on such parts as were raised above the water. The lower tribes of vegetables seemed to be universally destitute of them; the leaves also of those plants that were covered thickly with hairs on both sides had no pores. The form of the pores was commonly oval or elliptical, but in a few instances square or rhomboidal. In size they very much varied in different plants, but in the same plant the size was uniform. The largest pores were seen on the leaf of the white lily; the smallest on that of the French bean. (*Kieser's Mém. sur l'Organisat. des Plantes*, p. 144.)

Pores not essential to the Cuticle.

155. From these accounts of the occurrence of pores, and of the conditions necessary to their production, they cannot be considered as an essential, or indeed a primary character of the cuticle; but as owing their existence to the more perfect exercise of the vegetable powers. Hence the probability that they are caused by innumerable vascular productions from the larger fasciculi of vessels, which gradually penetrate the cuticle, and thus open a way for the discharge of their fluids, as the researches of De Saussure and Kieser seem to prove. That the exclusion of air and light should prevent the formation of pores in the cuticle, is nothing more than we see daily on a larger scale, with regard to branches themselves; for trees that grow very much crowded together, seldom produce branches from their sides; and if herbaceous plants be made to grow entirely secluded from light, they run altogether into stalk, and produce no buds or leaves from their sides.

### Article III.

### *Of Hairs.*

Description and varieties of Hairs:

156. From the surface of the cuticle, in many parts of herbaceous plants, and in the succulent parts of arborescent ones, hairs (*pili*) are seen to spring. They possess very different forms, and vary likewise greatly in texture. In a strict sense, they may be defined small filaments possessing considerable stiffness, which project from the surface, and stand out pretty erect. When they are very numerous, a little soft, and less erect, they take the name of *villi;* when still softer and less numerous, they are termed down *(pubes)*. Sometimes this down is composed of long hairs nearly resembling wool; at other times it approaches more to the character of cotton. When the hairs are stiff and ranged along the edge of a surface, like the lashes of the eye, they are named *cilia;* and if, with these characters, they are produced to a greater length, as in the beard or awn of wheat, they acquire the name of *barba* or *arista*. Sometimes they resemble the bristles of the hog, and are then called *setæ*. Many other varieties are enumerated by botanists, who farther distinguish them by various names, according as they terminate in a single point, or are hooked, or forked, or branched, or feathered, &c. In some instances, instead of appearing like one continuous substance, they are composed of many joints, or are said to be articulated. In figures 16. and 17. Plate XVIII. we have copied from Du Hamel a few of the varieties, both of single and jointed hairs; but the forms they exhibit are so numerous and diversified, that we must refer to the writers on botany for minuter information. In some examples, the point of the hair is terminated by a small rounded globulet, and sometimes by a fine filament that seems to proceed out of the hair.

their Position:

157. According to M. Decandolle, these several varieties of hairs appear generally on those parts of the stem and leaves that are destitute of pores; that is, on the prominent lines formed by the fasciculi of vessels, and which have been absurdly called the *nerves* of the leaves. They appear also on the edges of leaves, whose pores are never seen, so that, in position, the hairs and pores always differ. *(Mém. de l'Institut. Nat.* Tom. I.) On the petals of flowers, as well as on leaves, various capillary productions also occur, which frequently contribute much to their richness and beauty.

Structure.

158. With regard to the structure of these minute bodies, little that is satisfactory can be said. They seem to originate either directly from the cuticle, or from the cortical texture beneath it; but not often from the ligneous texture, except in those instances where they are very long and rigid, as in the awns of wheat. Du Hamel observes, that almost all of them are implanted on small bodies, similar to the bulbs which give origin to the hairs of animals. *(Phys. des Arbres*, Tom. I. p. 183.) They commonly resemble simple filaments, but often appear like elongated cells threaded on one another, and, instead of terminating in a sharp point, end in a small papilla or utricle, which yields, in many instances, a viscid or oily matter, or sometimes a coloured liquor, which has led many to regard them as exercising a glandular function. One species of these supposed glandular organs has been more particularly studied, and their fluid analysed by M. Deyeux, who gives the following account of it.

Hairs of Chick-Pea.

159. Soon after the seeds of the chick-pea (*Cicer arietinum*) are sown, its first leaves are seen to be covered with hairs, at the extremity of each of which is a transparent globule, about the size of a small pin head, consisting of a fluid matter. It abounds most in mid-day, when the air is warm and dry, and is scarcely perceptible at night, or when the air is cold and moist; after rain, indeed, it does not again appear for two or three days. When these fluid globules were removed, in a dry day, by blotting paper, they soon again reappeared; they were acid to the taste,

Common Textures.

reddened litmus paper, and caused an effervescence in carbonate of potass, when brought in contact with it. He regarded them as composed of oxalic acid, the properties of which they precisely resembled. (*Mém. de l'Instit. Nat.* Tom. I. p. 157.)

Hairs not Glandular.

160. These acid globules, and perhaps the other viscid, and oleaginous, or resinous substances furnished by hairs, are not, properly speaking, glandular secretions; but peculiar fluids, which, after their separation from the fluids of the leaf, experience certain changes from the agency of heat and light, during their passage through these delicate organs. There does not, therefore, seem any good reason for considering such bodies as glands. Many have considered these hairs, as the organs by which transpiration is carried on, and others, as those by which dews and fluids are absorbed—offices for which their structure seems but little fitted; and the transpiring and absorbing powers of leaves, are in proportion to the number of their pores, and not of their hairs. In many instances, they are obviously designed for protection against cold and moisture; but this is not the place to consider their uses, farther than is necessary to assist in establishing their anatomical character.

### Article IV.

### *Of Prickles.*

Definition:

161. It is not easy to discriminate between some of the harder species of hairs, described in the former article, and those to which the appellation of prickles (*aculei*) has been assigned. They are defined by Du Hamel to be excrescences, often hard, and always terminated by a sharp point, which are developed with the other productions of plants, but are not enclosed in particular buds; so that they may, for the most part, be regarded as hard and solid hairs.

Position:

162. They spring equally from the stem, the branches, the petioles of the leaves, and also from the leaves themselves in various plants; and in the Chesnut and some others, they are seen to cover the fruit. They are frequently strait, but in the Rose and many others are curved at the point, as in fig. 18. Plate XVIII.; and, according to Malpighi, possess sometimes in this plant a little head, which yields a viscid fluid.

Structure.

163. Regarding their structure, Grew remarked, that they were connected only with the skin or the bark, and he therefore named them *cortical*, to distinguish them from thorns, properly so called, such as those of the Hawthorn, which spring from the wood, and which he denominates *ligneous*. These latter, he adds, always ascend, while the cortical thorns commonly point downwards. (*Anat. of Plants*, p. 33.) In proof of their origin from the bark, Du Hamel remarks, that, if, after maceration in boiling water, the bark of such plants be stripped off, all the prickles come away with it, and leave not the smallest impression on the wood, nor even on the more interior layers of the bark itself. When a section also is made of the branch and prickle, as in fig. 18. Plate XVIII. the wood $y$ and the pith $z$ are both seen to have no connection with the prickle, but the inner layer of the bark $x$ is interposed between the base of the prickle and the wood. The prickle does not, however, spring from the skin, for it is formed of many layers like the bark. As the parts become more solid, it is less freely supplied with juice, and therefore hardens and turns brown. (*Phys. des Arbres*, Tom. I. p. 188.)

Prickle of the Nettle.

164. In the Nettle (*Urtica dioica*), Malpighi states, that, beside the common prickles on the leaves, there are among them others of a different description. They possess more of a ligneous character, are hollow internally, and contain a juice, which, when it gains admission beneath the skin, excites itching and tumour. (*Anat. Plantar.* p. 137.) Dr Hooke had previously given a much more minute account of the sting of this plant. Almost every part of it, says he, is covered with prickles, like sharp needles. Each prickle consists of two parts, very different in shape and quality from one another; one is shaped much like a round bodkin, is very hard and stiff, exceedingly transparent and clear, and hollow from top to bottom. When this bodkin is thrust into the skin, it does not at all bend; but a certain liquor is then seen to move up and down in it, rising towards the top, when the point is pressed down on the base. This base is formed by a little bag, is more pliable than the bodkin part, and within it is a cellular structure which contains a thin transparent liquor; see fig. 19. Plate XVIII.; it is this liquor that rises in the tube, and, being deposited beneath the skin after it is punctured, excites the irritation that succeeds. (*Micrographia*, p. 142.)

From the analogy in structure between thorns, properly so called, and branches, we shall defer their consideration until we come to treat of the structure of the branch.

## Section V.

### *Of the Glands of Vegetables.*

Ambiguity of the term Gland,

165. Perhaps, in the whole science of Anatomy, there is no word that has been employed with such latitude of signification, and is, therefore, exposed to so much ambiguity, as the term *gland*. In animal anatomy it was doubtless used at first to denominate certain organs from the external resemblance which they bore to certain fruits or seeds; and in that sense it is still employed on several occasions. Afterwards, it was understood to signify not so much the external form as the internal organization, and was considered to express a certain structure, by which alone the function of secretion could be exercised; but it is well observed by Dr Thomson, in his valuable work on Inflammation, that "the definition of a secreting glandular part must be taken from its function, and not from its structure; for nothing can be more various than the internal structure of those organs that are denominated glandular secreting organs; they consist sometimes of convoluted vessels, sometimes of follicles or small hollow bags, and sometimes of transparent membranes, in which neither convoluted vessels, nor mucous follicles, can be perceived." (*Lectures on Inflammation*, p. 318.) Besides these more simple structures, it is well known that most of the internal *viscera* are likewise denominated glands, though differing, in all their characters, from those just mentioned.

in Animal Anatomy.

Common Textures.

In Vegetable Anatomy.

166. The ambiguity which thus prevails in animal anatomy, in relation to the use of the term gland, has been increased tenfold in the applications that have been made of it to the organs of vegetables. It is justly observed by M. Decandolle, in reference to this subject, that the numerous approximations in structure between vegetables and animals have often promoted our researches into the former, but have sometimes led physiologists astray, and introduced into the language of botany many inexact expressions. In animal anatomy, the term gland is understood to express some organ that exercises a secretory function; but, in vegetable anatomy, this term has often been applied to bodies that are not known to be real secretory organs. Thus, the cells of the cellular tissue, which frequently contain resinous or oily matter, have been sometimes named *cellular glands;* the little globulets or utricles at the extremities of the hairs on the edges of leaves, *utricular glands;* the small organs formed by the pores on the leaf, *cortical* or miliary *glands;* certain fleshy tubercles on the leaves, *urceolar glands;* and the little scales that cover the fructification in ferns, *scaliform glands.* The *nectarium* of the flower commonly contains a sweet juice, and is, therefore, deemed a gland; but Linnæus, with his usual disregard both of the structure and function of organs, considers as a nectary, not only the body which may secrete, but any other that may serve as a receptacle of the secretion; and, indeed, is said to comprehend under this term all those bodies which have no resemblance to the other parts of the flower, in whatever variety of form they may appear, or whatever purpose they may serve. (*Willdenow's Prin. of Botany*, p. 87.) In some other instances, the term gland has been used not to express the secreting organ itself, nor even the receptacle of the secretion, but the solid excreted matter on the surface of certain leaves; and others consider hairs, and every other protuberance that projects from the surface, and contains a fluid different from the common sap, as entitled to the distinctive appellation of gland.

Difficulty in defining Glands.

167. Amid such diversity of opinion concerning the structure, position, and function of these minute organs, and such vagueness in the methods employed to characterize them, it is extremely difficult to define their true nature, or declare the principle on which this definition should proceed. The mere existence of a fluid, distinct from the common sap in any organ, cannot be considered as bestowing on it the title of gland, otherwise the greater portion of some plants would come to be regarded as glandular; those varieties of structure, which exercise no secretory function, may also be excluded from the list of glands; and so likewise the hairs of plants, though containing peculiar fluids, may be excluded, since these peculiarities appear to arise frequently from circumstances foreign to the action of the organ itself, and even if they do not, some specific variation of the general name they bear is preferable to the employment of so ambiguous a word as gland. But where any organ is distinct from the common textures of the vegetable, and, by the peculiarity of its structure, is fitted to produce those changes on the vegetable fluids which we name secretion, it may be deemed a secreting organ. This secretory function, however, may sometimes be exercised, as in animal bodies, by membranous surfaces, and sometimes by small isolated bodies, to which, perhaps, may properly belong the denomination of glands.

Modes of naming them:

168. But, even though this method of defining glands were adopted, it still is a matter of no small difficulty to distinguish their species by appropriate appellations. In animal anatomy, no settled rule obtains; but the name of the gland is assigned from some accidental circumstance of situation, figure, use, &c. In vegetable anatomy, the botanist, regarding glands only as aiding the discrimination of species, refers commonly to their situation, and speaks of foliaceous, stipular, or petiolar glands, according as they happen to be seated on the leaves, the stipulæ, or the petioles. The anatomist imposes names according to their forms, as they chance most to resemble a globule, an utricle, or some other figure; and the physiologist is chiefly directed by ideas which indicate their functions, distinguishing them into mucous, oily, resinous, or nectariferous glands, according to the nature of the fluid they furnish. Of these different modes, that which proceeds on the apparent form, where it can be discovered, seems the most precise; but as this cannot always be accomplished, the situation of the organ, or the nature of the secreted fluid, must occasionally be had recourse to.

are placed externally.

169. Of these bodies, it is to be remarked that they differ in one respect from most of the corresponding organs in animals, almost all of them being seated on the *external parts* of the plant, like several of the more simple glandular bodies in animals. This arises from the greater simplicity of vegetable organization, particularly as it regards the absorbent system, the mode of growth, and the permanence of the organs produced; whence it happens that the living parts of aged perennial plants are situated only at, or near the surface; and it is only in such parts that active secretory functions can have place. Hence it is on succulent stems, on leaves, flowers, and fruits, during the active state of vegetation, that the glandular functions of vegetables must be exercised, and which parts, therefore, are the appropriate seat of glands.

Species of Glands,

170. In some leaves a secretory function extends over a great part of the surface, as in some species of *Cistus*, of Sugar-maple, of Larch, and others, enumerated by Du Hamel, on which various collections of saccharine, gummy, and resinous matter are found. (*Phys. des Arbres*, Tom. I. p. 183.) On the leaves of Sage, Hooke mentions the occurrence of an infinite number of round balls resembling pearls, and which, says he, are nothing but a gummy exudation. (*Micrographia*, p. 142.) M. Gnettard has described not fewer than seven species of glandular bodies on the leaves of different plants, to which he assigned names, chiefly from the appearance of their form; these are the *miliary*, the *vesicular*, the *squamous*, the *globular*, the *lenticular*, the *utricular*, and the *urceolar* glands. Of these reputed species, those called miliary are no longer held to be glands, but cuticular pores; and the squamous species is found

by Gnettard:

Common Textures.

to be identical with the thin scale that covers the fructification of ferns. Others add to this list the organ called nectary; but the very vague notions entertained of its nature and use altogether preclude the possibility of assigning to it any precise anatomical character.

by others.

171. Other writers have proposed to reduce all the bodies called glands to two classes, the *cellular* and the *vascular*, according as they conceive them to be formed of cellular tissue simply, or of this tissue and vessels combined. But such an arrangement would lead us, in some instances, to confound the mere receptacles of secreted fluids with the organs that secrete them; would bestow a secretory function on organs, considered by these writers to be *non-vascular;* and convert the entire cellular tissue of the plant into a simple glandular body. The glands of plants may indeed possess the form and size of cells; but they are not, like cells, close cavities; they resemble more the follicles and mucous glands of the animal system, and, from the nature of their function, must always be regarded as vascular.

Of organs so minute, and so very imperfectly known and characterized, nothing can be attempted in the way of anatomical demonstration. This, however, is the less to be regretted, as the glandular system in plants appears, in general, to be of much less consequence in the vegetable, than it is in the animal economy.

# PART II.

## THE ANATOMY OF THE INDIVIDUAL MEMBERS AND ORGANS OF VEGETABLES.

Preliminary Observations.

172. In the preceding Part, we have described, in general, the nature of the elementary organs and common textures that compose the entire plant; and we come now to the second division of our subject; viz. the description of individual members and organs. Following the method of Grew, we shall first exhibit the anatomy of the seed, and the changes of form and structure displayed in its evolution. We shall next treat of the mature plant, and exhibit views of the more remarkable varieties of structure observed in its several members, as the trunk, the branch, and the root. The organs that originate from these members, as buds, leaves, flowers, and fruits, will then be duly noticed; and we shall terminate our descriptions by a brief exhibition of the formation and structure of the vegetable *ovum* in its progress towards the state of the perfect seed.

The limits within which, in a work like the present, we are necessarily circumscribed, will render our view of these individual structures, when compared with the immense variety that obtains in nature, exceedingly imperfect; but our purpose will be accomplished, if we succeed in exhibiting a correct and tolerably comprehensive outline of the great features of vegetable organization, as they are displayed in the individual parts and organs of the more perfect plants.

### CHAP. I.

#### THE ANATOMY OF SEEDS.

#### SECTION I.

#### *Of the Structure of Seeds in general.*

#### ARTICLE I.

#### *Of the External Characters and Component Parts of Seeds.*

The Seed:

173. The seed or egg of vegetables *(semen vel ovum)* is formed at the base of the pistil of the flower, in an organ called the ovary *(ovarium)*, hereafter to be described. To this organ it is attached by a small stalk, called the umbilical cord *(funiculus umbilicalis);* but sometimes, it is said, this cord, probably from its extreme tenuity, or implication with other organs, cannot be discovered. When the seed has attained to maturity, the umbilical cord dries up and breaks; and the ovary, in different plants, opens in various ways, to permit the escape of the seed.

its attachment to the Ovary.

174. The seeds of different plants exhibit the greatest diversity in number, size, and figure. Sometimes they are few; in other instances very numerous. In one plant of white Poppy, Grew reckoned 32,000 seeds; and on the spike of a species of *typha*, he numbered 40,176 seeds; so that, upon the three spikes which one stalk of this plant bears, there are every year produced more than 120,000 seeds. (*Anat. of Plants*, p. 198.)

Numbers of Seeds:

175. In figure, the varieties in seeds are so numerous as to baffle description; and, with respect to size, many are so minute as not to be visible to the naked eye, and others so large as to reach several pounds in weight. The minute corpuscles, which are held to represent the seeds of certain cryptogamous plants, have received particular names from different writers; but mere difference in size seems not, in an anatomical view, to afford any just reason for such distinctions.

their Size and Figure.

176. The part at which the seed has separated from the ovary, is indicated by a small mark or scar, called by Malpighi *fenestra;* by Linnæus *hilum;* and by Gærtner *umbilicus.* In some seeds, this scar is of considerable extent, and is the only mark that is visible; in other instances, there seems to be present a *foramen* in addition to the scar. All seeds, says Grew, have their outer coats open, either by a particular aperture, as in the bean C. fig. 21. (*a*) Plate XV., or by the breaking off of the cord, or by the entrance of the cord into the substance of the seed, as in those which have a shelly or stony covering. In the Bean, this aper-

Umbilicus of the Seed.

Of the Seed. ture is placed on the side; in the Chesnut, on the top; in the Gourd, at the bottom; and in each case, the point of the radicle is opposed to the aperture, and first pushes forth through it. (*Anat. of Plants*, Book I.) In many seeds, however, the radicle is not thus opposed to the umbilicus; but, according to Gærtner, is variously placed with regard to it; and in the seeds of the Apple and Pear, Malpighi considers no proper umbilical aperture to exist, but only an *hiatus* to be formed by the relaxation of the tunics, through which the radicle makes it way. (*Anat. Plantar.* p. 9.)

Varieties in its Form. 177. There can be no doubt, that, in every case, a connection subsisted between the seed and the ovary, during the formation of the seed; but this, in different examples, may have much varied. In all cases, an umbilical cord must have existed, and appears, in many examples, from inspection of mature seeds, to have been the only visible medium of connection. In the Bean, however, beside the umbilical cord, there are marks of a connection also between the coats of the seed and those of the ovary that contained it; so that the scar or cicatrix, in that and similar cases, is distinct from the umbilical aperture. The scar is the mark left by the separation of the tunics continued from the ovary; the foramen is the aperture produced by the separation of the umbilical cord. It will be afterwards stated, that the outer coat of the seed appears always to have originated from the inner coat of the ovary; so that it forms a sheath about the umbilical cord. If, therefore, as in the Bean, these coats are thick, and the umbilical cord short, then traces of the separation, both of the coats and of the cord, will remain on the seed; if, on the other hand, the coats are thin, and the cord more elongated, this latter will be closely invested by the former, and the umbilical scar will present the appearance only of a simple aperture, as is common to many seeds.

Opinion of M. Turpin. 178. A late writer, M. Turpin, regards the umbilical scar as consisting of three parts, viz. the proper cicatrix itself, in the centre of which he describes an aperture through which the nutrient vessels passed to the embryo, and near to it another smaller aperture, through which he believes the spermatic vessels to have passed. The former he calls the *omphalode*, the latter the *micropyle*; and declares, that he observed it in more than 1200 seeds. (*An. du Mus. d'Hist. Nat.* Tom. VII. p. 199.) Aware, however, of the fallacy of microscopical observation employed on such minute objects, we shall suspend our belief in the existence of this structure, until it receive confirmation from some other observer. As yet, we believe, no one has been able to share with M. Turpin the benefit of this discovery.

Regions of the Seed. 179. From the situation of the umbilicus, the several parts or regions of the seed have been defined. They are six in number. The part where the umbilicus itself is placed, is termed the *basis*, and the point at the opposite extremity, the *vertex* of the seed; the upper or back part is named the *dorsum* or back; and the part opposite to it the *venter* or belly; while the two lateral portions are called the sides (*latera*). The point where the umbilical cord is inserted into the inner coat has been named the *internal umbilicus*. This point usually coincides with that of the external, but, from a change in the relative position of the parts during their formation, this coincidence is not always to be observed. (*Gærtner de Fructib. et Seminib. Plantar.* Vol. I.)

Internal Umbilicus.

Coats of the Seed. 180. When examined in its mature state, the seed is found to be composed of certain coats or tunics, which enclose a kernel or *nucleus*, that also consists of several distinct parts. At an early period of growth, while the parts are still green and succulent, two coats are easily distinguished; as in the transverse section of the bean, D. fig. 21. Plate XV.; in which the inner coat appears much thicker than the outer, and the radicle ($b$) is seen rising through it.

Its Nucleus, When these coats are stripped off, the other parts, which form the *nucleus*, are brought into view. They consist, in the Bean and most other seeds, of two distinct parts, the lobes or cotyledons, as they have been called, and the radicle and plume. These several parts can be seen only by separating the two lobes from each other, as is done in fig. 22., where the letters ($cc$) denote the cotyledons, ($d$) the radicle, and ($e$) the plume. Such seeds as have thus two cotyledons are named *dicotyledonous*.

in Dicotyledons.

181. In many seeds, however, the part called cotyledon is single, and bears but a small proportion to the entire bulk of the seed. An example of this kind is presented in fig. 23. which represents a section of the seed of *Canna Indica*. The nucleus enclosed in its two tunics, forms, as before, the chief bulk of the seed, and in its centre appears an oblong body ($f$), which is the cotyledon, at the base of which the minute radicle and plume ($g$) may be discovered. The little oblong body below, represents the cotyledon alone. Seeds, which have thus but one cotyledon, are named MONOCOTYLEDONS; and to this division the seeds of wheat, barley, and all the grasses belong.

In Monocotyledons.

Acotyledons. 182. Some botanists have alleged, that several orders of the lower tribes of plants are entirely destitute of a cotyledon, and have given to such the title of ACOTYLEDONS. This title was formerly considered to apply to all cryptogamic plants; but the researches of the elder Jussieu and of Hedwig, are said to have proved it to be inapplicable to Ferns and Mosses; and the seeds of the *Algæ* and *Fungi* have not yet been discovered. Others assert, that some seeds have more than two cotyledons, and such seeds they have denominated POLYCOTYLEDONS; but others again choose to consider these appearances not as distinct cotyledons, but only as deep fissures, or divisions in two primary lobes—and hence conclude, that all seeds may be classed under the two divisions of mono and di-cotyledons. We are not competent to decide on the merits of these opposite opinions; but shall only observe, that they seem to be governed as much, at least, by preconceived views of system, as by unprejudiced observations of nature.

Polycotyledons.

ARTICLE II.

*Description and Structure of the Coats of Seeds.*

183. Having given this general view of the several parts that compose the seed, we proceed now to a more particular description of their structure; and,

Of the Seed.

as the tunics come first into view, we shall begin with them. These tunics, in some seeds, are two; in others, three, in number. By Grew, they were named coats or covers; by Malpighi, *secundinæ;* and by Gærtner, *testa* and *membrana interna.* We shall speak of them in the familiar terms of the outer, the inner, and the middle coats, or tunics.

Number of Tunics.

Outer Coat.

184. The outer coat or *testa* of Gærtner, is described as a constant and essential part of the seed. It existed before the period of fœcundation, and is sometimes the only apparent covering possessed by the mature seed. Some seeds have indeed been considered to possess no tunic whatever; and have therefore, says Gærtner, been named *acocca;* but in such seeds there existed a coat before they arrived at maturity, and its apparent absence has been inferred from its extreme thinness, or its condensation with the sides of the surrounding ovary. (*De Fructib. Plantar.* Vol. I. p. 132.) A distinguished botanist, however, Mr Brown, is said to have lately discovered two examples of seeds absolutely destitute of a covering, from their first appearance to their state of maturity. (*Thomson's Annals of Philosophy,* Vol. I. p. 310.)

Its Structure.

185. In different seeds, this tunic possesses a very different structure, being in some thin and membranous; in others of a spongy or fleshy nature; and in others, again, it approaches to the consistence of leather or bone. But how various soever in this respect, it is always an entire tunic, and has no aperture but that of the umbilical foramen. Its colour is usually deeper than that of the other parts of the seed, and in this particular it presents every possible variety. It has rarely any connection with the nucleus, except in some monocotyledons. (*Gærtner.* Vol. I. cap. 9.) With regard to its origin, Malpighi describes it, in its earliest state in the Almond, as derived from the ovary itself, being composed of reticulated vessels, which spring from the surrounding organ. In other instances, it is thicker, and is distinctly seen to be cellular, as well as vascular; and in the Bean and Pea, little tubes are said by Malpighi to originate from the cells, and terminate by open mouths on the surface. (*Anat. Plantar.* p. 9.)

Its Origin.

Pellicula.

186. Both Malpighi and Grew discovered, in some instances, a very thin membrane to cover this outer coat, which, according to Gærtner, may be found in most seeds, if the parts be scrupulously examined. Its structure is sometimes membranous, often downy, and sometimes mucilaginous; it possesses occasionally considerable thickness, and at other times is a mere pellicle; and thence has been named *pellicula.* It covers the whole seed, and does not ever separate spontaneously from it. (*Gærtner de Fructib.* &c. Vol. I. cap. 9.)

Arillus.

187. Besides this pellicle, another fine tunic named *arillus,* is sometimes observed on the surface of the seed, as in the seed of Euphorbia. It originates from the umbilical cord at the base, and extends more or less completely over the body of the seed. Its structure is very various, being sometimes soft and pulpy; at others, thin and membranous; and in others, forming a husky covering. It forms, in some instances, only a loose and partial covering; and in others, it invests the seed so closely and completely, that it can scarcely be distinguished from the outer coat itself. Both in figure and colour it often varies greatly; but, like the pellicle before described, it is regarded rather as an accessory, than a necessary integument.

Appendages of Outer Coat.

188. To the exterior coat of the seed, various appendages are sometimes attached, as down, wings, spines, hooks, all designed either as a defence to seeds, or to facilitate their dispersion. They are distinguished and described by the botanist; but are, in general, of too fine a texture to be made the subject of anatomical demonstration.

Inner Coat.

189. The inner tunic (*membrana interna* of Gærtner) is a common, but not constant part of the mature seed. It appears sometimes to be wanting, when in reality it is present. During the formation of the seed, it is frequently so extenuated, or coalesces so completely with the outer coat, that it cannot be properly distinguished. In its earlier state, it is represented by Grew as a very spongy and succulent body, and as thick and bulky as one of the lobes itself; but it dries and shrinks up as the seed approaches maturity, so that it is sometimes scarcely discernible. (*Anat. of Plants,* p. 47.) In the seeds of most plants, it closély invests the nucleus, but is easily separable from the outer tunic. In those of the *Gramineæ,* where the bulk of the seed consists almost entirely of inorganized matter, no separation of this tunic from the contained parts occurs; but its inner surface is formed into a cellular tissue, in the cells of which the nutrient matter is lodged. In other instances, the inner surface is prolonged into processes, which penetrate into the nucleus, and intersect it in various directions.

Its Origin and Structure.

190. This inner tunic does not, like the former, exist before fœcundation, but is formed subsequently to it. It is composed of vessels and cellular tissue. The cells are commonly larger than those of the outer coat. It has no aperture, says Gærtner, not even an umbilical one; but resembles a shut sac, over whose external surface the umbilical vessels creep, and open, in an insensible manner, within its cavity. (*De Fructib.* &c. cap. 9.) The distribution of the vessels throughout the whole of this coat Grew compares to that in the leaf.

Inmost or third Coat.

191. Beneath this inner tunic, Grew describes another fine membrane, which immediately invests the lobes or cotyledons of the seed. In the Bean, it is exquisitely thin, and so firmly continuous with the lobes, that some dexterity is required to accomplish its separation. It is spread not only over the convex surface of the lobes, but also over the inner or flat surfaces, where they are contiguous, extending likewise over the radicle and plume, and so over the whole nucleus of the seed. It does not, like the other tunics, cease to grow in germination, but is augmented and grows with the organic parts. (*Anat. of Plants,* B. I. ch. 1.) This tunic may be regarded either as a covering to the nucleus, or as an actual portion of it, as Gærtner, who speaks only of two coats, seems to have considered it. It appears, however, more proper to regard it as the inmost coat, and thus to conclude with Grew that the covers in most seeds are three. (*Ibid.* B. IV. ch. 3.) The coat last described must, in that case, be considered as the middle tunic, being situated between the outer

Of the Seed. one, and that which is continuous with the nucleus. In many seeds, however, only two coats are distinctly visible.

Uses of the Coats. 192. The foregoing tunics not only contain the nutrient matter, and afford a mechanical protection to the organic parts, but seem fitted also, by their chemical constitution, to resist the operation of agents that might otherwise effect their decomposition, and that of the nucleus they enclose. From the experiments of Fourcroy and Vauquelin, on the tunics of certain seeds that grow in marshy situations, it appears, that, beside the usual ingredients of vegetable substances, there exists in them a compound, formed by a combination of tannin with a peculiar matter of an animal nature, in union with a vegetable acid. This combination of tannin with the matter just mentioned, renders these tunics insoluble in water, and enables them to resist putrefaction, although buried for long periods in the moist earth. The tunics of those seeds, which do not possess this chemical constitution, may, it is added, by their ligneous or horny texture, or by the oily matter with which they are penetrated, present similar obstacles to the action of decomposing agents. (*An. du Mus. d'Hist. Nat.* Tom. XV. p. 77.)

### Article III.

*Description and Structure of the Nucleus of the Seed.*

Nucleus, its several Parts. 193. We proceed next to describe the parts contained within the above-mentioned coats or tunics, and which constitute the *nucleus* of the seed. These parts, as already observed, consist of the radicle, the plume, and cotyledons, together, in most instances, with the nutrient matter destined to support their future growth. The three former bodies are completely organized, but the nutrient matter is wholly inorganic, varies greatly in quantity and proportion in different seeds, and is very variously situated with respect to the organized parts.

194. These parts, which, in the progress of their evolution, give birth to the new vegetable, derive their visible origin from a medullary point, that succeeds to the act of fœcundation. By some, these organized parts have been called the *corculum;* by others, *embryo;* by others, *fœtus;* and by others, *plantula seminalis.* The primary point or particle, from which they originate, may, with propriety, says Gærtner, be termed *corculum,* since it is the source and seat of vegetable life, and from it the whole vascular system of the embryo proceeds. In some instances, this corculum increases so little as to be scarcely visible even in the mature seed; or exhibits only a palish spot, which has been termed *cicatricula.* In others, it forms a roundish radicle, whose apex is free, and rises above the nucleus, but whose base is firmly connected with it. In others, again, the corculum is still more disengaged, enlarging at each extremity, and producing at one end the radicle; and separating at the other into the two lobes called cotyledons, between which the first bud or plume of the future plant is situated. From this varying growth of the corculum, an embryo, more or less perfect, is produced. When the embryo presents only a mere germinating point, it is stiled *imperfect;* when it exhibits a simple radicle, it is deemed *incomplete;* when it possesses both radicle and cotyledon, it is considered *perfect;* and when it consists of radicle, cotyledon, and plume, it is pronounced *complete.* (*Gærtner de Fructib.* &c. Vol. I. cap. 13.)

Corculum. Embryo.

Description of the Embryo. 195. In the mature seeds of the less perfect plants, the embryo is altogether invisible until after germination, and even, in many other instances, its characters cannot be accurately traced. Its general figure is determined by that of the radicle and cotyledons, and is exceedingly various in different seeds. In size, it ranges from a minute point to that of a body of considerable magnitude. In consistence, it is almost always soft and herbaceous, but its radicle possesses sometimes a ligneous hardness. No seed contains more than one embryo, except in cases of *superfœtation,* of which Gærtner saw one instance in *Pinus Cembra,* a seed of which contained two embryos within one and the same cavity. (*De Fructib.* Vol. I. p. 168.) Malpighi also records a similar occurrence in a seed of *Prunus Armeniaca;* and the seeds of the *Gramineæ,* as will afterwards be shown, are capable of evolving an indefinite number of embryos. Every *complete* embryo is said to consist of three distinct parts, beside cotyledons. These are the radicle, the stem, and the plume.

Its Radicle. 196. The radicle (*radicula*), called *rostellum* by Linnæus, is the most constant part of the embryo, being found in some seeds, in which no other trace of that body can be discovered. In the seeds, however, of the less perfect plants, and even in those of some monocotyledons, no radicle is visible antecedent to germination. In some rare instances among dicotyledons, as in *Nelumbo nucifera,* no radicle exists; but, in germination, the stem first rises upward, and afterwards emits rootlets from its sides. (*An. du Mus. d'Hist. Nat.* Tom. XIII.)

197. The size of the radicle is very various, and so also is its figure, being either conical, cylindrical, filiform, or tubercular, &c. It always, says Gærtner, occurs solitary, except in *Secale, Triticum,* and *Hordeum,* to which alone, of all known seeds, three, four, or six radicles, properly formed, and distinct from each other, are furnished to each embryo. (*De Fructib.* &c. p. 169.) This plurality of radicles in the *cerealia* had before been remarked by Malpighi. M. Du Hamel describes the seed of Misletoe (*Viscum Album*), as emitting numerous radicles like those of wheat. (*Mém. de l'Acad. des Sciences,* 1740.)

Its Stem. 198. The stem (*scapus*) of the embryo is a continuation of the radicle, and connects it with the plume. It is frequently wanting altogether, nor, when it is present, can we fix precisely on the point where the radicle ends and the stem begins. What is called stem, descends frequently into the earth, and becomes a true root; so that every part of the embryo, situated beneath the cotyledons, might, without impropriety, be denominated radicle. The place of junction between the radicle and stem was called by Grew the *coarcture,* from its presenting often an evident degree of contraction; but M. Bonnet, and others, have given it the more appropriate name of the neck (*collum*) of the seed.

199. The plume (*plumula*) is the first bud of the

Of the Seed.

new plant. In seeds that possess but one cotyledon, it is very generally wanting; and, even in those which have two cotyledons, it is not unfrequently absent, or is at least concealed within the stem. In most of the latter sort of seeds, however, the plume is met with. It is placed on the top of the stem or radicle, and lies between the cotyledons, by which it is variously compressed and folded on itself. In the greater number of seeds it is not entire, but, at its free end, is divided into several pieces, all closely couched together, like feathers in a bunch, and thence called the *plume* by Grew. In different seeds, its several little leaves vary much, both in figure, size, and number. The structure, both of the radicle and plume, will be most advantageously displayed in connection with that of the cotyledons.

The Cotyledons;

200. Of the organized parts of the seed, the organs called by Grew *lobes*, or *dissimilar leaves;* by Malpighi, *seminal leaves*, or cotyledons, remain to be described. The cotyledons derive their origin from the embryo itself, of which they constitute a part. The seeds, however, of some tribes of vegetables, as before remarked, are held not to possess these organs; and in many others, the mass of nutrient matter has been confounded with them. When present, they are either simple or divided. The simple cotyledon is formed by the mere extension of the corculum, and is in truth scarcely distinguishable from the stem itself. The double, or conjugate cotyledons, are produced by fissures which usually divide that part of the embryo that is opposed to the radicle, into two or more equal portions or lobes. These lobes have, at first, the appearance of mere tubercles, and in many seeds they retain this form unchanged; but, in others, they gradually expand into *lamellæ*, or plates, which augment in size, and finally exhibit the proper form of cotyledons. This form is very various, as likewise is the size of these organs. Sometimes they are so small as to be scarcely visible, and sometimes so large as to form the chief portion of the seed. Their substance is either thin, or thick, or turgid. Their colour is commonly white, but sometimes yellowish, purple, or green; the colour into which they all pass during germination.

their Structure.

201. Concerning the structure of the cotyledons, it may be said that, in the more perfectly developed seeds, they are formed of cellular tissue, through which vessels are everywhere distributed; and, as we have already remarked, they are everywhere covered by a fine pellicle, or coat, which prevents alike their adherence to the plume and to each other. This cellular structure of the cotyledon is well displayed by Grew (fig. 24. Pl. XV.) in a slice of the cotyledon of the recent bean; and it is easily seen in a thin slice of almost any mature seed, if it be held against the light after it has been soaked in water. This cellular structure extends into the radicle and plume, but in much smaller proportion, constituting, according to Grew, about $\frac{3}{5}$ths of the plume, $\frac{5}{7}$ths of the radicle, and $\frac{9}{10}$ths of the cotyledon.

202. Through all the organs that compose the nucleus, vessels are distributed, by the medium of which a general communication is established among them. This vascular system is likewise exhibited by Grew in the dissection of a Bean (fig. 26. Plate XV.), in which the vessels are seen to branch off on each side from the radicle, and spread themselves, by innumerable ramifications, through the cotyledons. From the radicle, vessels also pass upwards to the plume. These vessels of the radicle are visible when a transverse section is made through it, as in fig. 27. E, in which they are seen to occupy the middle of that body. When the section is made higher up at the neck of the embryo, as in the same fig. F, then the central trunk, surrounded by several smaller fasciculi of vessels, passing to the different parts of the plume, is still more clearly exposed. In many seeds, however, the organized parts are so small that their general structure cannot be traced, except during the progress of their germination. We shall therefore defer the description of them, till we come to treat of their evolution; and shall then also go more fully into the structure of the parts just mentioned.

Contain Albumen.

203. Within the cells of the cotyledon, in many dicotyledonous seeds, the nutrient matter, destined to support the future growth of the embryo, is entirely contained. In other instances, this matter is only in part received into those organs; and in the *Gramineæ*, and other monocotyledons, it is often placed almost entirely exterior to the cotyledon. This matter is produced from a clear liquor that is secreted in the tunic during the formation of the seed. To this liquor Grew gave the name of *albumen*, from its likeness not only in appearance, but, as he conceived, in use also, to the white of egg in animals. By Malpighi, this matter, considered in connection with the tissue that contains it, is often called the flesh *(caro)* of the seed; and from its being sometimes situated around the embryo, it has been denominated *perisperm* by M. Jussieu. We follow Grew and Gærtner in the use of the term *albumen*, meaning to express thereby, not the primary animal compound to which chemists have of late assigned that term, and which is found but in few vegetables; but that compound substance which, whatever be its situation, quantity, or colour, constitutes the nutrient matter of the seed.

Positions of the Embryo and Albumen.

204. This albumen is a very constant part of the mature seed, but its proportion, in some seeds, is so extremely small, that the seeds in which this occurs have been termed *exalbuminous;* and, in a few instances, it seems to be entirely wanting. Its quantity, situation, and figure, in different seeds, are subject to very great variation. In the seeds of the *Gramineæ*, where the embryo acquires only a very small size, the albumen constitutes almost the entire bulk of the seed, and is placed wholly exterior to the embryo. In the *Leguminosæ*, on the other hand, the embryo is more completely developed, and the whole of the albuminous matter is contained within the cotyledons. In beet *(Beta)*, and many others, the albumen is partly received into the cotyledons, and lies in part exterior to them; and where this occurs, the embryo sometimes encircles the albumen, and is sometimes encircled by it. In *Rheum*, the embryo is placed in the centre of the albumen; in *Rumex*, and some others, it is applied on the side of it; in *Atriplex*, the long cylindrical embryo surrounds the albumen; in *Böerhaavia*, the embryo and its cotyle-

Of the Seed. dons cover entirely the granulated substance of the albumen. (M. Jussieu, *An. du Mus. d'Hist. Nat.* Tom. V. p. 224.) In the Onion *(Allium cepa)*, the embryo makes several curves within the substance of the albumen; and in dodder *(Cuscuta)*, it is twisted around it in a spiral form; so that the relative positions of the embryo and albumen, as well as their quantity, proportion, and figure, are subject to endless variation.

Albumen of Wheat. 205. But however much, in these respects, the albumen may vary, it is always contained within an organized structure. Sometimes this structure is that of the cotyledon, as already exhibited in the Bean, fig. 24. the cells of which contain this albuminous matter. Where the albumen is placed exterior to the embryo, as in the seeds of Wheat, it is nevertheless contained in a cellular tissue. This is exhibited in fig. 25. Plate XV. copied from Leuwenhoeck, in which cells of an hexagonal form are seen to be filled with the albuminous particles that constitute the white matter or flour of that seed. This mealy part of Wheat he describes as consisting of minute globules, enclosed in a kind of membrane so exquisitely thin as scarcely to be observed, within which the globules are contained, as it were, in cells. The globules appeared to be of different sizes, not perfect spheres, but having an indentation on one part, which led him to suppose that they were not formed by simple accretion, but by some mode of growth, and that "the membranes which enclose them in cells, must be provided with so many veins or vessels, that every particle of meal may have its separate vessel." He even conceived the globules themselves to be enclosed individually in a thin skin or shell; but this opinion he never brought to ocular demonstration. (*Select Works by Hoole*, Vol. I. p. 169.) It may, therefore, be presumed that, in this instance, his imagination went beyond the powers of his microscope. Similar observations on the albuminous part of Wheat have since been given by Mirbel; and Kieser and others have delineated the globular particles contained in the cotyledonous cells of the Bean and other seeds; so that whether the albumen be situated in the cotyledons, or be placed exterior to them, it is, in every case, contained in a similar and distinctly organized structure.

Varieties of Albumen. 206. In consistence, the albumen varies; it is said to be either farinaceous, fleshy, or cartilaginous; and it may exist in various intermediate states. The farinaceous kind is readily reduced to powder, and is dissolved by water into a viscous mass. The embryo is generally placed exterior to this species of albumen, as in the *Gramineæ*. The fleshy albumen is more frequent. It is softer than the former, and dissolves by water into a gelatinous mass. It is often entirely contained within the embryo and its cotyledons, and yields the thick oil that is expressed from many seeds. Lastly, the cartilaginous species has a horny consistence, is difficultly soluble in water, and not easily reduced to powder. The embryo is never placed exterior to it, and when it contains oil, this is usually very thin. (*Gærtner de Fructib.* Vol. I. cap. x.)

Uses of Albumen. 207. In many seeds, the albumen serves as a support and defence to the embryo as well as for nutriment. If it be removed previous to germination, as was done by Mirbel (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 157.), in the seed of the onion, and by Dr Yule (*Wern. Trans.* Vol. I. p. 591.), in different species of *Gramineæ*, the embryo, though planted in a rich soil, and carefully tended, grows but feebly, and for the most part dies.

Vitellus. 208. Besides the albumen above described, Gærtner has revived the use of the term *vitellus*, but employed it to designate a very different part from that to which it was originally applied by Grew. The latter made use of this term to designate the inorganic matter of the mature seed, which, in the early stage of its production, he called albumen (*Anat. of Plants*, Book iv. ch. iii.); but it is employed by Gærtner to indicate a small membranous body, which, in many seeds, is placed between the embryo and albumen, and is closely connected with the former, but separates easily from the latter. The figure of this small body is described as being very various in different seeds. It is said not to rise out of the earth during germination; but, like the albumen, seems destined to afford nutriment to the embryo. It forms the chief bulk of the seeds of the *Cryptogamia*; and in those of the *Gramineæ*, it represents a thin scale interposed between the albumen and embryo, to which, from its shield-like form, he gives the name of *scutellum.* (*De Fructib. Plantar.* Vol. I. cap. xi.) There can be no doubt that this scutellum of Gærtner is the little "conglobate leaf" first observed in Wheat by Malpighi, and which later writers have denominated the cotyledon of that seed. In the next section, its form and situation will be clearly displayed.

### Section II.

#### *Of the Structure of Monocotyledonous Seeds, as displayed in their Evolution.*

Classification of Seeds: 209. All seeds have, by some botanists, been distinguished into such as possessed one or more cotyledons, and such as were entirely destitute of them; others maintain that every known seed possesses at least one cotyledon, and that no seed has more than two; and others again think there are some seeds which possess many cotyledons. It is not within our province to discuss the merits of these several opinions. We only beg to observe, that, in treating of seeds under the two divisions of Mono and Dicotyledons, we would not be understood to deny the existence of seeds that have no cotyledon, nor of others that possess more than two. We employ these words only as convenient general terms, under which the greater number of known seeds may be arranged.

their Evolution observed 210. Some seeds are so extremely minute, that, until lately, their existence was not clearly ascertained; and it is only during their germination that their general form and character can be detected. In many others, the organized parts are so small as to be scarcely capable of demonstration, except by following the progressive changes of form they exhibit in their evolution. We propose, therefore, to select, from each of the two divisions of Mono and Dicotyledonous seeds, an example or two of the successive appearances displayed in their evolution, which will,

Of the Seed. besides, form perhaps the best introduction to a knowledge of the structure of the mature plant. To the division of monocotyledons, the seeds of Mosses and Ferns have been referred, and with them, therefore, we shall commence our description.

in Mosses by Hedwig: 211. At the end of March, or beginning of April, Hedwig procured the mature capsules or ovaries of a species of Moss *(Mnium hygrometricum)*, and opening them over pots of earth, prepared to receive them, the fine dust of their seeds fell out. For several days they exhibited a dullish appearance, scarcely visible; but on the 7th day the surface became green. On the point of a needle, several of the young plantules were now taken up, and, being immersed in a drop of water, they were examined with a microscope that magnified 62 times. Innumerable seeds were visible, which had already put forth a very tender white radicle on one side, and on the opposite side a very simple obtuse corpuscle, extremely pellucid, and at its margin of a light green colour. Of these parts, a representation is given in fig. 28. G. Plate XV., in which the little globular body in the centre denotes the seed; and the radicle and lobe or cotyledon are seen, in opposite directions, to spring from it. The little node or seed was of a dusky colour, evidently swollen by the imbibition of moisture, and on its sides were marks of rupture made by the shooting forth of the radicle and cotyledon: these organs were themselves covered by an appropriate tunic. Sometimes, instead of one lobe, two or three sprang from the seed, as represented by the letter H. of the same figure.

212. In three days more, a second radicle issued from the seed, and the cotyledon also became divided into branches, as represented in fig. 29. For the next eight days, nothing remarkable occurred, except that the green colour increased in intensity. The proper leaves of the Moss now began to spring, and many succulent threads issued from the root. By the month of October, the young plantule was so much grown, that the parts of fructification could be distinguished. Its appearance, at this period, is exhibited, on a reduced scale, in fig. 30. Towards the end of November, the parts of fructification were completely developed, and from them seeds were obtained, which vegetated when committed to the earth in the following spring. From some other species of Mosses he obtained similar results, so as to leave no doubt that these plants are propagated by seeds, which at first put forth a radicle and cotyledon. (*Fundamentum Hist. Nat. Muscorum*, Pars 2da, p. 54.) His discoveries have been confirmed by several other botanists.

n Ferns: 213. In another order of the *Cryptogamia*, the Ferns (*filices*), the parts of fructification are placed on the back of the leaf, or *frons*, as it is termed by botanists. They there form clusters of small globules or capsules, which are secured in their place by a little scale. When the seeds are mature, the capsule bursts, and the seeds are scattered. Some observations were made on the germination of the seeds of se-

y Lindsay: veral species of Ferns by Mr Lindsay. In the climate of Jamaica, no alteration was visible in the seeds of *Polypodium lycopodioides* until about the 12th day after they had been sown, when they put on a greenish colour, and began to push out their little germ in the form of a small protuberance: this germ gradually enlarged, and exhibited, according to his delineations, several whimsical shapes, which subsequent observers have not been able to recognize. At length the green surface of the plantules assumed the form of small scales (fig. 31. Plate XV.), which appeared of a roundish figure, and somewhat bilobate, as seen in the enlarged view below. From this membranous leaf, a small leaf of a different figure afterwards sprang, which was followed by others, and in three months the developement was complete. (*Linnæan Transactions*, Vol. II. p. 93.)

by Mirbel: 214. With this last representation of the appearance of the germinating seed of the Fern, the observations of M. Mirbel coincide. He describes the seeds of the *Asplenium creticum* as producing, a few days after they are sown, a small heart-shaped cotyledonous leaf, represented of its natural size in fig. 32. It is formed entirely of cellular tissue, but exhibits no appearance of vessels. After some time, numerous small threads shoot from its point, corresponding in office to the radicle of ordinary seeds; and at length a plume, in the form of a crook, is said to shoot from the same part. Gradually, the cordiform figure of the cotyledon disappears, and it seems as if made up of two lobes, from the middle of which the crook-shaped plume continues to grow. (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 71.) See fig. 33. Plate XV., and its enlarged representation below.

by Yule. 215. The germination of these minute seeds has also lately been observed by Dr Yule; and his account differs, in some particulars, from that of his predecessors. He describes the first appearance of the young plantule, as resembling a dark green point, which, when closely examined, exhibits the form of *two* seminal leaves, rising out of the seed, and gradually expanding to the diameter of more than a quarter of an inch. From a circular opening in these seminal leaves, the frond or permanent leaf arises, and is afterwards followed by a second. He regards the first leaves as cotyledons, within which the embryo is included, and from which it springs, as in dicotyledonous seeds. He notices also, the absence of vessels in these cotyledonous leaves, and the circumstance of their emitting minute rootlets, by which they derive nourishment, previous to the shooting of the true root. His observations have been given to the public, in the article "*Filices*," in a contemporary work, the *Edinburgh Encyclopædia*.

Evolution of Wheat. 216. In most of the seeds of this division, the cotyledon does not, however, appear above the soil during germination, but is retained within the coats of the seed, and consequently undergoes but little alteration in size. As an example of the evolution of a monocotyledonous seed, we shall select that of Wheat (*Triticum hybernum*), because its developement has been studied with great care, and, in common with some others of the same natural family, it exhibits some striking peculiarities, which add greatly to its productive powers. The successive appearances exhibited in its evolution, have been given with great accuracy by Malpighi, who has carried its anatomy farther, in some points, than most of his successors.

Of the Seed.

In the earlier stages of growth, some very accurate representations of it have also been given by M. Poiteau, and Dr Yule has likewise obliged us with some valuable observations. From these different authorities, confirmed generally by our own observations, we shall endeavour to present a concise view of the structure and evolution of this very important seed.

Description of Wheat.

217. If we take a grain of Wheat, and examine its convex side, we observe, at its base, a small oblong body, fig. 34. Plate XV. lying in a semicircular depression, which is well defined through the tunics that cover it. These tunics are two in number, an outer one, to which the chaffy filaments at the vertex of the seed are attached, and which readily separates when moistened; and an inner one, which everywhere adheres closely to the cellular tissue that contains the albumen. If these two tunics be raised and thrown back, as is done in fig. 35. the little oblong body ($h$), with its semilunar appendage ($i$) placed behind it, are brought into view; and together, they constitute the embryo.

218. Let next a vertical section of another seed be made in the direction of the furrow that runs along its flatter side, and let this section pass through the embryo, as is represented in fig. 36.—we then observe the seed to be composed almost entirely of albumen ($k$), with which the embryo ($l$), consisting of minute convoluted leaves, is in close contact. The part of the embryo that is applied against the albumen is the cotyledon, which, on that surface, is convex, and on the opposite one concave.

219. In fig. 37. the entire embryo has been removed from its connection with the albumen, and a front view of it, considerably magnified, is there given, in which the letter $o$ denotes the cotyledon, in the concavity of which the plume ($n$) is lodged, and ($m$) indicates the protuberances from which the radicles afterwards spring. If now, this same embryo be reversed, as is done in fig. 38, then the convex back of the cotyledon only is seen, with the extremity of the principal radicle at the base. It is this side of the cotyledon that was applied against the albumen; and its polished surface, says M. Poiteau, proves that it nowhere adhered by any organic structure. Gærtner also remarks, that the connection between these parts is not organic, but merely superficial—an observation that is true, as far as relates to the embryo itself and the albuminous matter, but not as applied to the tunics which envelope them; for, at the base of the seed, the inner membrane, which contains the albumen, appears to be continuous, as Leuwenhoeck remarked, with that which covers the cotyledon, being reflected from the albumen over the cotyledon, much in the same way as the *pleura* and *peritonæum*, that line the sides of the great cavities in animal bodies, are reflected over the *viscera* they contain. Such are the appearances presented by this seed antecedent to germination; let us next follow it through the several stages of that process.

Germination of Wheat observed

220. After a seed of this species has been in contact for 24 or 30 hours, with the humidity necessary to its germination, its embryo becomes swollen, and when removed from the other parts, and moderately magnified, presents the appearance exhibited in fig. 39. In this figure, the radicle is rendered more protuberant, and the fine tunic that invests it has undergone an alteration, being changed from a smooth, opaque, and solid texture, to one that is villose, transparent, and cellular. A vertical section of the same embryo, as exhibited in the next figure (40.), shows the elongation of the principal radicle ($p$) which caused the protuberance below, and the sprouting of the two lateral radicles ($pp$), which push forth more slowly on the sides. These three radicles soon force their way through the sac that envelopes them, which then forms sheaths around their origins: In the same figure, the letter $q$ denotes the plume, consisting of several convoluted leaves, and resting on the cotyledon. In fig. 41. the appearance of the seed, in a stage a little more advanced, is exhibited. The plume ($r$) is now seen to have risen above the cotyledon ($s$), and the three radicles, surrounded at their origins by their proper sheaths, have greatly increased in length, and innumerable capillary rootlets are emitted from their sides. (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 383.)

by Poiteau

by Malpighi:

221. The daily appearances exhibited in the evolution of this seed, as previously given by Malpighi (*Anat. Plantar.* p. 103.), accord well with the above representations of M. Poiteau; and he has noticed some additional particulars of considerable importance. On the first day of germination, he represents the plume of the embryo as beginning to open, and the protuberances, which indicate the eruption of the three radicles, as beginning to form. The radicles, at this period, are completely enveloped in a membranous sac or involucrum; and the body of the embryo is closely connected with a "conglobate farinaceous leaf by which nutriment is administered." This conglobate leaf is the cotyledon before-mentioned, and its connection with the radicle and plume is well shown by Malpighi. In fig. 41. (I.) he exhibits a front view of the radicle and plume, as they appear when separated from the cotyledon; and at the letter K. of the same figure, a back view of the same body is displayed, in which the letter $t'$ points to the mark or scar that denotes the place of separation. Malpighi believed these parts to be united with each other by a little node, hereafter to be described; but it is by the medium of vessels that this connection between the cotyledon and the other parts of the embryo is maintained; and by this route alone can the nutrient matter or albumen be conveyed through the cotyledon to the radicle and plume. To these vessels M. Bonnet gave the distinctive appellation of *mammary:* the union they form between the different parts of the embryo is so close, that, at this part, says Gærtner, the cotyledon, and radicle, and plume, form one undivided body. (*Gærtner de Fructib. Plantar.* Vol. I. p. 149.)

on the 1st day:

the 2d day

222. On the second day of germination, the exterior tunic of the seed, according to Malpighi, gives way; the plume rises upward; the radicles do not as yet pierce their investing sac, but this sac is turgid with juice, and is covered exteriorly by a fine white down: the cotyledon, also, at this period, is rendered moist.

the 3d day

During the third day, the cotyledon is quite turgid with juice; the plume is much enlarged, and be-

Of the Seed. gins to look green; the three radicles have pierced the enveloping sac, and are everywhere thickly covered with hairs; and above the two first lateral radicles, two small protuberances, *v. z.* fig. 43, the origins of two more radicles, are now seen to emerge, while the sac that envelopes them is observed sensibly to waste.

4th day: 223. When the third day has elapsed, the plume, enclosed in a fine transparent membrane, is still more elevated, and acquires a greenish colour; the protuberances of the two new radicles are more prominent, and the three former radicles have greatly augmented; the cotyledon is much softer, and as if milky, yielding, when compressed, a white and sweetish liquor.

5th day: 224. After the completion of the fourth day, the plume *w*, fig. 44. continuing to ascend, pierces the membranous covering *x*, and pushes into day a permanent leaf, green and convoluted, around which the membrane forms a sheath. Inferiorly, the three first radicles have greatly extended, and the two others *yy*, are much increased: the outer coat of the seed now begins to lessen, but still contains a sweetish liquor. M. Poiteau gives a section of the entire plantule about this period of its growth, which agrees very exactly with the figure of Malpighi. In this section, fig. 45. the plume $a'$ is seen to have pierced the membrane $b'$ that formerly enclosed it; the albumen $c'$ is diminished; the cotyledon $d'$ retains its situation and form; and the five radicles $e'e'$ are nearly of a length, and covered with hairs.

6th day: 225. About the sixth day, the plantule, still invested by its sheath, begins to open and expand; the seminal tunics shrink, and the surface of the outer coat is corrugated. If these tunics are cut open, the cotyledon within is observed, in some parts, to be firmer than before, and has the appearance of a concave leaf; but in other parts, it is more vascular, and filled with juice, especially in that part near to the *mammary* vessels.

11th day: 226. After the eleventh day, these tunics still adhere to the plantule, but appear much wasted, and the juice they contain is mixed with bubbles of air; while the stem, forming many knots, and the radicles emitting innumerable rootlets, continually augment in size. Where the vegetation has been very active, the whole original contents of the seminal tunics are by this time exhausted, and, when compressed, they yield only a watery fluid.

28th day. 227. After the lapse of a month, when the parts, already developed, are still farther advanced, new buds break out from the primary seat of growth and rise upward; and new radicles push forth and descend. So readily are these radicles produced, that sometimes, if the primary ones be removed, others in crowds spring forth; at the same time, new buds or shoots, protected in their proper sheaths, arise from the same part, and, surrounding the primary plantule, are borne upward with it. Of these appearances accurate delineations are given, and they may be observed in every field of growing wheat.

Error of Malpighi: 228. The foregoing descriptions of Malpighi are, in general, very correct, and his figures, though somewhat rude, exhibit, as usual, faithful delineations of the objects they are destined to represent. In one or two points, however, he has fallen into error, which, in the above statement of his opinions, to avoid confusion, we corrected as we went along. Thus, though he distinctly points out the "conglobate farinaceous leaf," as the organ by which nutriment is administered to the radicle and plume; he assigns to the sac that, in an early state, envelopes the radicles, the function of *placentula;* and even gives to the exterior tunic of the seed the title of seminal leaf. The true cotyledon, however (which never in this seed is produced into a seminal leaf), is the little conglobate body above mentioned; and the common tunics of the seed have no title to the appellation of seminal leaves. To this cotyledon, Gærtner, from its shield-like form, gave, as before observed, the name of *scutellum.* He held it to be characteristic of the *gramineæ*, and analogous to the organ to which, in some other seeds, he gave the name of *vitellus.* (*De Fructib. Plantar.* Vol. I. p. 139.) But most later writers, as Jussieu, Smith, Brown, and Poiteau, have all restored to it its proper office of cotyledon. of Gærtner:

229. M. Poiteau has gone even farther, and asserted the existence of a second cotyledon in this seed, and in the oat, which he describes as situated directly opposite to the former. (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 388.) In this instance, however, he has mistaken the rudiment of the second bud for a second cotyledon, as Dr Yule ascertained by "tracing the growth of this supposed cotyledon from its first becoming visible, to its final developement as a plant." (*Werner. Transac.* Vol. I. p. 594.) M. Mirbel considers the sac that invests the plantule to be the cotyledon of this seed; and this cotyledon to form the *first ensheathing leaf.* (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 148.) But, as already remarked, the cotyledon never, in this seed, rises out of the tunics; and, as Dr Yule observes, differs totally in situation, structure, and consistence, from the ensheathing leaf of the plantule. of Poiteau: of Mirbel.

230. A very remarkable peculiarity in this family of plants is their great productive power, as displayed in the indefinite number of new plants which we have seen to be evolved from one primary seed. Malpighi not only observed this peculiarity, but has described the structure from which it originates. He considered the radicle and plume of the embryo to be connected with the cotyledon, not by the mammary vessels, as we have stated, but by a little body which he called the *umbilical node.* In a section of the lower part of the stem of the plantule, made after the third day of germination, he delineates this node as situated at the junction of the radicle and plume, as represented by the letter $f'$, fig. 46. Plate XV.; and describes it as solid exteriorly, and softer and more medullary within. If a section of the same part be made on the fourth day, as in fig. 47. the stem ($g'$) of the plantule will be seen, says he, to spring from this node, from which also the radicles equally take their origin. Peculiarity of Structure in Wheat. Opinion of Malpighi:

231. This peculiar property in the *Gramineæ*, was also observed by Leuwenhoeck, though he seems not clearly to have apprehended the nature of the organs from which it proceeded. In the embryo of wheat he describes three points, from which not only of Leuwenhoeck.

Of the Seed. three distinct radicles spring; but they are also, he adds, "the beginnings of three several spires or stalks of wheat; so that from every grain of wheat (which is well worthy of observation), there will arise not merely a single stalk, but three distinct ones, which are formed in the seed itself." *Select Works by Hoole*, Vol. I. p. 169; and in Vol. II. p. 289, are to be found similar observations on the seeds of Oats, Barley, and Rye.

of Mirbel: 232. By M. Mirbel, the umbilical node of Malpighi is considered as a fleshy knot *(un nœud charnu)*, by the medium of which the plume and radicle are united. The lateral radicles, which issue from it, he regards as distinct in their nature from the primary one, and as resembling those which spring from knots in the stem; he therefore names them *articular* roots, *les racines articulaires*. (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 149.) According to Dr Yule, however, this fleshy knot is to be considered as a *tuber*, analogous to the tuberous substance, interposed between the bulbs and roots of the *Liliaceæ* and other monocotyledonous tribes; and which is destined to produce an indefinite number of young plants, a greater or less number of which are subsequently evolved by the joint agency of the roots and leaves. The "articular roots" of M. Mirbel he regards as in reality young plants, the roots of the *Gramineæ* being invariably fibrous. It is by means of these lateral shoots and their *tubera*, that bushes, consisting of from sixty to several hundred stems, are sometimes seen to originate from one seed.

of Yule:

233. The above important peculiarities in the germination of the seeds of the *Gramineæ*, are very perspicuously displayed by Dr Yule in the three figures which we have copied from his Memoir. In fig. 48. Plate XV. Dr Yule represents the embryo of wheat as it appears when detached from the albumen, a short time after germination has commenced; the ascent of the plume covered with its membrane, and descent of the three primary radicles, which have pierced their containing sac, are clearly exhibited, and the letter $h'$ points to the little cotyledon, placed at the junction of the two parts just mentioned. In fig. 49. the germination of the same seed is shown in a more advanced stage; the plume ($i'$) has now risen to a considerable height, and pierced the investing membrane; and at $k'$ a second bud or plume (which M. Poiteau mistook for a second cotyledon), is seen to shoot from the tuber like the first: the letter $l'$ denotes the seminal tunics. At a still more advanced period, four young plants, $m'$ $m'$ $m'$ $m'$, fig. 50. of the second month, with their sheaths in part withered, are seen to have sprung from the same part; but the two seminal tunics of the seed, exhausted of their contents, still remain attached, as indicated by the letter $n'$. (*Wernerian Trans.* Vol. I. p. 589.)

234. The description given above of the evolution of wheat is applicable, with little variation, to the seeds of all the *cerealia*. The seed of the Oat emits from four to six radicles, all of which break through their enveloping sac at the same place, and thus appear to be contained in one sheath; such too is the case with Barley, the plume of which extends beneath the seminal tunics, and pushes out at the vertex of the seed. Of the Seed.

235. This peculiar constitution of the seeds of the *Gramineæ*, is attended with important advantages in their culture, and explains the source of their great productive power. A single grain of Barley was observed by Du Hamel to have produced 200 ears, each of which yielded 24 grains; so that one single seed planted in a good soil, has produced 4800 grains. Curtis and others, by transplantation of the several plantules of Wheat, obtained still higher returns from single seeds. For the same reason, these plants are better enabled than others to resist the injurious effects of accident or disease. If a seed, says Dr Yule, be buried under a stone or lump of indurated clay, the seminal plantules cannot shoot upward; but stems are then sent off in a horizontal direction, until they can effect their escape upward. Sometimes it happens, that a small insect (*Musca pumilionis*) deposits its egg in Wheat, and the grub is lodged in the very centre of the stem, just above the root, by which the stem is invariably destroyed, and the root so materially injured, as to prevent its throwing out fresh shoots on each side, or *stocking* itself, as the farmers term it. Nevertheless, the plants thus attacked are not permanently injured; for, in the instance where these depredations occurred, the crop of Wheat was good, and the ears large and fine through the whole field; so that these injured plants, by the production of lateral shoots, yielded an abundant crop. (*Lin. Trans.* Vol. II. p. 76.)

Productiveness of Wheat.

236. In the germination of other monocotyledonous seeds, a similar succession of phenomena present themselves, with the exception of those which relate to the multiplication of so many individuals from a single seed, and which seem to be peculiar to the *Gramineæ*. In all, the radicle first shoots forth, and the plume soon follows; the cotyledon is commonly of small size, and is retained within the tunics. As the embryo grows, the albumen is taken up and conveyed through the cotyledon to the young plantule; and, before the albumen is exhausted, the embryo is enabled to draw its nutriment from the soil in which it grows. Evolution of other Seeds.

237. In many instances, it appears, that the primary radicle of these seeds, after a short time, becomes dry, and falls off, and is replaced by a great number of secondary rootlets. M. Poiteau regards this last circumstance as common and peculiar to monocotyledonous seeds. He has remarked it in many hundred palms, not one of which had a descending or tap-root. No plant in the numerous family of the *Liliaceæ* is said to possess such a root. The radicle of the *Cyperaceæ* does not, perhaps, perish so soon, but it does not continue long. This premature and constant destruction of the radicle he considers as the cause of the bulbs and truncations which occur, particularly in the *Liliaceæ*; for the lateral roots not being capable of receiving all the descending sap, it collects at the lower part of the stem, and occasions these different enlargements. (*An. du Mus. d'Hist. Nat.* Tom. XIII. p. 392.) Destruction of the Radicle by Nature:

238. The effects which thus succeed to the spon-

Of the Seed. taneous destruction of the radicle, occur partly in other plants, in which the first radicle is naturally permanent, if it be artificially removed. Du Hamel found, that, if the extremity of permanent radicles were cut off, lateral rootlets were produced; that even mechanical obstruction to the descent of the radicle frequently gave rise to divisions in it, and the production of these lateral rootlets. He ascertained, also, by experiment, that roots extend invariably, not by an elongation of parts already formed, but by new matter added to their extremities; and hence it is, that roots, whether ligneous or herbaceous, do not elongate, if even the smallest portion of their extremity be cut off. (*Phys. des Arbres*, Tom. I. p. 83.) The results of observations on the growth of Carrots, in different soils, by Mr Knight, correspond with those of M. Du Hamel.

by Art.

### Section III.

*Of the Structure of Dicotyledonous Seeds, as displayed in their Evolution.*

Modes of Evolution.

239. From the greater number of seeds which have two cotyledons, the phenomena of their evolution may be expected to exhibit at least as great variety as those of the division last described. In different species they differ in this respect as much from one another, as they do from monocotyledonous seeds. Some seeds of this class raise their cotyledons above ground during germination; in others, these organs are wholly retained within the tunics. Of each of these modes of evolution we propose to give an example, selecting, as before, those seeds which have been most accurately observed, or which, by the forms they exhibit, seem best calculated to illustrate the general laws, by which their evolution is accomplished.

240. In the seeds of this division the embryo is commonly much more completely developed than in those of the class last described; so that the several organs of the plantule become distinctly visible. The radicle and plume are readily distinguished, and the cotyledons are frequently so large as to form nearly the entire mass of the seed. Within the cotyledons, the albuminous matter provided for the nutrition of the embryo during its evolution, is often entirely contained; and these organs, as before remarked, rise sometimes out of the earth, increase greatly in size, and, after a certain period, decay. In other instances, no increase in size, nor elevation above the surface, occurs; but, like the greater number of monocotyledons, they remain beneath the soil, and yield gradually their nutrient matter for the support of the embryo. Even in plants of the same natural order, the *Papilionaceæ*, for example, some, as *lupinus*, says Dr Smith, raise their cotyledons into the air and light; while others, as *lathyrus*, retain them under ground, concealed within the tunics of the seed. As an example of the latter, we shall give from Malpighi an abridged account of the successive appearances exhibited by the common pea *(pisum)*, which, in its evolution, approaches, in some respects, to that of the seeds last described.

Evolution of the Pea.

241. The figure and size of this seed are familiar to every one. After being placed for a day in circumstances favourable to its germination, it is much increased in size; its outer coat is rendered softer, and becomes more white and thin; the umbilical aperture continues closed, but near to it an irregular opening or laceration is visible. If the outer coat be now stripped off, the *nucleus* comes into view. It is seen to consist of two distinct parts or lobes, which are the proper cotyledons of the seed. These cotyledons are closely invested by the inner tunic; externally they have a convex surface, but internally, where they are in contact, their surfaces are nearly plain. Between them, in a small depression formed in their substance, lies the plume; it is composed of a number of yellowish leaves, folded on each other, and bent inward, and is united by a little curved stem, to a small white conical body, the radicle. These appearances are exhibited in fig. 1. Plate XVI., in which one of the cotyledons has been removed, so that the inner surface of the other, together with the plume and radicle, are fully brought into view: the letter *a* denotes the cotyledon, *b* the plume, and *c* the radicle. This radicle at its neck, or point of junction with the stem, sends off on each side a little stalk or pedicle to each cotyledon. In the above figure, one of these pedicles has been cut through, and the other, that remains attached to the cotyledon, is concealed behind the plume. It is by these pedicles alone that the two cotyledons are connected with each other. — 1st day:

2d day:

242. When the second day of germination is completed, the cotyledons are rendered more tumid, the tunics give way, and the radicle begins to protrude. Soon after, the cotyledons separate a little, and become somewhat concave internally. After the third day, the radicle has pushed out through the tunics; it is white, except at its point, which is more deeply coloured, and it emits on all sides fine capillary rootlets; the cotyledons are now farther separated, and by degrees the stem of the embryo, with its curved plume, are disclosed.

5th day:

243. About the fifth day, the stem (*d.* fig. 2.) mounts upwards: it is white, and bears on its summit the plume (*e*) still curved, and now becoming green: the stem now also begins to exhibit the marks of knots at particular parts: the radicle (*f*) is farther advanced, and small protuberances, the origins of future rootlets, appear on it: the cotyledons (*g*) retain their place, are turgid and solid, and still surrounded by the lacerated tunics.

7th day:

244. At the close of the seventh day, the plantule is much more advanced; the knots on the stem (*h. h.* fig. 3.) are quite distinct, and its apex is furnished with broad green leaves, but which are not as yet unfolded. The substance of the cotyledons is still solid, and when compressed, yields a bitterish juice: the radicle is much elongated, and has emitted numerous rootlets.

9th day.

245. After the ninth day, the plantule is completely formed: its stem (*i.* fig. 4.) is now erect, and the leaves of the plume (*k*) are expanded: the cotyledons (*l*) are reduced in size: and the radicle (*m*) or root, as it may now be termed, with its numerous rootlets, is greatly augmented. Every part of the plantule, except the cotyledons, continues daily to increase; at

Of the Seed. the end of a month, these organs are still found to adhere; but are wrinkled, thin, and exhausted of their nutrient matter, with which the stem and other organs are filled.

Evolution of the Gourd.

246. The progress of evolution in those seeds that raise their cotyledons above the earth, is exhibited by Malpighi in that of the Gourd (*Cucurbita.*) This seed is of an oblong figure, and has a flattened form. It possesses three distinct coats or tunics: the outer one is thick, tough, and coriaceous; the middle one thin, membranous, and of a greenish colour; and the inmost is that transparent colourless pellicle that closely invests, and is inseparably connected with, the cotyledons of the seed.

247. After this seed has been made to imbibe moisture, the outer and middle tunics readily separate, and expose the *nucleus*, which is seen to consist of two leaf-like cotyledons, which have no connection with each other, except by the medium of the little conical body, or radicle, at their base. The size and figure of these cotyledons, and the situation of the radicle that connects them, are represented in fig. 5. Plate XVI. Their external surface exhibits to the naked eye prominent lines which indicate a vascular structure, the vessels of which proceed from the radicle at their base. They are commonly five in number, and from their main fascicular trunks, ramifications are produced, which, in their distribution, form a finely reticulated appearance over the whole organ. On their inner side, the cotyledons are quite plain, and closely applied against each other, but, as already remarked, are nowhere connected, except at the base. This surface is displayed in figure 6, in which the great vascularity of the organ is rendered more apparent. It is between the two cotyledons that the plume, consisting of minute convoluted leaves, is lodged and cherished. In figure 7., a part of the nucleus of this seed is represented a little enlarged, and the two cotyledons have been removed at different places by transverse sections, to show more clearly the situation of the radicle and plume. The letter *n* denotes the place from which one of the cotyledons has been removed, so as to bring the plume (*o*) into view, and *p* points to the conical radicle below.

1st day:

248. When this seed has been twenty-four hours in circumstances favourable to its germination, it is rendered tumid, and the umbilical aperture at its base is enlarged by the swelling of the parts within: the cotyledons become turgid, and the plume is augmented in size. After the second day the outer coat is much softened, the middle one appears as if torn and decaying, and all the parts within still farther augmented in size. During the third day, the colour of the outer tunic becomes darker; the cotyledons are more swollen; their vessels more conspicuous, and the radicle pushes out through the umbilical aperture.

4th day:

249. When the fourth day has elapsed, the plantule is still retained within the tunics, and if these be now removed and examined, the middle one is found to be dry and thin; the cotyledons (*q*, fig. 8.) are whitish, soft, and flexible, but the vessels on their surface are much more distinct; the radicle (*r*) is elongated and covered with down, as likewise is the stem (*s*). At the top of the radicle, a protuberance is seen, which is white and soft; and farther down appear several smaller tumours, indicating the places of rootlets about to break out. Of the Seed.

6th day:

250. About the sixth day, the cotyledons *q*, fig. 9. emerge from beneath the tunics, representing the "dissimilar leaves" of Grew, and the "seminal leaves" of Malpighi, but which we shall, in future, denominate *cotyledonous leaves*. They are thick, soft, and a little separated from each other; their position is pendent; their colour yellowish; they are very vascular, and between them the plume is still concealed. The radicle (*r*), at this period, is much elongated, and rootlets everywhere spring from its sides; the stem (*s*) is also lengthened and curved, and, in common with the radicle, is everywhere covered with a white curling down.

9th day:

251. Towards the ninth day the cotyledonous leaves (*q*, fig. 10.) assume an erect position. At their points, they are still yellowish, but elsewhere green, and their cellular tissue is filled with a greenish yellow juice; they begin to separate a little, but still entirely conceal the plume. The stem (*s*) at this period is greatly elongated, and its lower extremity has become green; the protuberance that existed at this part is greatly lessened; and below it, the radicle (*r*) is continued, from which numerous rootlets, covered with fine capillary productions, break out.

21st day.

252. During the following days, the cotyledonous leaves continue to enlarge, the stem to elongate, and the plume to augment in size; but it is not yet unfolded. About the twenty-first day, the developement of the plantule appears to be completed. A representation of its foliage at this period, is given in fig. 11.; the cotyledonous leaves (*q*) have now reached a great size, are of a deep green colour, and very vascular; they rise, by a short pedicle, from the summit of the stem. On each leaf, seven fasciculi of vessels are visible, which, beyond the middle, terminate in a net-work, from which is produced the cellular structure that contributes to form the breadth of the leaf. In the axil, formed by the cotyledonous leaves, the plume (*t*) lay concealed; it is now disclosed by the removal of one of those leaves. At first, the leaves of the plume are curled and convoluted, but afterwards they expand, and their figure is then seen to differ entirely from that of the cotyledonous leaves; they have notched margins, and their surface is covered with down. In this manner the young plant continues to increase, and acquires at length its full magnitude, in the progress towards which the cotyledonous leaves waste gradually, and finally fall.

Evolution of other Seeds.

253. The seeds of the Radish (*Raphanus*), of the Lettuce (*Lactuca*), and of the Kidney-bean (*Phaseolus*), are represented by Malpighi as exhibiting, in their evolution, a similar succession of appearances. In all these seeds, and in many others of this division, the radicle first pierces the seminal tunics; next the cotyledons come into view, and assume generally the form of leaves, between which the tender plume is for a time concealed, and at a later period is disclosed. In different seeds, however, the forms of these organs, and the periods of their successive evo-

Of the Seed.

lution, are subject to the greatest variation, not only as relates to the species of seed, but to the soil, the climate, and season in which it is destined to grow.

Internal Structure of the Pea:

254. Having thus surveyed the changes in *external* form, which the germinating seed exhibits, we shall conclude our description by a display of the peculiarities of its *internal* structure. This we shall find to consist entirely of vessels and cellular tissue, variously proportioned and combined. In a longitudinal section of the radicle of the Pea, in an early stage, Malpighi represents it, as in fig. 12. to be composed entirely of cellular tissue exteriorly, in the centre of which the vascular system, separating at the top into three divisions, to supply the plume and cotyledons, is placed. A similar section of the radicle (fig. 13.), on the seventh day, exhibits corresponding sections of the rootlets it puts forth, which are seen also to consist of cellular tissue, and of vessels that come off from the central fasciculus of the radicle.

255. The stem, when about a month old, is composed of a thick bark formed of cellular tissue, within which are two rings of vessels, as seen in the transverse section, fig. 14. The inner ring ($v$) is said to consist of sap and spiral vessels; and exterior to this, a zone of vessels ($w$), yielding a peculiar juice, is said to be placed. In some very thin slices of the stem of the pea, viewed through a microscope of considerable power, the arrangement and distribution of the vessels and cellular tissue appeared to us as represented in fig. 20. The centre of the stem was occupied by cellular tissue, round which was a zone of vessels ($v$), forming four principal fasciculi. Exterior to this zone was a small ring of thickened cellular tissue, and beyond this, the proper cellular substance of the bark. Near the circumference of the stem were four larger fasciculi, which may probably be considered as the "proper vessels," while those near the centre may be deemed the sap-vessels.

of the Gourd:

256. In the plantule of the Gourd, a similar structure is observable. Fig. 15. exhibits a longitudinal section of the plume and radicle of that seed, considerably magnified, as they appear before germination, and shows the position of the vessels $x$, as they pass up towards the plume $y$. In the next figure (16.), a similar section of a radicle, on the second day of germination, is shown, in which the vessels that form the rootlets are seen to originate from the fasciculi that exist in the radicle. In figure 17. is represented a longitudinal section of the stem and radicle of the same plantule on the ninth day. In the stem, the vessels are disposed in a circle that surrounds the pith; but as they descend towards the root, they approach each other, and give off ramifications to form the rootlets. In a transverse section of the stem, on the 21st day, Malpighi describes it as hollow in the centre, fig. 18. around which six fasciculi of vessels are disposed, and the intermediate portion is occupied by cellular tissue. Hedwig, however, and Kieser, enumerate not fewer than ten fasciculi of vessels in the stem of this plant, some of which are placed next the pith, and others near to the bark.

of the Bean.

257. To these representations of the structure of the Pea and Gourd by Malpighi, we shall add that of the Bean, in its early stages, as delineated by Grew, who has traced the distribution of the vessels in the radicle and cotyledons with great minuteness. In fig. 19. is exhibited a vertical section of a young Bean, which is made to pass through the cotyledons, the plume, and radicle. From the extremity of the radicle, the vessels ascend in fasciculi to the neck of the plantule, where they are seen to diverge towards each cotyledon, and ramify through it, while a central vascular portion is continued to the plume. In fig. 21. the vascular and cellular structure of the germinating Bean, at an early period, are shown in conjunction, in a highly magnified representation, presented here in a reduced size from Grew. In this figure, $a'$ denotes the cotyledon; $b'$ the enveloping tunics; $c'$ the cellular tissue; $d'$ the vascular system continued from the fasciculus $e'$ in the radicle, and ramified through the substance of the cotyledon; the letter $f'$ points to the plume, which also receives vessels from those of the radicle; and $g'$ indicates a depression in the cotyledon, in which, antecedent to germination, the plume was partly lodged; a similar depression existed in the other corresponding cotyledon.

Of the Trunk.

## CHAP. II.

### THE ANATOMY OF THE MEMBERS OF VEGETABLES.

### SECTION I.

### *Of the Structure of the Stem or Trunk.*

#### ARTICLE I.

#### *Of the Stem in Herbs.*

Stems.

258. In the foregoing chapter we have traced the successive changes of form which the seed exhibits in its progress to constitute the perfect plant; we have next to display the structure of the plant itself, in its more remarkable varieties and forms. The leading features of this structure have already been laid before the reader, when discoursing on the *common textures* of plants; it remains now to exhibit individual examples of it, as they occur in the several members of the trunk, the branch, and the root.

Varieties of Structure.

259. We have already noticed the very striking difference in the proportion and arrangement of the elementary organs, which obtains in different plants. While in some, the component textures are perfectly distinct from each other, in others, they are completely blended together; so that the characteristic distinctions of pith, and bark, and wood, are entirely lost. M. Desfontaines, as we remarked, has sought to connect this diversity of structure in the stem with certain peculiarities in the form of the seed; but it will appear, as we proceed in our descriptions, that such limitations and circumscriptions are perfectly arbitrary; and that Nature does not move by saltations, as the systems of naturalists would prescribe; but by a progress so gradual, and advances so continuous, that the lines and boundaries which denote the perfection of *artificial* classification, are, in truth, but so many evidences of the immaturity of *natural* knowledge. In the case of Ferns,

Of the Trunk.

the structure of whose seeds has been displayed in a preceding section, we have a striking example of the insufficiency of this theory; for, while the stem possesses that simplicity of structure, which is said to appertain only to plants that spring from monocotyledonous seeds, the seed itself appears, from the observations of Dr Yule (214.), to belong clearly to the division of dicotyledons. Without any reference, therefore, to the form of the seed, we shall exhibit the structure of the stem and trunk of different plants, as they appear on dissection, beginning with the more simple, and proceeding gradually to the more complex forms.

Names of Stems.

260. Botanists employ different terms to distinguish the different kinds of stems or stalks that support the leaves, and the organs of fructification. These are the stem (*caulis*), which is considered peculiar to herbaceous plants, and the trunk (*truncus*), which is proper to herbs and trees; the straw (*culmus*), which is the appropriate stem of the grasses; and the stalk (*scapus*), which differs from the other varieties in bearing only flowers, but not leaves. For the peculiarities in external form and character, which distinguish these several kinds of stems, as they occur in different species of plants, we must refer to the writers on botany; and shall proceed to exhibit a general outline of their internal structure.

Stem of Sugar-Cane.

261. Perhaps there is no plant in which the simplicity of vegetable organization is more clearly displayed than in the Sugar-cane, which belongs to the family of *Gramineæ*. In its stem or culm, the cells and vessels are comparatively large, retain much of their more perfect forms, and are quite distinct from each other. When treating of the cellular tissue (82.), we referred to the cells of this plant, exhibited in the very thin transverse slice, fig. 22. Plate XVI. as illustrative of their hexagonal figure, and of their being bounded, on every side, apparently by a single membrane. In some parts, when the observer is viewing these cells through the microscope, some of them appear quite transparent, from the upper and lower bounding membranes being entirely removed, and the light, in consequence, being freely transmitted; but in others, one or both of these membranes remain, and, though they are exquisitely thin, yet, when viewed by a strongly reflected light, a degree of refraction seems to be produced, which communicates to the surface of the membrane an irregular appearance, such as it has been attempted to express in the darker cells of the same figure. The deception that arises from viewing two layers of these cells in conjunction, which imparts the appearance of double sides, as in fig. 23. was before noticed; and the longitudinal appearance of the same organs, as seen both in a single and double series of columns (figures 24. and 25.), was at the same time described.

262. It is through this cellular structure that the vessels, which constitute the other component part of the culm of this plant, are distributed. They occur in fasciculi, which, towards the centre, are placed at considerable distances from each other, and preserve a symmetrical arrangement; but nearer to the circumference, they are more numerous, and their distribution is much less regular. In fig. 26. Plate XVI. a very thin transverse slice of this plant is exhibited, in which this regular disposition of the vessels at and near the centre ($h'k$), and their crowded state near the circumference ($i'$), are well shown; the cells, too, at the centre, are larger, and have a more perfect form than those near the circumference of the figure. In fig. 27. a very thin longitudinal slice of this same plant is delineated; it is considerably magnified; the letter $l'$ denotes the cellular tissue, and $m'm'$ two fasciculi of vessels which ascend through it.

Of the Palm.

263. In the Palm, which, though belonging to the division of trees, we shall notice in this place, a similar disposition of the elementary organs is observed; but both the vessels and cells are smaller than in the Sugar-cane, and the fasciculi of vessels are also much more numerous. This structure is exhibited in the transverse section of the trunk of the Palm, fig. 28., in which the dark spots indicate the vascular fasciculi, and the whiter portion the cellular tissue. As before observed in the Sugar-cane, the vessels are seen to be less numerous at the centre than at the circumference, where they are much crowded together, and very irregularly distributed, in consequence of the peculiar mode in which the growth of these trees is accomplished.

264. In fig. 29. of the same Plate, we have also copied from M. Desfontaines a portion of the longitudinal section of the trunk of another species of Palm (*Dracæna draco*), which displays more clearly the irregular direction which the vessels take in the lax cellular tissue through which they are distributed. It was before remarked, that these plants do not naturally produce branches; but that their vascular system is expended wholly in the production of leaves at their summit, and their trunk is perfectly cylindrical. If, however, the top of the plant has been cut off, or broken by accident, a division into branches is said to take place. (*Mém. de l'Instit. Nat.* Tom. I. p. 486.)

Of Asparagus.

265. In the stem of Asparagus, the elementary organs possess an arrangement similar to that of Palms; but in the progress of its growth, branches are given off continually, and consequently the stem diminishes in size as it ascends. In fig. 30. is given a vertical section of a part of the stem ($o$) of this plant, at that period of growth in which it is usually brought to table; the buds $p'p'p'$, protected by the imbricated leaves, present a very beautiful appearance. At each place where a bud springs, a part of the vessels of the trunk go off to form it, and are finally expended in its production; the diameter of the trunk above is consequently diminished, and the more central vessels are continued on, to be successively employed in a similar manner, till they terminate in a bud at the apex. We have thus an example where, though the elementary organs are uniformly distributed, as in Palms, yet, in consequence of the production of lateral branches, the diameter of the stem continually diminishes, and assumes the form of a cone, in which it differs from that of the Palm and Sugar-cane.

266. As in these plants the ligneous and cortical textures are uniformly blended together through the

Of the Trunk.

entire stem, it must be presumed that the *sap*-vessels and *proper* vessels are everywhere associated. This fact is accordingly pointed out by Malpighi as occurring in several species of the *Gramineæ*, who, as we before remarked (62.), delineates a *proper* vessel as existing in each fasciculus of sap-vessels.

Stem of the Gourd,

267. The next variety of structure we shall notice, is that of certain herbaceous plants, in which the proportion of cellular tissue in the stem very much exceeds that of vessels, and in many of their characters they come near to the plants last described. In the sections already given (figures 18. and 20. Plate XVI.) of the stems of the Pea and Gourd, the greater portion of the stem is seen to be made up of cellular tissue, but several fasciculi of vessels are dispersed through it. In fig. 31. Plate XVI. is a transverse section of the stem of the Gourd, of its natural

by Hedwig:

magnitude, copied from Hedwig, in which the dark spots indicate the relative positions of the ten fasciculi of vessels that are observed in this plant. In fig. 32. a small portion of the preceding figure, comprehending only two fasciculi of vessels $rr'$, and highly magnified, is exhibited; the vessels are seen to be of different sizes, and, by their enlargement, they press upon and diminish the size of the neighbouring cells; the cells themselves are also of different sizes; in some parts, as denoted by the letter $q'$, they are comparatively large. Their figure is generally hexagonal, though not always regularly so; and near to the vessels, they exhibit various irregular shapes. A very fine cellular tissue, placed exterior to the outer range of vascular fasciculi, forms the cortical texture of this stem, and from the succulent cuticle jointed hairs of various sizes are seen to spring; the centre of the stem is hollow. (*Fundament. Hist. Nat. Muscor.*)

by Kieser.

268. The stem of this plant has been examined with great minuteness by M. Kieser, who has represented, in several sections, both transverse and longitudinal, its appearance in different parts, and at different periods of its growth. The number of fasciculi that exist in the mature stem he makes, with Hedwig, to be ten; but the number of vessels in each fasciculus varies at different periods, and even in the different parts of the same plant. In a mature plant, the number in each fasciculus, near to the summit, does not exceed six or seven; below the first knot from the top they are more in number; below the second knot, they amount to nineteen; and they increase in number in the next internodial space. In the centre of the stem, there are twenty-three vessels in each fasciculus; and near to the root, when examined in autumn, they amount to twenty-nine. In the trunk of the root, ten fasciculi of vessels may also be reckoned; but in the principal rootlets only four fasciculi are observed, each of which contains thirty-seven vessels.

269. The size and general characters of these vessels are represented as varying with age, not less than their numbers, and hence they have different forms in different parts of the same plant. At an early period, when few in number, they are very small near the summit of the plant, and consist only of *simple spiral vessels;* in a later period, and lower down on the stem, they are of larger size, and some of them exhibit the characters of *annular spirals;* in the third internodial space, their size is still greater, and two or three of them are now transformed into *punctuated spirals;* and still lower on the stem, the number of punctuated spirals is increased. In the centre of the mature stem, *six large punctuated spirals* are visible, and near to the root, in autumn, of the twenty-nine vessels that compose each fasciculus, *twenty-three are punctuated spirals*, and only six simple spiral vessels are now to be seen. The characters of these vessels now also approach to those of arborescent plants; their sides are thickened, and their transparency is almost lost, and the cavities of some of them are filled by membranous vesicles, which form within them a sort of cellular tissue. In the root, at this period, the simple spiral vessels have altogether disappeared, and only punctuated spirals, smaller than those in the stem, can be discovered. This successive disappearance of the simple spirals, and augmentation in the number of the punctuated variety, is urged by M. Kieser as a proof of the transformation of the one into the other during the progress of vegetation. No mention is made of the existence of proper vessels in these fasciculi; and the representations of the cellular tissue, of the ligneous texture, and of the bark, correspond with those given by Hedwig. (*Mém. sur l'Organisat. des Plantes*, p. 134.)

270. In the stem of the Gourd, as thus described, we observe an arrangement of parts in many respects according with that of the Sugar-cane. In both, the cells are large, and their figure is well preserved; and the vessels are distributed in distinct fasciculi through the cellular tissue. In the Gourd, however, the vessels are fewer in number, and do not suffer that displacement, during the progress of vegetation, which those of the Cane experience. In neither plant are the vessels so numerous, or so situate, as to compress the cellular tissue into transverse partitions, nor is there, in the transverse section of either, any appearance of concentric layers. In neither stem is there any proper pith, the central part of the Sugar-cane being occupied by cells and vessels, and that of the Gourd being alike destitute of both. The cortical texture of the Gourd is represented as composed entirely of cellular tissue; but in it probably are situated the *proper* vessels, whose place has not yet been accurately noted.

271. In the sections of various herbaceous stems, represented by Grew and Malpighi, the number of vessels, and their disposition, exhibit the greatest variety, and approach more or less to the arrangement of parts that is found in shrubs and trees. Thus, in Holly-hock (*Alcea*), Grew describes the vessels of the bark as yielding a thin mucilage, and within them are the sap-vessels, postured in short rays, which comprise twelve or sixteen vessels. In *Scorzonera*, the "proper vessels" in the bark yield a milky fluid, and are postured in a radiated manner with the sap and spiral vessels that extend to the pith, all of which form parts of the same radiated lines. (*Anat. of Plants*, p. 103.) In Endive, Malpighi describes the structure of the stem as approaching in character to that of trees. Near the circumference the vessels, says he, are disposed in lines directed towards the centre, and are separated by small ranges of cellular tissue, which is compressed into a solid and dense form; and more interiorly, the vessels are larger, and

Other Stems, by Grew; by Malpighi.

Of the Trunk.

extend a considerable way in rays through the stem. (*Anat. Plantar.* p. 25.) Where the vessels have this radiated position, the cellular tissue between them assumes the form of membranous partitions; but the greater portion of the stem of this plant is occupied by cellular tissue, not thus compressed into a membranous form. We thus clearly observe that, even in herbaceous stems, membranous partitions, extending more or less completely through the stem, are formed, whensoever the vessels are disposed in radii, and are sufficiently numerous to compress, on either side, the cellular tissue that envelopes them.

### Article II.

### *Of the Trunk in Shrubs and Trees.*

Structure of Trunks.

272. In shrubs and trees, the several textures that compose the trunk are commonly distinct from each other; and some parts that are but imperfectly distinguished in herbs, become in them well defined. In the trunks of these plants, however, though a general uniformity of structure is observed, yet particular modifications of it exist in every species, and these are still farther varied by the peculiar nature of the individual plant, and the mode and circumstances of its vegetation. Before descending to particular examples, it may be useful to exhibit a concise view of the parts that compose the trunk, and the terms employed to denote them.

The Skin.

273. Externally in every tree we have the skin or cuticle, the structure of which has been already described in a former section. In very young plants, and in young branches, it is succulent, and its surface is entire; but in older trunks and branches, it is frequently dried and broken, and, in some instances, is thrown off; so that the exterior covering of the plant appears to be formed by the cellular tissue of the cortical texture.

The Bark.

274. Beneath the skin is the bark, constructed, as we have seen, of cellular tissue, and of vessels collected into fasciculi, which at first are strait, and run parallel to each other; but, by the subsequent augmentation of the parts within, are separated at certain places, and touch only at a few points, so as to form a reticulated appearance. In the annual shoot, only a single ring of vessels is observed, and these, with the tissue in which they are placed, form the *cortical layer*, as it has been called, of that period. Within this layer, a new production of vessels and of cellular tissue takes place, and this being annually repeated, constitutes the series of layers of which the bark is ultimately composed. The new layer that is thus annually formed, and which appears to exercise an active vegetative function, was more particularly distinguished by the appellation of *Liber* by the ancients, from its being the substance on which, before the invention of paper, they were accustomed to write. Very frequently, instead of a ring, the vessels of the bark are collected into distinct parcels or clusters, which, in the progress of vegetation, assume very different shapes.

Its Cortical Layers.

Its Liber.

The Wood.

275. Next to the bark is placed the wood, constructed, like the bark, of vessels and cellular tissue. Like it, too, it consists in the young plant, and in the annual shoot of the older one, of a single ring of vessels, which immediately surrounds the pith. In the following year, a new ring of vessels is formed around the first, and in every succeeding year this process is repeated; so that the wood consists at length of a series of rings enclosing each other, and the number of which denotes the age of the tree. The outer ring of newly formed vessels is more succulent than those of older growth, and is generally of a whiter colour; whence it has received the names of sap-wood or *alburnum*. By Du Hamel, and most French writers, it was named *aubier*, and by Hill it was called the *blea*. In every annual shoot, the newly formed liber and alburnum are in contact; but in every succeeding year they are separated more and more from each other by the interposition of new matter between them; so that at length the first layer of bark, and the first ring of wood, occupy respectively positions the most distant; those, namely, of the centre and circumference of the tree.

Its Alburnum.

Its Radiated Vessels.

276. The vessels that are thus annually formed, and constitute the alburnum, are disposed in *radii* which extend more or less completely from the circumference to the centre. In some trees, the vessels are much more numerous than in others; and, in the progress of vegetation, they frequently suffer great alterations in size and external figure, as was before observed when treating of the vascular system. In the alburnum the size of the vessels is very uniform, and so it continues ever after in some trees; but, in others, it is very various, some being enlarged more than others by a greater influx of sap. With this increase of size, the vessels seem to acquire the spiral character. They are also frequently closed up, in the more aged parts of trees, by the production of vesicles within their cavities; and, in common with the smaller vessels and the cells, they are, in some trees, ultimately filled with gummy or resinous matter. In other instances, where the proper juices of the plant differ but little in quality from the common sap, the vessels, when no longer employed in active vegetation, become dry, and appear, in some plants, like empty capillary tubes, and, in others, from the minuteness of their size, no aperture is visible. In this state, they have been regarded as solid filaments, and denominated the *ligneous fibres* of the plant.

Ligneous Fibres.

Transverse Septa.

277. From the disposition of the vessels in *radii* more or less regular, the cellular tissue, by which they are surrounded, will be more or less compressed in the same direction, and form those transverse partitions between the several rays of vessels, which we have already so frequently noticed. In addition to these fine partitions, described both by Grew and Malpighi, which are thus *interposed between* every ray or line of vessels, larger portions of cellular tissue are observed, at certain distances, which extend in the same direction through the wood, and, in some instances, are continued through the bark also. By the authors just mentioned, these partitions were described as stretching from the bark towards the pith, and were named *insertments* by Grew, and *transverse utricular ranges* by Malpighi. Others have held them to proceed rather from the pith to the bark, and have called them *medullary rays*. We shall venture to name them, in future, *transverse septa*, which name

Of the Trunk.

denotes simply their direction, and the fact of their forming partitions between the vessels, without expressing any opinion concerning their origin. For similar reasons, the finer partitions of cellular tissue, previously described, may be denominated the lesser transverse *septa*.

Longitudinal Septa.

278. Beside these transverse septa, there are sometimes portions of cellular tissue intercepted between the vessels in a longitudinal direction. This was remarked, both by Grew and Malpighi, in the oak and several other trees: they appear sometimes to be very short, and sometimes to form nearly a continuous ring around the trunk. It is probable they are formed simply by the pressure of the vessels acting in a direction opposite to that by which the transverse septa are produced; they may, for distinction sake, be named the *longitudinal septa*. In many trees, they are not to be observed, or, if they exist, are so thin as to form only a sort of *fascia* on the adjacent vessels. To the cellular tissue, promiscuously intermingled with the vessels, some writers give the name of *parenchyme* of the wood.

Parenchyme.

The Pith.

279. The only other part of the trunk that remains to be mentioned is the pith. It is situated at the centre, and is surrounded commonly by a ring of vessels, but sometimes, in part, by thickened cellular tissue. Its proportion in shrubs is usually much larger than in trees; and in the young shoots of trees it occupies more space than in the older branches. At first in the young plant it is succulent, but afterwards becomes dry; and in aged trees it frequently is entirely obliterated, or at least rendered solid.

280. In a description of the growth of the trunk in a young plant of chesnut, Malpighi has given clear views of the gradual developement of these several parts, and exhibited the appearances successively displayed in the first years of growth. (*Anat. Plantar.* p. 35.) In the Vine, some of these parts are very distinct. Fig. 1. Plate XVII., represents a transverse section of the annual shoot of this plant. The pith ($a$) in the centre is large, and composed of cells of different sizes. From the pith to the skin in the Vine, and, according to Grew, in the Elm and some other trees, extend the transverse septa ($b$). In some places, the cellular structure of these septa in the recent plant is still visible, as at ($c$); but generally they have the appearance of thickened membranes. Between every two septa, two, or sometimes three lines or rays of sap-vessels are interposed, which, from their size, are readily visible, and their place and disposition are indicated by the dotted marks ($d$): the circular ring that bounds these vessels seems to be formed of condensed cellular tissue, and exterior to it the proper vessels are placed in the cellular tissue of the bark.

Trunk of the Vine:

of the Apple:

281. In the next figure (fig. 2.) is exhibited the transverse section of an Apple-branch of one year's growth, which, like the former, is considerably magnified. The angulated figure and relative size of the pith at this period are shown: from the pith to the bark proceed numerous very fine septa, possessing somewhat of a curved direction, and between them innumerable black points, indicating the sap-vessels, are seen: these vessels are disposed in radii, and are bounded exteriorly by the thickened tissue of the bark: the bark is proportionally large, and in the midst of its cellular tissue clusters of proper vessels ($g$) are observed.

282. In a similar section of the Apple-branch of two years growth, fig. 3., more highly magnified, the pith ($h$) is seen to have assumed a rounder form: from the pith towards the bark the transverse septa extend, between which the vascular radii are situate. The letter $i$ denotes the place of junction of the two years growth; $k$ the newly formed alburnous vessels, situate between the bark and the wood; and $l$ two ranges of "proper vessels," placed in the cellular tissue of the bark. Grew gives a highly magnified view of a section of this same plant about the third year of its growth, in the 25th table of his work, the appearances of which correspond with those just related, except that the transverse septa, as in all his figures, are made to represent strait lines, which, in the earlier periods of vegetable growth, does not appear to be quite correct.

283. Proceeding next to the plant of more mature age, we shall copy from Grew part of a section of the Oak, which in fig. 4. is exhibited on a reduced scale. The letter $m$ denotes the bark; $n$ the alburnum; $o$ the wood; and $p$ the pith. In this section, the larger transverse septa ($q$), and the smaller ones ($r$), are very distinct, between which the sap-vessels of different sizes, indicated by the dark points, are situate: the letter $s$ points to the proper vessels of the bark, some of which are collected into round parcels, and others form a ring.

of the Oak:

284. Beside the transverse septa that intersect the diameter of the tree, we observe, in this figure, other lines ($t$) placed at right angles to them, and which appear to be interposed between each annual ring of wood. Grew considered it probable that these lines were produced in the Oak, and also in the Fig-tree and Walnut, by a peculiar sort of sap-vessels that existed once in the bark, as did the turpentine vessels distributed through the wood of the Pine. (*Anat. of Plants*, p. 115.) Hill also calls them sap-vessels, seated on the outer edge of each annual circle, which, in the young plant, contain sometimes a limpid liquor, and, at other times, appear empty. He notices also the existence of proper vessels, containing a thick juice, in the alburnum of this tree. (*On the Construction of Timber*, p. 9.)

of very old Oak.

285. An examination of this wood at an age still more advanced, may contribute to throw some farther light on its structure. In fig. 5. is given the representation of a transverse section of the central portion of a piece of the wood of very old Oak, of its natural size and appearance. The pith ($w$) at the centre was completely obstructed, and its cellular character obliterated; the letters $x$ $x$ $x$ denote the larger transverse septa, rendered completely solid everywhere, and in some places partially obliterated; and ($y$) the white lines that extend in the opposite direction, and mark the boundaries of each year's growth. In the substance of these concentric lines, numerous traces of minute apertures were visible, and from one line to another, small irregularly curved lines, as represented in the drawing, were everywhere observed to extend. No vacuity was anywhere perceived to exist, but the whole formed one compact and solid mass.

286. A small and very thin slice of this wood,

Of the Trunk.

comprising a part of one of the larger transverse septa, and small portions of two of the concentric lines above mentioned, was submitted to a pretty highly magnifying power, and a delineation of its appearance is given in figure 6. In this figure, the letters $a'$ $a'$ denote the two concentric lines; $b'$ one of the smaller irregular lines that frequently extend from $a'$ to $a'$, but are often intercepted, and form irregular spots or patches, as traced in several parts of the drawing; $c'$, the smaller transverse septa, situated at unequal distances from each other; and $d'$, the larger septum, the cellular character of which is entirely obliterated. Several small irregular lines, running in the same direction with the larger concentric ones, are also observed; these, at their junctions with the lesser transverse septa, produce a number of little squares, the areæ of which are filled up with a dotted or punctuated membrane.

Structure of Oak,

287. This microscopical representation seems to confirm the opinion of Grew, that the concentric lines ($a'$ $a'$) are chiefly composed of vessels; for their apertures, now rendered visible, are of different sizes, and the canal of many of the larger ones is filled up with a vesicular substance, often observed in the vessels of aged plants. The substance that surrounds these vessels appears to be condensed cellular tissue, rendered perfectly solid by the resinous matter with which it is filled. The irregular thickened lines ($b'$) that run transversely to the former, are similarly composed of vessels and condensed cellular tissue, and the smaller patches, we have noticed, are made up of the same; both the large and small transverse septa consist of condensed cellular tissue alone, and such, too, appears to be the matter of which the fine lines or longitudinal septa that intersect them are composed. Some observations of Du Hamel, on the formation of the ligneous layers, may aid our inquiries into the nature of these latter septa, and the minute structure of the wood.

by Du Hamel;

288. In a transverse section of the trunk of the Oak, the Elm, or the Fir, says this very intelligent writer, the ligneous layers are distinctly visible, and it is commonly believed that each of these layers is the product of one year's growth. If, however, we cut obliquely a piece of Oak, each layer is then seen, with the aid of a common lens, to be composed of a number of thinner layers, which mutually cover each other. By macerating pieces of wood in water, he was able to separate the annual layers into a great number of leaflets thinner than the finest paper; and these primary layers, as they may be called, he afterwards ascertained, by experiment, to be formed successively during the whole period of active vegetation; so that the layer which is the product of one year's growth, is itself formed of a number of layers exceedingly thin. (*Phys. des Arb.* Tom. I. p. 31, and Tom. II. p. 19.)

Now, it is probable that, between each of these primary layers, cellular tissue is interposed; and this tissue, by its compression, gives origin to the minute lines which in this tree have been noticed. In several trees, however, no similar lines are visible, because, in all probability, they do not, like the Oak, afford secretions by which the tissue is thickened and rendered apparent. Even in a very thin slice of Oak, when viewed in the microscope by a strongly reflected light, these lines almost entirely vanish, while those of the two orders of proper transverse septa remain.

by Kieser.

289. M. Kieser examined the same wood, in the transverse slice of a tree of 100 years of age (*Mém. sur l'Organisat.* &c. Plate XIV.), and his representation of its structure is copied in figure 22. Plate XVII. In this figure, in which the appearances are magnified 130 times, $n$ $n$ $n$ represent the cellular tissue, or, as he calls it, the parenchyme of the wood. At the top and bottom the cells are obstructed, and appear like obscure points (as is the case also in fig. 6. of the same Plate); but in the middle of the figure, the cavities of the cells are said to be still visible: the letters $o$ $o$ denote the apertures of enlarged spiral vessels, all of which were filled with vesicles, but a few only are so represented, as in $p$ $p$; $q$ indicates the smaller vessels dispersed through the cellular tissue; $r$ a portion of one of the larger septa, and $s$ the smaller ones, which are often displaced by the augmentation in the size of the vessels.

290. In this highly magnified representation by Kieser, there is no appearance of the concentric lines or septa which intersect the transverse ones, as noticed by Grew and Malpighi, and exhibited in figures 5. and 6.; but the two orders of transverse septa remain. We before remarked, that, in a slice of wood so very thin, as, when viewed by a strong light, to become translucent, these lines, in a great measure, vanished, and in the figure of M. Kieser, this evanescence is made to extend even to the thickened portion that intercepts the annual layers. It is therefore probable, that all these appearances of concentric or longitudinal septa, are produced simply by the thickening and compression of the cellular tissue in the Oak, and such other trees as have viscid juices, and whose vessels are subject to irregular enlargement; for in whatever position these thickenings occur, numerous vessels are always to be observed. Hence, in very thin slices they entirely vanish, while the proper transverse septa, being formed by the condensation of continuous portions of membrane, remain visible. In these figures, it may also be remarked, that the surface occupied by cellular tissue seems equal nearly to that occupied by vessels; but it is probable that the apertures of many minute vessels dispersed through the tissue, have not been distinguished from the cells. In a highly magnified representation, however, of the wood of this tree by Grew (*Anat. of Plants*, tab. 3. fig. 7.), the proportion of the vascular to what is deemed the cellular part is still less.

Bark of Oak.

291. The vessels of the bark in the Oak, as delineated by Grew, fig. 4. Plate XVII. are represented as disposed partly in parcels, and partly in a ring; and in all the representations he has given of different trees, the greatest diversity, in regard to the position of these vessels, is found to exist. From the difference in the qualities of their juices, in the texture of the parts, and in the modes and circumstances of their growth, this variation may be expected to occur. In the Oak, the Pine, and many others, it seems certain also, that a part of the cortical texture, or at least vessels containing the proper juices of the plant, are constantly mixed with those of the ligneous texture, and with them contribute to form each an-

Of the Branch. nual layer of wood. In this respect, therefore, these trees may be said to approximate in structure to Palms, and those trees in which the two textures are uniformly blended, in some of which, the growth is said to take place at the circumference, as in ordinary trees. For examples of the diversity of structure exhibited in the trunk of a great many different trees, we must refer to the beautifully executed plates of Grew.

### Section II.

### *Of the Structure of the Branch and its Appendages.*

#### Article I.

#### *Of the Branch.*

The Branch. 292. From the trunk springs the branch, which, in structure, resembles very exactly that of the trunk itself. Indeed, most of the figures, which represent the structure of the trunk, are taken from sections of the branch; and hence the description of the one serves entirely for that of the other.

293. Branches, in common with leaves, originate from buds, of which we have subsequently to treat, introductory to a description of leaves. At present, we shall describe only the mode of connection between the trunk and the branch.

Its Connection with the Trunk. 294. The branch, says Grew, springs not from the surface, but so deep as to take with it not only the bark and the wood, but the pith also, making its way at the parts where the vessels are separated by the transverse septa, and carrying with it the skin, which is extended with it. (*Anat. of Plants*, p. 28.) The separation of the vessels of the trunk to form the branch is not like the separation of a few filaments from a skein of thread; but they spring, says Du Hamel, from a centre, and bear with them a part of each portion of the tree. Hence if a tree, that is divided into two branches, be cut a foot above the bifurcation, the surface of the sections resembles that of two trunks cut horizontally: if the section be made lower down, at the place where the branches spring, the same appearances of two series of concentric circles are seen at the axis of the trunk, but they are surrounded by other layers common to those which belong to each of the branches; and still lower on the trunk, the concentric circles belonging to each branch, diminish, and are finally lost in those which form the trunk from which they sprang. (*Phys. des Arbres*, Tom. I. p. 93.) These primary branches divide into others, and these again into still smaller branches, which form angles with each other, more or less great, according to the species of tree and other causes.

295. The position of the branches on different trees is very various, but in the same species it is generally uniform. From the measurements of Du Hamel, it appears that, in many trees, the solid matter of the branches that go out from the trunk, exceeds that of the trunk itself in the proportion nearly of five to four. (*Phys. des Arbres*, Tom. I. p. 96.)

Origin of Branches, 296. Parent and others have supposed that the branches proceeded always from, and were nourished by, the pith; but this opinion has been combated by Du Hamel and Hill. The latter gives a longitudinal section of the trunk of a species of American Dog-wood (copied in fig. 7. Plate XVII.), representing the origin of two buds ($ff$), which are seen in the state of pushing out on either side through the vessels of the wood. In this trunk, the pith is of a brown colour, the inmost ring of vessels green, and the outer ones white. Through the white rings, the inner green vessels are seen to shoot, and the brown pith is left entire behind; though the new branch at length obtains a pith for itself, which, however, has no connection with that of the trunk. In a similar section of an older trunk (fig. 8.), the branches are seen to spring also from the inmost circle of wood: the pith ($g$) is not at all disturbed, but each branch is furnished with its own pith $h\ h$. In a section of the Vine, fig. 9. a similar origin of the branches, from the inmost circle of wood, is observed; and not only is the pith ($i$) of the branch distinct from that of the trunk, but the pith of the trunk itself is intercepted by the shooting of a branch ($k$) across it. (*On the Construction of Timber*, p. 35.) This latter fact of the interception of the pith by the shooting of branches across it, was previously noticed by Grew in the Vine and some other plants. (*Anat. of Plants*, tab. 19.) Of the Branch. by Hill.

297. When a bud thus protrudes to form a branch, the perpendicular vessels of the trunk are compelled to separate, and they afterwards meet above, and pursue their former direction. This is shown in fig. 11. Plate XVII. copied from Du Hamel, in which the bud $p'$, in the act of sprouting, is seen to push to either side the vessels of the trunk, which again meet above it.

298. The vessels, both of the wood and bark, according to the same author, have their direction determined chiefly by the course of the sap. If the sap preserve a perpendicular direction, as in trees that have no branches, the vessels are perpendicular also; but if it move to one side, these vessels then change their direction. This is strikingly evinced in a tree that has been cut over above a branch; for then all the sap being obliged to pass to the young branch, the vessels all at once take the same direction; so that if a tree has been cut over in winter, and at the end of the succeeding spring, its branch below be examined, the new vessels of the branch will be seen to cross those of the trunk, as exhibited in fig. 12. $q'$, Plate XVII. (*Phys. des Arbres*, Tom. II. p. 53.)

299. In figures 7. 8. and 9. copied from Hill, the young branch, in every instance, is seen to originate from the most inmost ring of vessels that surrounds the pith; and he was of opinion that all buds and branches sprang from this part alone. To this vascular circle he gave the name of *corona*, and held it to be the most important part of the vegetable body, that it was like no other part of the plant, but contained within itself the essence of them all. (*On the Construction of Timber*, p. 21.) Corona.

300. It is however notorious, that trees in which not only this first circle, but almost every other circle of vessels has perished, produce leaves and shoots from the trunk where the bark is entire, as this author himself admits, p. 44 of his work.

Of the Branch.

There does not appear, either in the anatomical character, or in the functions of this circle, anything that distinguishes it from the others, except priority of formation, and its being, in consequence, the seat from which the *first* buds and branches spring.

Origin of Branches by Du Hamel.

301. A much more correct idea of the origin of buds and branches was entertained by Du Hamel, who illustrates it by the diagram, fig. 10. Plate XVII. Let us suppose this figure to represent a tree of four years growth, as indicated by the four ligneous cones which, at its base, envelope each other. In the first year, a bud ($l'$) springs from the inmost ring, which, by the fourth year, is seen to consist of four ligneous layers. In the second year, a second bud ($m'$) springs from the ring of that year, and consists only of three layers; the next year, a bud ($n'$) is developed on the first bud $l'$, and possesses only two layers; and the bud $o'$, developed the fourth year on the outmost ring of wood, is seen to consist only of one layer. (*Phys. des Arbres*, Tom. II. p. 53.) In this way, every ligneous layer may be considered equally capable of giving origin to buds and branches.

### Article II.

### *Of Thorns.*

Thorns are Abortive Branches.

302. Connected both in origin and in structure with branches are those appendages, frequently observed upon them, called thorns. They are very conspicuous on the hawthorn, and are constituted, says Grew, of the same parts as the bud itself, and in a like proportion. They spring from the outer portion of the ligneous texture, and may be considered as abortive buds. (*Anat. of Plants*, p. 33.) Malpighi describes them as being frequently produced in the axils of leaves, and to assume for a time the form of a branch; but at length to degenerate into a thorn. He considers them to arise from defective nutrition, and adds, that they disappear frequently under higher culture. (*Anat. Plantar.* p. 138.)

According to Willdenow, most species of our fruit-trees naturally possess thorns, but which disappear entirely and become branches, under higher culture. Even in the Black-thorn, the prickles diminish in number under improved culture, but do not entirely disappear.

Other Origins of Thorns.

303. Sometimes, however, instead of being produced from abortive buds, thorns owe their origin to the degeneration of other organs; the petioles of some pinnate leaves which are persistent become thorns, and the same thing is observed of the peduncles of some flowers. Certain stipulæ, also, as those of Mimosa, are said sometimes to change into thorns (*Principles of Botany*, p. 270.); and in the Date, according to M. Decandolle, a lobe of the leaf has been converted into a thorn. (*Théorie Elément. de la Botanique*, p. 344.) In other instances, as in the Holly, the leaf produces thorns round its entire margin, which are formed by the vessels that bound it. See fig. 11. Plate XVIII.

Structure.

304. When the bark is removed from a branch that possesses thorns, the thorns still remain, by which they are distinguished from prickles that originate from the bark. In fig. 20. Plate XVIII. is a representation of a branch deprived of its bark, in which thorns of different forms are seen to spring from the ligneous texture; and in fig. 21. of the same Plate, is a longitudinal section of another branch covered with its bark, in which the ligneous and cortical textures of the Thorn are displayed. For the descriptions of the varieties of thorns, and their external appearance, we must refer to the writers on botany.

### Article III.

### *Of Claspers and Tendrils.*

Description.

305. From the similarity in structure which these bodies exhibit to the branches from which they spring, we have placed them as appendages to those members. As is well known, they are met with only in certain plants, and their obvious use is to attach the different parts of the plant to one another, for mutual support, or to the objects in their neighbourhood. In a general manner, they are denominated *fulcra*; the most remarkable species are those which, like the claws of Ivy, called *claviculi* by Malpighi, are not rolled into a spiral form, and those of the Vine, named tendrils (*cirri*), which possess a spiral conformation.

Structure of Claspers.

306. According to Malpighi, the claws or claspers of Ivy possess a roundish form, and are covered with hairs, which yield a viscous humour, by which they are agglutinated to stones or to walls and trees. Their forms are exhibited in fig. 22. $e'$ $f'$, Plate XVIII. copied from Malpighi; and in the lower part ($g'$) of the same figure, their origin and structure are displayed; they are seen to spring from the ligneous texture of the stem, and to possess a similar structure.

of Tendrils.

307. The tendril is described by the same author as springing from knots between the origin of leaves. It possesses a round stem, which is sometimes covered with hairs, and this stem frequently divides into several branches. At first it is very tender, but gradually acquires solidity, and assumes the spiral character; its colour is green, and it is composed, like the trunk, of all the common textures. (*Anat. Plantar.* p. 139.) By Willdenow, it is regarded as an abortive leaf, being simply a prolongation of the petiole, without the leafy expansion. (*Principles of Botany*, p. 272.) Its form, as it occurs in the Vine, is exhibited in the upper portion of fig. 22. $h'$, Plate XVII.; but, in this particular, it is subject to the greatest variation.

308. The leaf itself, as well as the petiole, is said to be sometimes prolonged into a tortuous appendage resembling the tendril; and similar transformations are sometimes exhibited by the peduncle and petals of the flower. In one species of Vine, mentioned by Malpighi, the extremity of the tendril, which is at first pointed, becomes gradually incurvated and reflected, and at length is formed into a roundish body, which is furnished with small papillæ, that yield a viscous fluid, by means of which it attaches itself to walls or wood, so strongly as not to be easily separated. In Dodder (*cuscuta*), small tubercles are formed on the stem, which, according

Of Roots. to M. Decandolle, are so organized as to fix themselves on any other plant, and derive nourishment from it. (*Théorie Elément. de la Bot.* p. 344.) For descriptions of the several varieties of these organs enumerated by botanists, and for the terms employed to express them, we must refer to their works.

### Section III.

*Of the Structure of Roots.*

Varieties of Roots. 309. Roots possess very different forms, to which botanists have assigned distinct appellations. Some, as those of trees, branch out from one trunk beneath the soil, and are named *branched* roots; other plants have a number of equally sized roots collected into a bundle, and are called *fasciculate*, or sometimes *fibrous*. In other instances, the root is spindle-shaped, *fusiform*; or shaped like the hand, *palmate*; or composed of many joints, *articulate*. In the course of the root, knobs or tubers are sometimes found, giving to such roots the name of *tuberous*; in others, a fleshy bulb occurs, and such are called *bulbous*; others run horizontally beneath the soil, and are named *creeping*; and others are abruptly terminated, or as if bitten off, and called *præmorse*. For examples of these and many other varieties, we must refer to the writers on botany.

Parts of Roots. 310. The root (*radix*) of the mature plant, is held to consist of two parts; the stock or main body (*caudex*), and the ramified productions called radicles or rootlets. These parts are generally concealed beneath the soil; but, in the case of parasitic plants, they are inserted into other vegetables. Some of the lower tribes of vegetables have their roots attached to stones, and rocks; and the roots of others have no fixed attachment, but float loosely on water. The different species of *Tremella* have no root at all; but the functions of this part are performed by the general surface. With regard to duration, some roots speedily decay; others continue permanent. The varieties in their figure have been noticed in the enumeration of their names, and the direction they pursue in their growth, is either horizontal or perpendicular, or in some intermediate position.

Roots of Trees. 311. With respect to structure, the body of the root of *trees*, says Malpighi (*Anat. Plantar.* p. 145.), may be regarded as a production and elongation of the trunk beneath the soil; and is constructed of the same textures, disposed nearly in the same manner; wherefore it is unnecessary to detail them at any great length. Exteriorly is placed the cuticle, beneath which is the cellular tissue of the bark, with its accompanying cortical layers, the vessels of which have a reticulated form. The bark is thick; its vessels frequently contain the same "proper juices" as those of the trunk, and its cells are alike filled, in some roots, with concreted matter. From the bark to the centre, the two orders of transverse septa are observed to proceed; and are interposed between the rays of vessels, as in the trunk. These vessels, in the root, are often larger than those of the trunk; and instead of a pith, the central part of the root is commonly occupied by vessels. The primary rootlets, which spring from the principal stock, are often tortuous, and are propagated in several successive series, like the branches and ramulets of the trunk; from them proceed still finer ramifications (*capillamenta*), which are the true absorbents of the root, and may be termed capillary rootlets, as they are sometimes named by Du Hamel.

Roots of Herbs; their Skin; 312. In various *herbaceous plants*, the root has been particularly examined by Grew. (*Anat. of Plants*, Book II.) Its skin is of very different colour and thickness. In the early state, it is represented as an extension of that which covered the radicle of the seed; but in more aged plants, the exterior covering is derived from the cellular tissue of the bark. It is usually, if not always, compounded of vessels and cellular tissue; both of which are distinguishable in many roots.

their Bark; 313. Beneath the skin, the cortical texture is observed, making up, in some herbs, the greater portion of the root, while in trees it is commonly thin. It is composed of cellular tissue and fasciculi of vessels variously dispersed through it, and forming a network, the meshes of which are filled with the tissue. In these vessels, various gummy, resinous, and milky liquors, similar to those in the bark of the stem, are frequently contained; and it is by their presence that the *position* of the vessels is best distinguished. Very frequently they make a ring at the inner edge of the bark, "in which place and position," says Grew, "they stand in most, if not all roots, how variously soever they are posited also otherwise." They occur, however, in clusters in the bark of many roots, and in others are disposed in rays, or seen sometimes to be irregularly dispersed through the cellular tissue in common with the sap-vessels. The cells of this tissue sometimes preserve nearly an uniform size; in other instances they are of very irregular forms; and frequently are compressed into transverse septa, which everywhere intercept the vessels, and are of very various size and number; they are the receptacles of liquor, but are often found empty.

their Wood; 314. The woody part in herbaceous roots is described as consisting of vessels and cellular tissue; this tissue forms sometimes transverse septa, but in some roots it is disposed in rings. The vessels are disposed either in separate fasciculi, or in rays, or rings. In number and size they very much vary in different roots, and also in the same root; they generally appear empty, but may sometimes contain sap; they frequently occupy the centre of the root to the exclusion of pith; but near the top of the root, a pith is often to be found.

315. Having given this general description of the structure of roots, we shall now exhibit a few examples of it. In the young state of the herb, this structure has been already displayed in sections of the pea and gourd, figures 12. 13. and 17. Plate XVI. In the root of the Gourd, at a later period, M. Kieser delineates four large fasciculi of vessels, each of which contains between thirty and forty vessels; the larger vessels are situated near to the circumference, and the smaller ones towards the centre of the root; they all exhibit the *spiral* character, and many of them are obstructed by vesicles. (*Mém. sur l'Organisat. des Plantes*, Planche X.)

316. In fig. 13. Plate XVII. is a transverse sec-

Of Roots.

Root of Asparagus.

tion of the root of Asparagus, copied from Grew, but on too small a scale to show more than the relative position of the parts; the letter $r'$ denotes the bark, at the inner margin of which the proper vessels are placed in a ring; $s'$, the sap-vessels or woody part placed more interiorly; and $t'$, the pith at the centre. A very highly magnified representation of this root is given by Grew in table 10. of his work. If his view of its structure be correct, it exhibits a remarkable difference in the arrangement of parts in the stem and root; for the stem of Asparagus is one of those in which neither distinct bark, nor wood, nor pith, exists; but the cortical and ligneous textures are blended together.

Root of Mallow.

317. In the root of Mallow, the position of the vessels is quite different, as exhibited in fig 14., in which the letter $v$ denotes clusters of proper vessels, postured in a radiated form in the cellular tissue of the bark; within these rays is a portion of cellular tissue, through which a few sap-vessels are dispersed; but they are chiefly accumulated at the centre $(w)$ of the stem. In several of Grew's tables, transverse sections of various other herbs are given, which display the greatest possible variety, in the proportion and arrangement of the vascular systems of the bark and wood; to them we must refer the reader who may desire farther information.

Of the Vine.

318. In shrubs, the arrangement of the parts of the root is commonly more distinct than in herbs, and corresponds with that in the trunk. In the transverse section of the root of the Vine, fig. 15. the letter $x'$ denotes the place of the "proper vessels," situated in the cellular tissue of the bark; $y'$, the sap-vessels extending in radii to the centre of the root, which is altogether destitute of pith; and $z'$ marks the transverse septa which are interposed between the rays of vessels. Of this figure a very highly magnified view is also given by Grew in table 17. of his work. In table 16. the same author represents the structure of the root of Wormwood. His delineation of it is copied in Plate CCCCXX. (Article Plant) in the body of this work, to which we refer the reader. The disposition of the parts resembles almost exactly that of the Vine, except that the "proper," or "balsam vessels," as he calls them, are placed at greater distances from each other; and, from containing a viscid fluid, are enlarged, and rendered more distinct.

Origins of Rootlets,

319. We before noticed the manner in which the rootlets were given off from the radicle in the Pea and the Gourd. All parts of the root possess the power of emitting rootlets when they are placed in favourable circumstances; and this power is possessed also by the branch. If the branch of many trees be cut off and planted in the earth, it emits rootlets from its sides beneath the soil, and becomes at length an entire plant, possessing the several members of root, trunk, and branches. If even the bark of a branch be partially removed, so as to intercept the course of the *descending* sap, and the detached part be, at the same time, surrounded with moist earth in the manner of a graft, the upper portion of the divided bark will emit rootlets into the earth; and if, after a certain period, the branch be separated and planted, it will form a tree, sooner, it is said, than by most other methods. The simple immersion of the cutting of some trees in water, as of the Willow, is sufficient to elicit the production of rootlets. The origin of these has been traced by Malpighi (*Anat. Plantar.* p. 146.), and is exhibited in fig. 16. Plate XVII.; in which is represented a longitudinal section of the cutting of the willow, and of the rootlets it emits from its sides. These rootlets spring from the cutting, just at the surface of the water, not below it. They appear, at first, like small tumours in the bark, which protrude and gradually force their way through it, forming fissures, which are, as it were, bordered by a lip, and afford passage to the springing rootlets. In the figure just referred to, $a$ denotes the outer portion of the bark that forms the lip; $b$, the inner portion which protects the springing rootlet; $ccc$, three rootlets which are seen to originate from the perpendicular vessels of the wood.

in the Willow.

Structure of Rootlets.

320. The capillary rootlets which thus spring from the larger roots, and from branches, are much more simple in structure than buds, being made up chiefly of the ligneous texture of the trunk, which, in shooting, carries with it a portion of the cortical texture that covers it. They are the organs which absorb nutriment from the earth, and convey it into the larger rootlets, by which it is transmitted to the trunk. Hence, as Du Hamel observed, the earth is exhausted of its nutrient matter, chiefly where these capillary rootlets are distributed, and not in the neighbourhood of the larger roots. On examining the roots of trees, after a severe winter, he found these capillary rootlets to be generally dead, which led him to suspect that trees lose, in the earth, their rootlets, as, in the air, they lose their leaves. He found, that, even after slight frosts, during every period of winter, many of these capillary rootlets were destroyed; and that, when the temperature became milder, new rootlets were developed, which abundantly replaced the others. (*Phys. des Arbres*, Tom. I. p. 88, 89.)

Rootlets annually renewed.

321. Analogous to the production of rootlets from the branches, when the descending sap is intercepted, is that of the emanation of similar organs from the knots in the stems of many plants, as those of the *Gramineæ*. Wherever a knot of this description is brought into contact with the moist earth, numerous rootlets break out, and buds also, from which entire plants are produced. In the culture of the Sugar-cane, the propagation of the plant is continued entirely in this way, and never by means of seed; in the several modes of engrafting, and various other horticultural operations, the cultivation of vegetables proceeds on a similar principle; for the graft, which is attached to and becomes rooted in another tree, may, by a different method, be made, like the cuttings of willow, to furnish roots from its own substance.

Tuberous Roots.

322. In some plants, as *filipendula*, the roots and rootlets swell out into globular bodies, or tubers of the shape of olives: these tubers are composed of vessels with a large portion of cellular tissue, and from them other rootlets spring. In other instances, the tuber that forms on the root is a true bud, which acquires a large size, and from it the real rootlets,

Of Roots ‖ Of Buds.

possessing a filiform figure, also spring. (*Malpighi, Anat. Plantar.* p. 150.) The bulbs attached to the roots of many plants are likewise to be regarded as real buds, and will be briefly noticed in the next section.

Effects of Soil on Roots.

323. M. Du Hamel has made many observations and experiments on the effects of the soil in determining the form of the root. All roots that spring from seeds have, according to him, a spindle shape, if they are made to grow in soil that is easily penetrable. He has seen the root of a young Oak extend in such a soil to the depth of four feet in the form of a tap-root, when the stem possessed only six inches in height. If, however, at a small distance from the surface, it meet with obstacles, which oppose its descent, it then continues short, and divides into lateral branches. A similar production of lateral branches is observed, if, by any accident, the leading trunks of the root be destroyed.

If, on the contrary, a trench be dug in the neighbourhood of a root, and then filled up with fresh earth, the root will extend through the soft earth, without producing lateral branches; and the same often is observed to occur in very moist situations. The direction of roots is also greatly varied by the qualities of the soil, for they extend into that which is richest, while the barren parts are nearly destitute of roots. (*Phys. des Arbres*, Tom. I. p. 82.) So great, indeed, appears to be the influence which the qualities and texture of the soil exert on the growth of roots, that in many instances, before we could pronounce on the true form of a root, it would be necessary to define the kind and condition of soil that is most natural to it.

## CHAP. III.

### THE ANATOMY OF THE ORGANS OF VEGETABLES.

### SECTION I.

#### *Of the Structure of Buds.*

Buds.

324. In the preceding chapter we have described the larger and more permanent members of the plant, which produce and sustain all the other organs: we have now to delineate the form and structure of these organs, which have a more temporary existence, and present a more diversified character. They may all be said, either directly or indirectly, to originate from buds, with which therefore we shall commence our descriptions.

Definition.

325. A bud, according to Gærtner, is an organic body, sprouting from the surface of a plant. In the beginning, it is distinct from the proper and permanent members of the plant, but after some time becomes a part of it; or, if separated, is capable, by the increase of its own proper substance, of growing into a new plant, perfectly similar to its parent. (*De Fructib. Plantar.* p. 3.)

326. Buds may, in general, be easily distinguished from seeds; but in some of the lower tribes of vegetables, the conformity in external appearance and internal structure is said to be so great, as to render this a matter of much difficulty. This appears to arise principally from the extreme minuteness of the organs of reproduction in those plants, and the consequent uncertainty in discriminating their true character; so that botanists are not agreed as to what, properly speaking, should be termed a bud, or what may be deemed a seed; some choosing to regard as a bulb or bud what others denominate a seed.

Species of Buds. Propago.

327. Gærtner enumerates four species of buds, two of which are leafless, and two are provided with leaves or scales. The first, *propago*, is the most simple species of bud; it is leafless, and possesses different forms; sometimes it is entirely naked, and sometimes is enclosed in a bark-like case; it at length separates spontaneously from its parent, and is dispersed like a seed.

Gongylus.

328. The second species is termed *gongylus:* it is described as a perfectly simple, leafless, somewhat globular and solid bud, concealed within the bark of the parent plant, and never separating spontaneously, till the bark decays by age. It has a great affinity to the tuber of roots, but differs from it in not being a proper member of the plant, and in not possessing the principle of multiplication which resides in the tuber.

Bulbus.

329. The third species of bud is a compound germen, and named *bulbus*. Its figure is somewhat globular; it is nearly leafless, and formed of a very short keel (*carina*) and thick succulent scales, and at length separates spontaneously from its parent. Of this species there are two varieties, the one *solid*, constructed of a solid fleshy body, and having generally the rudiments of the new plant fixed outwardly upon it; the other *coated*, being formed of several concentric scales, in the centre of which the young plant is cherished.

Gemma.

330. The last species of bud, and that which is strictly so named, he denominates *gemma*. This is a bud composed of a subulate keel, and distinct herbaceous leaflets; it resembles a branch in miniature, and never separates spontaneously from its parent. It is named an *eye* (*oculus*) when it puts forth flowers alone, or flowers and leaves together; and simply a *gem* (*gemma*) when it is unfolded into leaves alone.

331. Of these several species, the last, *gemma*, is generally considered as alone entitled to the appellation of a true-bud, by those who consider scales and leaves as essential to its constitution; but this definition, says Gærtner, would exclude even bulbs, and it is better to derive our idea of a bud from a general agreement in properties, and particularly from similarity of origin in formation and evolution, than from the ever-varying condition of external form. The two former species of buds occur in the lower tribes of vegetables; the two latter are observed on the stems and branches, and roots of various plants. On the present occasion, we shall notice the latter only.

Structure of Bulbs.

332. That variety of bud which is called a *bulb*, and which springs from, or is variously attached to, the roots of many plants, has already been stated to exhibit considerable difference in structure. It is sometimes constructed of several thick scales or leaves enveloping each other, and is sometimes formed of a more continuous and solid substance. To the first description belongs the bulbous substance of the lily and tulip. Grew has given a section of the lat-

Of Buds.

ter, made in the month of September. It displays the tunicated structure of the bulb, at the base and in the centre of which, the young flower, destined to appear in the following spring, is observed. See his *Anatomy of Plants*, tab. 63., or Plate CCCCXXI. fig. 17., in the body of this work, accompanying the article PLANT. Of the tunicated variety, the common onion affords also a good example. The coats that compose its bulb, are to be regarded as fleshy leaves, and the true root, according to Du Hamel, is the fleshy plate that supports the bulb, from which the rootlets spring. The common potatoe affords an example of the solid bulb, on whose surface numerous buds, all capable of producing entire plants, are seen. Botanists enumerate a great many other varieties of bulbs, for which we must refer to their writings; and to the works of Malpighi and Du Hamel for the anatomy of many of them.

Names of Branch-buds.

333. The true bud of the stem and branch was distinguished by the ancients into two kinds, according as it produced either a leaf or a flower, and to it they assigned different names. "*Germen autem est id quod ex ipsis arborum surculis primo vere exit, ex quo deinde folium producitur*," says Pliny; and this he distinguishes from the flower-bud, "*nam gemma propriè floris est*." By Grew, the term *germen*, and by Malpighi, the word *gemma*, is employed to denote each variety of bud. By Linnæus, the term *germen* is used to denote, not the bud of a branch, but the rudiment of a seed; and not the rudiment of the seed only, but the organ also that contains it. The word *gemma* he uses to denote a bud. Gærtner adopts the word *germen* in a generic sense, to express every species of bud, and with Malpighi and Linnæus, employs the term *gemma* as indicative of that species now under consideration. This, therefore, as the most generally received appellation, we shall in future employ.

Description.

334. During summer, says Du Hamel, buds are gradually formed in the axils of the leaves, viz. in the angle which the petiole forms with the branch. They are at first exceedingly minute; are seen in winter chiefly on the young branches, sometimes on the larger ones; and more rarely on the trunk. They exhibit different forms, according to the kind of tree that bears them, and are attached to it by a very short pedicle. Their position on the branch was considered by M. Bonnet to be reducible to five classes; sometimes they are situated on opposite sides of the branch, but placed alternately, and sometimes they are placed exactly opposite to each other. In other instances, they form a kind of ring round the branch. Sometimes they have a spiral disposition; and at others constitute a sort of double spiral around the branch. In those cases, where the buds stand opposite on the branch, the extremity of the branch is frequently terminated by three buds; but where the buds are only alternate, the young branch is commonly terminated by a single bud. In the Pine, the true buds are placed, not in the axils of the leaves, but at the extremity of the branch alone. Some buds stand out a considerable distance from the branch; others are placed in close contact with it; and these varieties occur sometimes on the same branch in regard to the buds that issue from its sides and extremity. The shape of buds is also very various—some being long and pointed, others short and round; some again are hairy, others smooth; some very small, and others large. (*Phys. des Arbres*, Tom. I. p. 99.)

Leaf and Flower-buds.

335. Beside these varieties in position and form, which serve to distinguish the buds of different genera and species, there are also many sorts of buds to be observed on the same tree, whose characters are discoverable by their form. Those which are pointed, usually produce leaves and branches; and from those which are large and rounder, commonly proceed flowers. The former are named leaf or wood buds (*gemmæ foliiferæ*); the latter flower or fruit buds (*gemmæ floriferæ*); others, which possess both leaves and flowers, have been called mixed buds (*gemmæ mixtæ*.) In some trees, as those of Apple and Pear, two varieties of wood-buds occur, one of which is small, produces only a small bunch of leaves, and in the end becomes a fruit-bud; the other is larger, and gives origin to a branch.

Formation of Buds.

336. As the rudiments of the flower appear in the bulb of roots, the season before they are destined to bloom, so those of the leaf and the flower are distinguishable, at the same period, in the bud of the branch. They are to be perceived, says Du Hamel, in autumn, and continue to grow even during winter, appearing to be clandestinely formed in that season, when the movements of the sap seem to be suspended; and are thus prepared to shoot forth on the return of spring. It is, however, only in perennial plants that these phenomena are observed. Annual plants do not produce buds, and even those whose roots survive the fall of the stem, produce buds only on their roots. (*Phys. des Arbres*, Tom I. p. 103.)

Effects of Climate on Buds.

337. Climate appears to exert the greatest influence on the formation and evolution of buds. In cold regions, as we have just observed, the bud is formed many months before it is destined to shoot into a leaf or branch; but in warmer regions, scarcely any interval occurs between the periods of formation and evolution. The buds in such climates, are said to unfold themselves immediately from the bark into branches, without having remained, in the form of buds, for any length of time. Sometimes, in the milder seasons of our own climate, the evolution of buds rapidly succeeds to their formation, and the vegetative process with us, emulates the productive powers of more favoured climes. In some examples, however, the specific characters of particular plants overcome these general tendencies of climate; and thus hot climates are said to possess some bud-bearing plants, and in colder climates, there are a few shrubs which are said never to bud. (*Willdenow's Princip. Botany*, p. 273.) It seems, however, more correct, to consider all plants as bearing buds, from which the branches, the leaves, and the flowers, successively proceed; and to say that in warm climates in general, no suspension of the vegetative process occurs as in cold ones; and no marked interval is observed therefore between the formation and evolution of buds. The few exceptions that occur respectively in warm and cold climates, must be considered in reference to the specific characters of the individual plants. The process by which buds are

Of Buds. actually formed, has been called *Gemmation* or *Gemmification*.

Parts of Buds. 338. Having made these few general remarks on the nature and formation of buds, we have next to exhibit a few examples of their structure and evolution, confining ourselves at present to a description of those which produce either branches or leaves. The mature bud consists of two parts—one that forms the new branch or leaf, and in the language of botanists may be termed *persistent*—the other serving only a temporary purpose, and falling when that purpose is accomplished. To the former may properly be applied the term *germ* or *gem*, and the latter, from its office, may be called *hybernaculum*. In its leading characters, the bud bears a near analogy to the more perfect seed; for the germ very exactly resembles the plume; and the hybernaculum, as we shall see, in structure, office, and duration, approaches near to certain cotyledons.

Hybernaculum. 339. The leaves or scales which constitute the *hybernaculum*, and which, in future, we shall denominate the *hybernacular leaves*, vary much in number, size, and figure, in different buds. Even in the same bud, the inner ones are thinner, and much more tender and succulent than the outer, and are besmeared with a viscid humour which intimately unites them; while the outer ones are commonly hard, hairy, and of a scaly texture. Like the cotyledonous leaves of seeds, those of the hybernacle sometimes grow for a certain time with the germ, and fall successively, at periods more or less distant: they are also not less distinct in figure from those of the germ, than the leaves of the cotyledon are from those of the plume. This arises from the peculiarity in the distribution of their vessels, which do not spring from one common central trunk, as in ordinary leaves, but are derived from several distinct fasciculi at the base, like those of the cotyledonous leaf, as seen in that of the Gourd, Plate XVI. fig. 11. According to the manner in which they are disposed or folded up in the bud, botanists have assigned them different names, for an account of which we must refer to their writings. In the opinion of Du Hamel, they all derive their origin from the inner layer of the bark, of which they seem to be only a prolongation. (*Phys. des Arb.* Tom. I. p. 103.)

Germ. 340. The *germ* of the bud, which is contained within and protected by these enveloping leaves, is composed of one or more leaves generally folded and curled; but in some instances open and expanded. At first they are very small, and their form is indistinct, so that the pedicle alone is distinctly visible, from which branch off the vessels that form the middle rib, and are afterwards expanded to construct the lobes of the leaf. From the figure, which the germ possesses before its expansion, being like that of a keel, its vascular portion, at this period, has been named *carina*, and its softer part *medulla* or pith.

Origin of the Germ. 341. With respect to the particular portion of the branch, from which the germ internally derives its origin, opinions have much varied. Some have held that it proceeded from the pith alone; others from the first circle of vessels that immediately surrounds the pith; others from the tender wood alone; and others from the pith, the wood, and the bark conjointly. Grew held this latter opinion. (*Anat. of Plants*, p. 28.) Malpighi describes the germ as a tender ligneous substance, formed of vessels and cellular tissue, and surrounded by its proper cortical texture. (*Anat. Plantar.* p. 45.) According to Du Hamel, it originates from the ligneous texture and the pith (*Phys. des Arbres*, Tom. I. p. 103.); and Hill considered it to spring from the first circle of vessels alone, but not to carry with it any portion of the pith.

342. As every germ is composed of the cortical and ligneous textures, it may be said to originate in part from both, as all these writers seem to admit. Sometimes also the pith of the germ is continuous with that of the branch; but, in other instances, no such connection subsists, and there is nothing in the character of the pith of the trunk that renders it at all essential to the constitution of the germ. That, in many instances also, the germ springs from the first circle of vessels, is most certain; but it is not less certain that buds spring from trees long after this first circle of vessels has lost its vegetative power, or has been entirely destroyed. The view already given of the origin of rootlets from a branch, fig. 16. Plate XVII. seems very nearly to represent that of a bud, the latter possessing only a larger portion of cellular tissue in the composition of its bark and pith.

Bud of the Oak. 343. In the oak, Malpighi describes the entire bud as consisting of many scales enveloping each other, and forming an oval body. When evolution commences, these open and expand, and in part fall; but two generally remain and protect the springing germ for a long time. In fig. 17. Plate XVII. is represented one of the hybernacular leaves ($d$) of the Oak-bud, at the base of which the germ ($e$) is placed. The leaf ($d$) is described as possessing an oblong form, and is very evidently vascular; the germ is exceedingly small, and is represented as possessing at this period only one fasciculus of vessels. By degrees, three fasciculi become apparent, which are continued through the germ, and form three pointed extremities, as in fig. 18. A. These parts augment, and the vascular fasciculi separate, so as to produce successively the appearance in fig. 18. B. and in fig. 19. ($f$.) At length, the small curled leaf ($i$) rising between the two hybernacular leaves $hh$, fig. 20. is seen to resemble the plume of the seed, and to possess a form altogether different from the enveloping leaves, which, in appearance, resemble more the cotyledonous leaves of certain seeds. In fig. 21. is given a vertical section of the germ considerably magnified, in which $k$ denotes the pith that occupies the centre of its pedicle; it is enclosed by vascular fasciculi ($l$) that send off through the bark ($m$) ramifications to the several little processes that compose the serrated border of the leaf. (*Anat. Plantar.* p. 41. 45.)

Other Buds. 344. But the method of nature, in the evolution of buds, continues Malpighi, is not always the same; for the hybernacular leaves do not always waste and fall as those of the germ increase. On the contrary, in many trees, these leaves, especially those about the base of the bud, losing their primary figure,

Of Buds.

assume new forms, and are converted into the permanent leaves, with which the branch is adorned. Examples of this sort occur in Laurel, in the Apple, the Almond-tree, and many others. In other instances, as in the Rose, the permanent leaves seem to be generated out of those of the hybernacle, from the apex of which they emerge; and gradually the latter is changed into a sort of petiole, to the sides of which two slender appendages, the remains of the former hybernacular leaf, adhere. (*Ibid.* p. 41.) Similar transformations are said to occur in many other plants.

Buds on the ends of Branches.

345. The buds, such as they have been described, pullulate variously from the sides of stems and branches, and always above the insertion of the fallen leaves; but they spring also from their extremities, and produce the annual elongation of the branch or stem. The manner in which this takes place, and the appearance which the parts exhibit, have been well illustrated by the observations and dissections of M. Du Hamel. In the evolution of the seed, the plume, as we have seen, rises above the earth, and produces the stem which puts forth leaves. When these leaves fall in autumn, the stem continues, and is terminated by one or more buds. The roots, as already remarked (238.), do not increase in length, but at their extremity, and therefore never elongate, after the smallest portion of their extremity has been cut off. It is not the same with branches; for the newly formed part of the young shoot actually elongates, especially at its extremity, where it is most succulent and tender; less in the parts lower down where it is harder; and in its more ligneous parts not at all—as Du Hamel, by very simple and decisive experiments, ascertained. (*Phys. des Arbres*, Tom. II. p. 14.)

In Horse-Chesnut.

346. The appearance, structure, and evolution of a bud, at the extremity of a branch of the Horse-chesnut-tree, are given by the same ingenious author, whose candour, ability, and success in the prosecution of these curious researches, render him worthy to rank by the side of Malpighi and Grew. In fig. 1. Plate XVIII. is represented part of the annual shoot of this tree, terminated by its appropriate bud, formed in autumn, and which is the commencement of the next year's shoot. In fig. 2. a vertical section of the same bud is exhibited, in which the number and disposition of the hybernacular leaves that envelope and protect the germ in the centre are displayed. In the stem of the shoot, the letter *a* denotes the pith, which is surrounded by the wood *bb*, and this again is covered by the bark *cc*. In fig. 3. is represented a section of part of the bud, detached from the woody part of the shoot, and a little magnified, to show that the leaves of the *hybernaculum* take their origin from the inner portion of the bark.

Their Structure.

347. Proceeding next to the interior part of the bud, Du Hamel represents it as composed of numerous small leaves (fig. 4.), which are more and more minute as we proceed inward, and are covered with fine hairs. In fig. 5. is a branch-bud of the Peach, as seen in February, after all the enveloping scales have been removed. It is composed of greenish filaments, ranged nearly as they appear in the figure. When some of these filaments were detached, and viewed with the microscope, they appeared toothed at the edges, as in fig. 6., and were covered with hairs. All these filaments were afterwards detached, in order to disclose a small body lodged within them, and which appeared to consist of two small leaflets, folded and toothed at their edges, but not covered with hairs. It is represented in fig. 7. It occupied the centre of the shoot, and seemed to be connected with the pith.

348. In the next figure 8. is represented the bud of the Horse-chesnut, in the state of evolution. The letters *dd* indicate the scales of the hybernaculum thrust aside by the shooting of the germ *e*, accompanied by two permanent leaves *ff*. The letter *g* denotes the place of a second bud. A vertical section of the same bud is shown in fig. 9., from which all the scaly envelopes have been removed. It exhibits an entire shoot of one year's growth, attached to part of one of two years. From *h* to *i* denotes the growth of two years; and from *i* to *k* that of one year, with the germ *k* in the centre and the lateral leaves, as in the preceding figure. The letter *l* marks the pith, *mm* the wood, and *nn* the bark of the young branch. From *l* to *n*, the pith is white; from *n* to *o*, greenish; and towards *i*, it is of a brownish red colour. From *i* to *k*, which marks the extent of the annual shoot, the pith is green and succulent; and at *pp*, it is seen to be prolonged into the lateral branches. The wood of two years' growth, from *m* to *i*, is white, and forms a continuous tube round the pith, except where the branches go off. It is covered by another layer so thin as to be scarcely visible, but which will, in the end, become wood; and this layer is covered by the bark. The ligneous layer of the annual shoot appears to be a prolongation of the new layer of the older one, and, like it, possesses at first an herbaceous character. The cortical layer also seems to be a prolongation of that of the older shoot. As to the pith, though in both shoots it is continuous, it is to be observed, that that of the older branch is white and dry, and that of the young shoot green and succulent. (*Phys. des Arbres*, Tom. I. p. 117.)

Elongation of Branches,

349. It is thus by the formation of a bud in autumn at the extremity of a branch, and the shooting and growth of that bud in the succeeding spring and summer, that the trunk of the tree and its branches are annually elongated. During the first season, the shoot retains, in great part, its herbaceous characters; but, in the second, it becomes perfectly ligneous. In the axils of the permanent leaves of the young shoot, the rudiments of new buds become apparent, even in the first season.

as displayed by Du Hamel.

350. It was before remarked, that trees receive an additional circular layer every year, and that from these new layers buds successively spring, so that the earliest branches may contain as many ligneous layers as the trunk, and those of later formation a smaller number, according to the year in which they shot forth, and the circle of wood from which they sprang. Combining this growth in breadth with that in length, it will appear, says Du Hamel, that at the base and centre of a tree 100 years old, there is wood of 100 years of age; whilst, at the exterior part of the same tree, and at the extremities of its branches,

Of Buds ‖ Of Leaves.

there is wood of one year's age only. As the latitudinal growth was before illustrated by a diagram, a similar mode may be adopted to explain the longitudinal increase.

351. Let figure 10. Plate XVIII. represent in *q r* the ligneous portion of a tree that has proceeded from a seed in spring, and is observed in autumn. The following spring, a second shoot proceeds from the bud *r*, which reaches as far as *s*; but, at the same time, there is a second ligneous layer formed on the first shoot *q r*, by which its thickness is proportionally augmented; and, at the end of the second year, the tree has the form and extent of the unshaded portion of the figure *q s*. The next spring, the bud (*s*) opens and sends out another shoot to *t;* and ligneous layers are added as before to the two preceding shoots; and thus the tree is extended from *q* to *t*. The fourth year the same processes are repeated, and the tree extends from *q* to *w;* and each annual shoot, from the base to the summit of the figure, is seen to be composed successively of four, three, two, and last of one layer in thickness. This figure, therefore, illustrates the mode in which trees increase at the same time in height and breadth. The ligneous layers may be compared to a series of cones which envelope each other, and which annually augment the diameter of the tree by the two thicknesses of the layers. It shows also that trees grow much more in height than in breadth, and that this growth is effected by the successive formation and evolution of buds at the extremity of the stem, precisely as the first shoot issues from the seed. (*Phys. des Arbres*, Tom. II. p. 50.)

### Section II.

#### *Of the Structure of Leaves.*

Leaves.

352. These are organs of great importance in the vegetable economy; they are not, however, universal, for the *Cactus*, some species of *Schœnus*, and a few other plants, are considered to be destitute of leaves. Like other parts of the plant, they may be regarded with reference either to their external form, or their internal structure. The former view belongs more especially to the botanist, who has very happily applied his descriptive language to pourtray the almost infinite diversity of figure, size, and character, which the leaves of different species of vegetables exhibit. On this branch of the subject we shall but lightly touch, recalling simply to notice the more leading distinctions of the botanist, and such only of them as may appear to be more immediately connected with the *structure* of these organs.

Description.

353. The leaves *(folia)* are distinguished and denominated according as they are *simple* or *compound*. Simple leaves are such as have only a single leaf on the stalk or petiole that supports them, and where all the parts of the leaf are continuous with one another. Compound leaves are those which are made up of more than one piece, or where the leaf is formed of parts or leaflets articulated together. In regard to their place, situation, and insertion, leaves are said to be *determinate*. By the *place* of a leaf, is meant the part of the plant to which it is attached. By *situation*, is understood the disposition of the leaves on the stem or branch, which corresponds to that of the buds. By *insertion*, is expressed the mode of connection between the leaf and the stem or branch; and the *direction* of leaves is considered to bear reference to the position in which they stand to the stem.

Of Leaves.

Parts of Leaves.

354. The foregoing observations apply to leaves considered in connection with other members; when we regard them singly, we remark several parts which are common to almost all leaves, and to which particular names have been assigned. The part at which the leaf springs from the branch or stem, whether directly or by means of a petiole, is called the *base*, and the point opposed to this, the *apex* of the leaf. Each leaf has also two sides, faces or surfaces, as they are indifferently called. The prominent lines that appear on these surfaces were named riblets (*costulæ*) by Malpighi, and have very improperly been called *nerves* by most writers; for the term nerve denotes an organ of a totally different nature, of which not even the existence has yet been demonstrated in any part of the vegetable system. To the line that circumscribes and forms the boundary of the leaf, the term *margin* is commonly applied.

Their Characters.

355. The *figure* of leaves exhibits the greatest diversity, to express which various terms are employed; their *margin* also is either entire or variously fissured, notched, or toothed; their *surfaces* are naked and smooth, or clothed with hairs, and studded with excrescences; sometimes they are plain and flat, at others furrowed or plaited; and in all these particulars, the opposite surfaces present also the greatest diversity. In size, leaves exhibit the most remarkable differences; and, with respect to *substance*, some are exceedingly thin, and have a membranous texture, others very thick, and of a fleshy nature. As to colour, they exhibit every shade of green, from the most gay and lively, to the deepest and most obscure. In some, the tint of colour approaches to blue; in others to red; and previous to their fall, they all undergo those changes of colour which produce the diversified beauties of an autumnal scene. The period, however, at which this occurs, is very different. Some leaves fall early, before the summer has passed, and are termed *caducous;* others retain their place till autumn, and then fall, and are named *deciduous;* others continue beyond the summer, and are styled *persistent;* and others, which have a still longer duration, are denominated *perennial.*

Origin from Buds.

356. In the preceding section on the structure of buds, we exhibited the form and appearance of leaves in the earlier periods of their existence. They were shown to possess a very minute size, and to be curiously folded up, and concealed within their various scales or coverings, which effectually protected them from the rigour of the winter season. The germ of the bud, from which the leaves originate, was stated to be composed of the same elementary parts as the stem and branch from which it sprang. From the ligneous ring in the annual shoot, it derived its vessels, which, after having traversed obliquely the cortical layers, were prolonged into the pedicle by which it remained attached to the branch. This pedicle

Of Leaves. was shown to consist of a pith, encircled by vessels, which branched off through the cortical texture, to form the keel of the germ in its folded state; and, in its more expanded forms, to constitute the vascular riblets of the leaf. By subsequent growth, this gradually extends and elongates, becomes more ligneous, and is formed, at length, into the slender stalk or petiole, by which the leaf remains attached to the branch. (*Phys. des Arbres*, Tom. I. p. 123.)

Structure of the Petiole. 357. The vessels, which are given off from the branch to form the petiole, are not collected into one bundle, but constitute several fasciculi, which are disposed, in different ways, about the centre of the stalk. In some stalks there are three, in others five or six, and in others seven or more fasciculi, all placed, says Grew, either in an angular or circular posture, and at a greater or less distance from the centre. This centre is generally occupied by a pith, but sometimes it is hollow or tubular. In table 49. of the *Anatomy of Plants*, several transverse sections of the petioles of the leaves of different plants are given, exhibiting the different modes in which these fasciculi are dispersed through the cellular tissue that forms the greater portion of the stalk. In every instance, the pith and bark of these petioles are represented as forming one continuous substance. In some plants, the fasciculi of vessels that come off from the stem are not collected into a cylindrical figure, but, after being variously implicated with each other, expand at once into a leaf. Such leaves rise by a broad base, and, from being destitute of a petiole, are termed *sessile*, forming often a sort of sheath about the stem, of which several varieties are enumerated by botanists.

358. The petiole, as it springs from the branch, may be compared to a small stem, which, at the basis of the leaf, expands into numerous branches. Frequently, it is continued through the centre of the leaf, forming its middle rib, and giving off, in its course, numerous branches. At other times, on reaching the base of the leaf, it separates at once into three or more equal portions, which form as many distinct leaves or parts of a leaf, supported by their respective petioles. The structure of the petiole is the same as that of the branch, being composed of the ligneous and cortical textures, in which sap and proper vessels are discoverable, and the whole is invested by the cuticle.

Of the Leaf. 359. Where the petiole terminates, the proper or expanded portion of the leaf commences, the figure of which is determined by the number and distribution of the vessels. These vessels divide and ramify in various modes, till at their termination they form a finely reticulated structure. In many recent leaves this structure is very visible, but when the softer parts are removed by spontaneous decomposition, the vascular system of the leaf remains nearly entire, and its extent and form are then more completely exposed. In fig. 11. Plate XVIII. this distribution of the vessels is exhibited in a leaf of Holly. From the central fasciculus, branches are everywhere given off, which farther subdivide, and form smaller ramifications, that terminate, at length, in a minutely reticulated structure. Around the margin of the leaf, the vessels are continued, and, at certain parts, are prolonged into the thorns that bound the circumference of this leaf. Of Leaves.

360. In this, and similar instances, the vessels appear to be ramified out of greater into less: but, as already observed (sect. 9.), this does not appear to be really the fact, the vessels being all of the same size everywhere in the leaf, and all continued through it, like so many distinct tubes. This structure Grew represents in a highly magnified view of the leaf of Borage, in table 50. of his work; part of which is represented, on a reduced scale, in fig. 13. Plate XVIII., designed to show that the ramified vessels (*o*) are all clusters of tubes of the same size, which, though they separate continually, and come into contact, are never produced, or ramified one out of another. Neither do they ever inosculate or anastomose with each other, until, according to Grew, they come to their final distribution. Vessels of the Leaf.

361. The vessels thus distributed through the leaf belong chiefly to the order of spiral vessels, as was shown by Grew in the leaf of the Vine, and many others; and, from the observations of Malpighi, Darwin, and Knight, already related (sect. 57.), it appears, that "proper vessels" are everywhere associated with them. It would seem, from the observations of Darwin, that these two orders of vessels communicate in the leaf by continuation of canal, as the arteries and veins do in animal bodies. In the stalk he considered them to be disposed in two concentric rings, the inner one of which carried out the sap to the leaves, and by the outer one it was returned to the bark. (*Phytologia*, p. 43 and 58.) In branches of the Apple and Horse-chesnut, Mr Knight also observed coloured fluids to rise through the vascular fasciculi in the petiole of the leaf. These fasciculi were surrounded by others free from colour, and which conveyed a different fluid, and, on being traced down the stalk, were found to enter the inner bark, and to have no communication with those of the wood. The *returning* vessels he describes as being situated parallel to, and surrounding those which carry up the sap. (*Phil. Trans.* 1801, p. 336.) Its proper Vessels.

362. Beside the vascular system which thus, by its ramifications, forms the skeleton of the leaf, there is another structure that requires to be noticed. We have seen that the vessels, in their ultimate distribution, form a net-work, more or less fine and minute in different leaves; so that a great number of intervascular spaces are produced. These spaces, or areæ, says Malpighi, are occupied by cellular tissue, which springs from the vessels themselves, and seems to depend from them, and by its means the thickness of the leaf is formed. In the recent part of the Borage-leaf, represented in fig. 13. Plate XVIII. this cellular structure, occupying the reticulated spaces formed by the vessels, is observed; but it is most clearly seen in thick leaves, when the cuticle has been removed, and the vessels in part dissected away. The cells or utricles which form this *parenchyme*, as it has been called, are of different figures, and are mutually contiguous; they are composed of a membrane formed into the shape of a little vesicle or bladder, from the middle of each of which, a little vascular production issues; they are all connect- Cellular Tissue of the Leaf.

Of Leaves. ed with each other, and with the vascular system of the leaf. In fig. 12. Plate XVIII. this cellular structure is represented in the leaf of *Cactus* by Malpighi, in which the oblong cells are described as proceeding from the central vessel, and mutually communicating with each other. (*Anat. Plantar.* p. 52.) A similar idea of the formation of the cells seems to have been entertained by De Saussure. In different leaves, the cells possess very different sizes and forms, and sometimes the sides of the greater ones are said to be made up of smaller. In the experiments of M. De La Baisse, they are said to have become tinged by coloured fluids conveyed from the vessels. Whether they communicate with each other is not known; but analogy, derived from other similar structures, would lead us to suppose that they communicate only with vessels, as seems to be the case in the cotyledonous leaf of the seed.

Its Follicles. 363. Beside this cellular tissue, which forms so large a portion of the leaf, certain small *follicles* are described by Malpighi as being connected with it. Between the vessels and the cells of the parenchyme, in most leaves, variously figured follicles of this kind are stated to exist, from which a peculiar *halitus* or humour is discharged; their external orifice is bounded by a rising lip, and is often furnished with hairs. They are rendered more apparent as the more succulent parts of the leaf waste; and, in different leaves, possess very different forms. (*Anat. Plantar.* p. 52.) They appear to be the *glandular* organs, described as pouring out peculiar fluids on the surface of many leaves.

364. The whole structure of vessels and cells that constitute the leaf, is covered by a cuticle variously furnished with pores, hairs, and other appendages, as already described when treating of the cuticular texture.

365. To this division of our subject belong the small leaves called *bracteæ*, *stipulæ*, &c. which serve often but a temporary purpose to the flowers and leaves; and though of some importance in the descriptive details of the botanist, are but of small consideration with the anatomist. Like the scales that envelope buds, they probably derive their origin chiefly from the cortical texture.

## Section III.

### *Of the Structure of Flowers.*

Parts of Flowers. 366. The flower is understood to comprehend the organs by which *fructification* is accomplished, and those also which surround and protect them. These organs are the *Calix*, *Corolla*, *Nectarium*, *Stamina*, and *Pistillum*. The three first are not essential parts, but the two last are indispensable. All these parts are commonly borne on a stalk called the *peduncle*, which, expanding at its extremity, forms the *receptacle*, upon which all the other parts are supported. In fig. 1. Plate XIX., is the representation of a perfect flower, in which the principal parts above mentioned are exhibited. The letter *a* denotes the corolla, formed of six petals; *b* the stamens, *c* the pistil, and *d* the peduncle of the flower. In the next figure (fig. 2.), the corolla has been removed, and the parts within it are then more clearly displayed. At the base of the flower, the calix (*e*) is seen; the pistil is composed of three parts, the ovarium (*f*), the style (*g*), and the stigma (*h*); the stamens are each distinguished into the filament (*i*), and the anther (*k*). Of Flowers.

367. The flower, as well as the leaf, originates from a bud, and, in many respects, the buds of flowers resemble those of leaves; they are covered and protected in the same manner, but they are generally larger, and have a more rounded form. They consist of two parts, the gem or eye (*oculus*), as it is sometimes called, and the *hybernaculum*, or protecting envelopes. In some trees, they spring from the extremity of particular branches; in others, from the branches in common with the leaf-buds; in others, from the axils of the leaves; and in others, from the leaf itself—but in the same *genus*, the position of the flower-buds is uniform. In fig. 3. Plate XIX. is a portion of the branch of the Peach-tree, bearing two flower-buds (*ll*), between which the smaller and more pointed leaf-bud (*m*) is placed. Flowers originate from Buds.

368. Grew discovered, and has exhibited many examples of the complete formation of the flower many months before it is destined to bloom. (*Anat. of Plants*, tab. 63, 64.) Of this fact also, Du Hamel has given several examples. In fig. 4. is a longitudinal section of the flower-bud of the Peach-tree, made in the month of February, to show the complete formation of the stamens and pistils within the surrounding envelopes of the bud. In fig. 5. is another representation of a similar bud, from which the enveloping scales have been removed; it displays the calix, which, at this period, completely envelopes the other parts of the flower. When the leaflets of the calix are separated, as is done in fig. 6. then the stamens and pistils are fully disclosed; the petals also of this flower were visible, but at this period were very small. Even the anthers were found to contain a fine dust, but no rudiment of the future embryo could be detected in the ovary. In the flower-bud of the Pear, examined in February, the parts of fructification were also visible, but indistinct; a month later, all the parts were more advanced, and the stamens, petals, and pistils were distinct; and towards the end of March, even the rudiments of future seeds were visible in the base of the pistil. (*Phys. des Arbres*, Tom. I. p. 200.) Thus it appears, that, through the winter season, the several parts of the flower are clandestinely formed, though still extremely minute. As they enlarge, their position within the bud is very various in different species; they gradually expand, and form the perfect flower, whose several parts we have next briefly to describe. Flower-buds formed in Autumn.

369. The greater number of flowers contain both stamens and pistils, and are then styled complete or perfect; but frequently it is otherwise, and such flowers are deemed incomplete or imperfect. In most instances also, there is only one set of organs of fructification on the same flower, when it is deemed simple—in others, there are more than one, and it is named compound. Our limits will permit us to describe only one of these varieties, which we shall select from the division of complete simple flowers. Kinds of Flowers.

370. The peduncle of the flower, by which all the other parts are connected with the stem or branch, is frequently single, but often divides into several Structure of the Peduncle.

Of Flowers. parts or *pedicels*, as they are named, each of which supports one or more flowers. The modes in which the flowers are disposed on the pedicels, have received different names from botanists, and to the general circumstance they assign the term *inflorescence*. The peduncle, in structure, resembles the stalk of the leaf, being formed, like it, of the several common textures. In size, in length, and other external characters, it exhibits all the varieties already noticed in the petiole of the leaf.

Structure of the Calix; 371. At the extremity of the peduncle, is placed the flower-cup or *calix*, which has very different forms, and has received, in consequence, different names. Even in its most common forms, it exhibits great variety. It is sometimes composed of a single piece, and has a tubular form; in others, of many pieces, which vary in number, position, and size, and for an account of which, we must refer to the writers on botany. In some instances, this organ falls when the fruit has set; in others, it continues till the fruit is mature; and in others, the fruit is formed within it, to which it becomes a permanent covering, and exercises the office of pericarp. The colour of the calix is commonly green, but sometimes partly red, or white, or yellow. To some flowers it is entirely wanting. From the dissections of Grew and Malpighi, it appears to be constructed, like the leaves, of a cuticle, a pretty thick cellular tissue, and of vessels, all of which exist in the peduncle, and are derived from the common textures of the plant.

of the Corolla. 372. Above the calix, the *corolla*, the chief ornament of flowers, is borne. It is enclosed by the calix, but surrounds the interior parts of the flower, and is commonly of some other colour than green. It consists of one piece, or of several; these pieces are called *petals*, and according to the number of these pieces, the corolla is variously denominated. The monopetalous corolla, or that composed of one piece, is also distinguished into several parts, expressive of form, position, or quality; and in the polypetalous variety, which consists of several pieces, each petal has its claw (*unguis*) situated at the base, and by which it is attached to the calix or receptacle, and its expanded part (*lamina*), which is of very various figure, size, and colour. At the base of the petal, a tuft of hairs is often observed, and their surface is frequently covered with a fine down, or sometimes with jointed hairs bearing globulets, as occurs on leaves. With regard to structure, Malpighi describes it as composed of the same textures as the common leaf, as is distinctly visible in the thicker varieties of it. Grew showed it to possess *spiral* vessels, a proof, as Du Hamel observes, that it is partly derived from the ligneous texture, since such vessels are not found in the bark. The odour these organs possess, leads to the belief, that they contain also a peculiar juice. (*Phys. des Arbres*, Tom. I. p. 215.)

Nectary. 373. The organ next to be noticed, is that called the *nectary* (*nectarium.*) It was observed and described by Malpighi, as a small organ situate at the base of some flowers, to which, from its figure, he gave the name of *concha*. Linnæus considered it to be the organ which bears the honey, and as belonging to the flower only; but his descriptions of it are so exceedingly vague and inconsistent, that no attempt to define and exhibit its anatomical character can be made with any hope of success.

Of Flowers. Of the Stamens. 374. Having thus described the several parts that envelope the *sexual organs*, we must now briefly notice them; and first, the *stamens*.—These, in different flowers, vary greatly in origin, size, number, figure, and mode of attachment; and upon these differences, chiefly, the Linnæan *classes* are founded. In general, each stamen is said to consist of two parts—the filament and the anther. The filaments exhibit various shapes, and are of very different size in different flowers; they are inserted occasionally into the corolla, the calix, or even the pistil; but more commonly, like the calix and corolla, are attached to the receptacle. Malpighi describes the filaments as originating from the ligneous texture, being formed of vessels and elongated cells. As they originate sometimes from petals, they must necessarily, he adds, be composed of the same parts (*Anat. Plantar.* p. 64.); and it is well known that, by culture alone, they are often reduced entirely to the condition of petals.

375. The anther is a little case or sac, formed by a thin but vascular membrane, and borne on the summit of the filament. It is filled with innumerable small particles, of various colour, size, and figure, in different plants, to which the name of *pollen* has been given. In fig. 9. A. is exhibited one of the filaments, bearing its anther, as it appears when detached from the pistil of the flower of Mallow, fig. 8. in which the particles of pollen are seen; and in fig. 9. B. these particles are represented as viewed by a still higher magnifying power. The anther itself is of very various size, figure, and colour, in different flowers; and its mode of attachment to the filament is not less subject to variation. The Anther.

376. The pollen, contained in the anthers, is described by Grew as consisting of numerous regularly figured small particles, which, in different flowers, possess a very different figure, colour, and size. Many of their forms are delineated by Grew in table 58. of his work; and in fig. 10. Plate XVIII. several representations of these forms have been copied from Du Hamel. (*Phys. des Arbres*, Tom. I. lib. 3. Plate III.) The number of particles in each anther is very great, extending, it is said, from a few hundreds to several thousands. In some flowers, the pollen consists of transparent globules; in others, they are white, purple, blue, or brown, or more frequently yellow; their surface is either smooth or rough; they are regularly organized, and when examined under the microscope, may be seen to burst, and yield a fluid, in which, according to Du Hamel, small particles are seen to float. This fluid is represented as being sometimes thin, or viscid, or oily, and is said, by Hedwig, to be discharged at once on the bursting of the little capsule that contains it; while, according to Köelreuter, it is slowly transmitted through pores in the side, or hairs on the surface of the capsule. (*Willdenow's Prin. of Botany*, p. 310.) The Pollen.

377. The parts of the flower, hitherto described, are constructed, says Malpighi, with reference to the female organ, in which the seed, the last result sought by nature, is curiously formed, and carefully guarded. This organ, called *pistillum*, consists of The Pistil.

Of Flowers. three parts, as represented in the pistil of the Almond-flower, fig. 11., in which the letter $p$ denotes the stigma, $q$ the style, and $r$ the ovary. To this latter organ Malpighi gave the name of *uterus ;* Linnæus of *germen ;* but we prefer the appellation of *ovarium*, assigned it by Gærtner. Like the stamen, the pistil exhibits great variety in form, size, number, and mode of attachment; upon which, and other peculiarities, many of the *orders*, in the Linnæan system of classification, are founded.

Its Ovary. 278. The ovarium, situate at the base of the pistil, differs greatly in size, shape, and structure, in different plants. It is the part in which the seed is formed, and, antecedent to fœcundation, vesicles, which are the rudiments of future seeds, may frequently be detected in it. Its cavity consists often of but one cell or *loculament*, in which one or more seeds are produced; sometimes it is formed into many loculaments, with which only one style communicates; and sometimes the several loculaments have communication with distinct styles. Its structure will be noticed in treating of the changes of form it undergoes in consequence of fœcundation.

Style. 379. The style, which is seated on the ovarium, and is commonly so situate in the flower, as to be surrounded by the stamens, exhibits, like all the other parts, the greatest diversity in all its external characters. It is commonly a hollow tube, which communicates, as observed above, with the ovary. Most commonly there is but one style to one ovary, but frequently more than one. In some instances, the pistils correspond in number with the loculaments, into which the ovary is divided; in other instances, every seed that is formed has its distinct pistil connected with it; while, in other examples, only one pistil is allotted to a great number of seeds. In some flowers, there is no proper style, but the stigma is placed directly on the ovary.

Stigma. 380. The stigma, which forms the summit of the pistil, presents also the greatest diversities of appearance. It sometimes terminates the style by an open mouth; sometimes it appears like a small bud; in other instances, it is variously divided or forked; sometimes it is smooth, and is sometimes covered with hairs. The number of parts into which it is divided, corresponds, in many flowers, with the number of loculaments in the ovary, as in the *Liliaceæ*, the *Umbelliferæ*, and others. (*Phys. des Arbres*, Tom. I. p. 225.) At the period of fructification, the stigma is rendered moist by a peculiar secreted fluid. Its structure resembles that of the other parts of the flower, being composed of all the common textures, and a peculiar secreting structure. Some have professed to have discovered hollow channels in the stigma, which are described as being continued through the style to the umbilical cord of the seed; but this must be regarded as doubtful.

381. The foregoing descriptions apply, in detail, only to the more perfect flower, and that variety of it which is denominated simple. For an account of the numerous diversities of form, size, position, number, and attachment, exhibited in the sexual organs of the flowers of different classes and *genera* of plants, we must refer to the writers on botany; and to the works of Malpighi and Grew for the anatomy of many of them. We have room only farther to remark, that all the several parts of the flower seem very nearly to approximate in *internal* structure; for, under particular modes of cultivation, almost any individual organ may be made to lose its original character, and to assume that of any other. Of Fruits.

## Section IV.

### *Of the Structure of Fruits, and Formation of Seeds.*

382. In the preceding section we described the structure of the flower, antecedent to fructification; we have now to exhibit, as concisely as possible, the changes of form it undergoes after that event, and particularly as it regards the production of the seed.

383. After fœcundation has been effected, the calix, corolla, stamens, and even style of the pistil, commonly fade and fall; the ovary alone remains, and undergoes very different changes of form in different plants. In the latter periods of its enlargement, it is usually called *pericarp* (*pericarpium*), a term which is understood by botanists to apply also in certain cases to the calix, the corolla, or any other apparatus of organs that serves as a support and defence to the seed. For an account of these varieties in the pericarp, and of the terms employed to express them, we must refer to the writers on botany, and more especially to the carpological labours of Gærtner, who, in his learned and elaborate work, already so often referred to, has delineated the forms, and, to a certain extent, described the structure of the pericarps and seeds in more than 1000 genera of plants. Changes from Fœcundation.

384. In its early state, the ovarium is described by Gærtner as possessing at first a simple cellular structure, which, at a later period, assumes the form of distinct cells or loculaments. Within these loculaments, minute globules or papillulæ are afterwards seen, which are the rudiments of future seeds. At this period, they are mere pulpy globules attached to their containing cells, but, in some instances, approach to the character of small vesicles. So far the rudiments of the *ovulum*, like the entire bud, are produced without fœcundation; but if that function be not performed, they scarcely acquire any increase, and at length spontaneously degenerate. The progressive series of changes that occur in the ovary itself, and in its contained ovulum, subsequent to fœcundation, have been exhibited in the almond by Malpighi, whose observations we shall briefly detail.

385. In fig. 11. Plate XIX. is represented the pistil of the Almond, as it appears soon after fœcundation, in which the ovary ($r$) is seen to be somewhat enlarged, and has an oval form. In the next figure (fig. 12.), a longitudinal section of the same pistil is exhibited, exposing the cavity of the ovary ($s$), within which a small vesicle ($t$) is placed. As the ovary (fig. 13.) enlarges, it becomes rounder, its style is contorted, and diminished in size. If in this stage it be laid open, as in fig. 14. its vessels, which, in the peduncle ($w$), are disposed cylindrically, are observed to be dilated at the place of the calix ($x$), and to give off branches to the ovary itself, and to the shell ($y$) that now begins to be formed within it. In the centre, the ovulum ($z$) is now seen to be much increased In the Ovary.

Of Fruits. in size. All the parts continue to augment; the ovary (fig. 15.) becomes rounder, and the appearance of the style is obliterated. On exposing its cavity, as in fig. 16. the ovulum (*a*) in the centre is observed to be much increased, and the outer layer (*b*) of the shelly covering that invests it now begins to harden. Such are the changes of form and structure exhibited by the ovary: we have next to trace more minutely those of the ovulum that is produced within it.

Structure of the Ovulum. 386. The earlier appearances of this body have been exhibited in figures 12. and 14. When removed from its seat, a few days after fœcundation has been accomplished, and viewed by a moderately magnifying power, it exhibits the form and appearance represented in fig. 17. Externally it is covered by a vascular tunic (*c*), derived from the inner coat of the ovarium, a part of which coat adheres to it at *d*. If in this stage the ovulum be laid open by a vertical section, as in fig. 18. it is seen to be composed of two tunics or sacs, one within the other; the inner one is filled with a cellular tissue that contains a transparent juice. To this inner tunic, the term

Its Chorion; *chorion* may be properly applied.

387. At a period a little later, when the ovulum is examined, a tubular body (*e*, fig. 19.) is observed to extend through the chorion or tunic last mentioned. Shortly after, this tube expands at its apex, and is found to contain a small vesicle. In fig. 20. which represents a section of the entire ovulum, the outer tunic, the chorion, and this tube (*f*), expanded at its

Its Amnios; apex, are exhibited. To it, the appellation of *amnios* may be given; for it is the organ in which the *embryo*, or rather the *corculum*, as at this early period it may be called, is first seen to emerge. Through several successive days, the expanded portion of this tube enlarges, and forms a sort of sac, which is filled with cellular tissue, and the summit of which, says Malpighi, the embryo is seen to occupy. In fig. 21. this amnios is separated from the other tunics, and,

its Embryo. at its summit, the embryo (*g*) is observed. If removed from its seat, the embryo presents the appearance *h* (fig. 22.), and when expanded, as in fig. 22. (*i*), is seen to consist of a body and two little wings.

Growth of the Ovulum. 388. Having thus viewed the several parts of which the ovulum is composed in their separate state, let us next observe them in connection, and trace the series of appearances they exhibit, and the effects they produce on each other. In figure 23. is given a vertical section of the entire ovulum in a more advanced state; the outer coat (*k*) still envelopes the others; the embryo (*l*) occupies the summit of the amnios (*m*), whose lower part, still tubular, is continued through the chorion (*n*). In the next figure (fig. 24.), from which the outer coat has been removed, the embryo (*o*) and the amnios (*p*) are represented as enlarged; but the chorion (*q*) is partly exhausted of its juice, and has fallen down in a collapsed state. At this period, the embryo, when separated from the amnios, has the form (*r*) fig. 25. and in its expanded state is represented by the letter *s* of the same figure. The bulk of the embryo (*t*) fig. 26. continually augments, and encroaches on the capacity of the two tunics (*v x*,) whose forms are constantly changing; and from being successively emptied of their juices, with which the embryo becomes filled, they are gradually pressed downward. At last, the embryo (*y*) fig. 27. is so much augmented as to fill the cavity of the outer tunic, and by this time the amnios and chorion, exhausted of their fluids, exhibit the shrunk and corrugated forms in which they appear at the bottom of the figure. According to this representation, the outer tunic (*k*. fig. 23.), derived from the ovary itself, and the fine membrane that immediately invests the embryo, form the only permanent coverings of the mature ovum or seed; for during the progress of formation, the chorion and amnios, which are successively produced subsequent to fœcundation, are again obliterated by the growth of the contained embryo. Malpighi describes the process of formation in many other seeds to be nearly similar; for his descriptions of which, we must refer the reader to his work. (*Anat. Plantar*. p. 71.)

389. In the above descriptions of Malpighi, the several parts seem to be clearly exhibited, except in one important particular, namely, the situation and course of the *umbilical cord*. In almost every instance, he designates the tube, which we have represented as the first form of the amnios, as the umbilical vessel (*vasculum umbilicale*), which the subsequent appearances it exhibits shows to be erroneous. In the descriptions of Grew, this deficiency in the representations of Malpighi is supplied. He has particularly observed the formation of the seed in the Apricot, which, in many respects, resembles that of the Almond; and we shall subjoin an abridged account of his observations.

Fruit of Apricot. 390. In this fruit, the pericarp that envelopes the seed is seen, in its mature state, to be composed of the pulpy part (*a*) fig. 28., within which is the osseous envelope (*b*), and at the centre, the kernel or true seed (*c*). At an early period, both the pulp and stone are observed to consist of cellular tissue; and through the stone, the vessels, passing from the peduncle, are continued. At the base of the figure, the letter *d* denotes one fasciculus of vessels continued through the stone, and turning inward where it reaches the apex of the seed. These vessels form the umbilical cord or seed-branch of Grew, while the fasciculus (*e*) that runs on the opposite side, is continued to the flower. In fig. 29. a vertical section of the ovulum, as well as pericarp, is exhibited, as it appears at a very early period; in which *f* denotes the pulp, *g* the stone, through which the umbilical vessels pass and enter the outer tunic (*h*) of the ovulum, around which they make a ring. Within this tunic is another (*i*) filled with cellular tissue, and through its axis a small tube extends, at the apex of which the embryo (*k*) is first seen to emerge.

Its Structure. 391. In fig. 30. these several parts of the ovulum are exhibited on a larger scale; the letter *l* denotes the outer tunic that immediately lines the stone; *m* the inner one, corresponding to the *chorion* of Malpighi; and *n* the tube answering to the *amnios* of the same author. Through the outer tunic, Grew represents the umbilical vessels to pass and be continued to the middle tunic; the cavity of which is occupied by large cells that contain a pure lymph. At first this tunic is entire, but soon there appears in it the small duct (*n*). This duct is not at first

Of Fruits. wider than a hair, and is dilated at each extremity into an oval cavity that contains a pure lymph. A few days after, a soft node is seen to emerge in the upper cavity of this tube. This node (*o*) fig. 31. is described to possess a conical figure, and to be another tunic filled with very minute cells. It is at first entire, but when about the size of a Carraway-seed, it becomes a little hollowed near its apex, at which part the vessels enter and terminate in another very small node, fig. 32., which is the first appearance of the embryo of the seed. This embryo, when about one-fifth part as big as a cheese-mite, begins to be distinguished by a little fissure, which marks the division of the lobes, as in fig. 33. When the lobes have increased, and are more fully formed, the node contracts at its base, fig. 34., indicating the place of the umbilical cord, which subsequently becomes the radicle of the seed. (*Anat. of Plants*, p. 209.)

392. This description corresponds nearly with that of Malpighi as far as regards the situation and general form of the tunics, and the place in which the embryo is seen first to emerge. It also displays the course of the vessels to form the umbilical cord; but the growth of the embryo in this seed, does not seem to produce the obliteration of some of the tunics in the manner delineated by Malpighi.

Structure of the Pear.

393. An example of a different kind is observed in the Pear. Its structure has been described by Grew, and more minutely by Du Hamel. In its mature state, it consists of a pulpy matter, in the centre of which are five loculaments that contain each two seeds. These appearances are exhibited in the transverse section, fig. 35.; and in the longitudinal section, fig. 36. the seeds are farther shown to be attached by a small umbilical cord. The pulp of the fruit is made up of a very fine cellular tissue, filled with the proper substance of the fruit, and is everywhere furnished with vessels. Through this pulpy matter a number of solid particles are met with, which are more particularly accumulated at the top and about the core. They are formed of an assemblage of small particles, of a stony consistence, with which a little knot of vessels (fig. 37.) is everywhere connected. In fig. 38. is a thin transverse slice, showing the relative position of these stony particles, as indicated by the knots of vessels with which they are associated. The stony matter is not observed at an early period, but seems to be deposited from the juices in a more mature state.

394. By long maceration in water, the pulpy matter is dissolved, and the vascular system is obtained separate. In the peduncle of the fruit, fifteen principal fasciculi of vessels are contained. Ten of these are distributed to the seeds and flower, and the five others are dispersed through the pulp. This vascular structure is represented in fig. 39. after the removal of the pulpy part; the larger vessels embrace the core, and, after variously ramifying, terminate in the little vascular processes before described as connected with the stony matter of the pulp. In fig. 40. is represented one of the loculaments of the capsule, with the seed in it, receiving vessels from fasciculi continued from the peduncle; and in fig. 41. an entire seed is represented, and also a section of the same, in which the umbilical vessels that enter at the base are shown, as in other instances, to be continued, beneath the tunic, to the apex of the seed. (*Phys. des Arbres*, Tom. I. p. 242.)

Ovulum of Wheat.

395. The last variety we shall notice in the formation of the seed, is that of Wheat (*triticum*), as given by Malpighi. In fig. 42. A. is represented the pistil of the flower of this plant, consisting of the ovarium (*q*), the two styles (*r*), and the feathered parts that form the stigmata. Previous to fœcundation, the ovarium is found to contain a little vesicle, fig. 42. B. which is the rudiment of the future ovulum. After fœcundation, the styles soon fall, and the ovarium acquires a more pointed figure, as in fig. 43. If now it be opened, the little vesicle has changed its appearance, and contains within it another smaller vesicle (*u*), fig. 24. The ovarium continues to alter its shape, and assumes a more oblong form, fig. 45. and the appearance of styles is now quite obliterated. Gradually the little vesicle is formed into a small plantule, convex anteriorly, fig. 46. but more hollowed within, fig. 47. and which is situated at the base of the ovarium. The two portions thus described in figures 46. and 47. are the minute germ and cotyledon of this seed, which are represented in their appropriate place in fig. 48., in which the letter *x* denotes the germ, resting in the concavity of the cotyledon; *y* the albumen that forms the chief bulk of the seed; and *x* the ovarium which, in this seed, continues permanent, and forms its outer tunic. (*Anat. Plantar.* p. 73.)

396. We have thus, in different examples, exhibited the structure of the seed; have followed the changes of form displayed in its evolution; and, in various instances, have demonstrated the construction of the several members of which the mature plant is composed. We have then described the formation of buds on the trunk, the branch, and the root, and displayed their structure in the successive stages of their evolution, by which not only new roots and branches, but leaves and flowers, are produced; and, lastly, we have followed the changes of form and condition manifested in the flower itself, from which a new seed originates, fitted to undergo and exhibit the same series of changes.

The external agents required to the accomplishment of these various changes, the circumstances in which they act, and the modes of their operation, belong to the department of PHYSIOLOGY, and will form the subjects of future consideration. (Q.)

Anchor.

ANCHOR. Referring to the body of the work for a short history and description of this important Instrument, in its common form, we shall here briefly notice some recent improvements, and shall then give an account of the present method of making anchors.

Anchor with one Fluke.

The form of the common anchor is delineated in fig. 1. Plate * XX. Fig. 2. represents a new kind of anchor proposed by Mr Stuard, for which he took out a patent some years ago. It is made with one fluke instead of two; and the object of this alteration is, to prevent those accidents which sometimes happen when one ship comes in contact with the uppermost fluke of the anchor of another; and also to prevent the anchor from being tripped by the cable taking hold of it when the ship swings. In order, says Mr Stuard, in his Specification, "that this anchor may be sure to fall the right way, with the fluke downwards, I would have the shank very short; whereby, when suspended by the cable, it will cant the most, and when it has hold in the ground, the ship will ride safer; as a long shank has more power to loosen and break the ground, and is more likely to be bent or broken from its hold. Let the form of the shank, and arm of the anchor, be as AA, fig. 2. Plate * XX.; and that the parts may be stronger than if made separately, and shut together, I would have the bars which compose them in one length, so that there be no weld or joining in the whole length of the shank and arm. The hole B, is to receive the ring for the cable, and the hole C, for the stock, which is composed of a wrought-iron bolt, as A, fig. 3., covered with cast-iron at its ends, BB. The palm to be in shape as D, fig. 2., and shown detached in fig. 4., made either entirely of cast-iron, or a cast-iron shell filled with lead, which is of much more specific gravity than iron. The back of the palm to be formed either with concave surfaces, or flat surfaces, making angles at the centre. The anchor is also to have a small shackle, fixed on the bend of the shank and arm, as at E, fig. 2., for the buoy-rope to be made fast to. The shank may be made without the hole C, and the hole B, made octagonal; or if round, it should have a small fillet projecting from the stock, and a small cavity on one side of the hole B, to receive it, thus to prevent the stock from turning round; and instead of a ring for the cable, to have a shackle, fitted on the stock, on each side of the shank, and that the shackle may not turn on the stock, and fall too low, a stop is to be fixed on each side at the upper end of the shank." See *Repertory of Arts*, &c. Vol. V.

New Mooring-Anchor.

Mooring-anchors are commonly made by choosing one of the largest anchors, used for first-rate ships, weighing 80 cwt., and by bending one of the arms close down upon the shank, to prevent it catching the cable or mooring-chains whilst the ships are riding. These anchors are lowered down into the water with a very strong iron mooring-chain fastened to the ring, to which the ships are fastened; they are usually made from such as are damaged in one of the flukes or arms; but if one of this description is not to be found, a new anchor must be taken at a great expence. A new kind of mooring-anchor of cast-iron was described by Mr Hemman of Chatham, to the *Society for the Encouragement of Arts, &c. in* 1809, for which he obtained a silver medal from the Society. AA, fig. 5. Plate * XX, represents the palm or heavy part of the anchor, made very massive of cast-iron, and of considerable breadth, so that the edge B, or part which enters the ground, may have a great hold; the shank C, is made also of cast-iron, and fixed firmly to the head by passing through it, and has a small ring at *a*, where the buoy-rope is fixed; the other end of the shank goes through the stock DD, which is formed of two large wooden beams hooped together in the same manner as the stocks for common anchors; the end of the shank projects through the stock, and has a strong wrought-iron shackle E, fixed to it, by a bolt passing through both; and with this the mooring-chain is connected. The great advantage of this over the common mooring-anchors, arises from its great weight and breadth of edge to act against the ground; and being made of cast-iron, it is also more durable. A pair of these anchors, weighing 150 cwt. each, will, with the mooring-chains, cost about L. 874 less than a pair of the common anchors, which, with their chains, cost L. 2472. See Transactions of the *Society for the Encouragement of Arts, &c.* Vol. XXVIII.

Method of making Anchors.

Anchors are made from assemblages of several small bars of iron united together, by welding them into solid masses. This mode is preferable to making a single bar of sufficient size by the forge hammer in the original preparation of the iron, because the compounded bar is not liable to have any internal flaws or cracks, or at least they will not be in a transverse direction; for the bars are all examined separately before uniting them, and any which are imperfect are rejected; if, therefore, after the welding, any cracks are left between the bars, they must be in the length of the anchor, and will not deduct so materially from the strength of the whole.

The hearth AA, of the anchor-smith's forge, see fig. 6. Plate * XX, is built of brick-work, raised about 6 or 9 inches above the ground, and 6 or 7 feet square; in the centre is a large cavity, to contain the fire; at the back of the hearth a vertical brick wall B, is erected, supporting and forming one side of the chimney, which is little more than a dome placed over the hearth, and opening at top with a low chimney to carry off the smoke. Behind the wall, the bellows CD, are placed; the noses of the pipes, being about the level of the hearth, and coming through the wall; which at that part is defended from the action of the fire by a facing of fire-stone. In this fire-stone the tue-iron is fixed; it is a tube, made of wrought iron, and very thick in the substance, that it may not burn away in the fire; the pipes of the bellows are inserted in the tue-iron, and thus convey the stream of air into the centre of the fire.

The bellows are not like those which ordinary smiths make use of; but two large pair of single bellows CD, are placed horizontally by the side of each other, the pipes of both being inserted into the same tue-iron, and directed to blow to the same focus, in the centre of the fire: these bellows are exactly like those in use for domestic purposes, which only throw out air when the upper board is pressed down. The two are worked alternately by

means of chains *c d*, attached to the ends of the upper boards, and united to the end of the working levers HI, placed over each pair of bellows. From the opposite extremities of these levers, other chains *e f*, are extended to the opposite side of a long lever GG; which moves upon the pivots of a vertical axis E, and is loaded at the ends by heavy weights to give it *momentum*. Now, two or more men pushing in opposite directions, can give it a motion backwards and forwards, and by the communication of the chains and upper levers HI, they will alternately lift up the upper boards CD, of the bellows, which being sufficiently loaded, will subside themselves, and force their contents of air into the fire. The men who work the lever G, are aided by six or eight more, who place themselves upon the board of one pair of bellows, and as soon as it subsides, they step upon the other pair, which also sinks, and then they return: they have ropes suspended from the roof to enable them to lift themselves, and mount from one bellows upon the other with more ease. The common tue-iron, which is simply a cone of wrought-iron, set with clay into fire-stones, composing the back of the hearth, is very soon burnt by the great heat. The most improved forges, therefore, are now furnished with what is called the water tue-iron; which is made hollow, and water introduced into it to keep it cool. For this purpose, two cones are formed of thick iron plate, each with a small aperture at the vertex; these, when put one into the other, are welded together at their bases and their points, so as to form one cone, which is hollow, with a small space all round; two pipes communicate with the hollow, one bringing a continual supply of cold water, and the other conveying away that which is heated by the fire. By this means the tue-iron is kept cool, and can never acquire any such degree of heat as to be burned away: this tue-iron is set with fire clay into a frame of cast-iron built up in the brick-work of the wall B.

The anvil K, is only a cubic block of cast-iron placed on the ground, much lower than the ordinary smith's anvil; because, as the anchor-smiths always strike by swinging their hammers over their heads, at arms length, they have more force when the work lies low on the ground than if raised up. At a distance of eight or nine feet from the hearth AA, a strong crane gib LM, is erected, so as to turn freely upon the vertical post M; it has no tackle, but the upper beam L, which must be horizontal, has a large iron loop *n* hung upon it, with a roller *o*, which admits it to run freely backwards and forwards upon the beam; the lower end of the loop suspends the anchor; therefore, by moving the rollers along the beam of the gib, and by turning the gib round on its pivots, the anchor can be placed in any position in the fire or upon the anvil. To give motion to the roller *o*, a rack *p* is connected with it; and this is moved by a pinion upon the axis of the wheel *t*, which has an endless rope hanging down, so that a labourer can reach it, and thus remove the anchor nearer or farther from the centre, however great its weight may be. The workmen employ scarcely any other tools than their sledge-hammers, and a few large punches, cutting chissels, and sets or prints, which, when urged by the hammers, will give any particular figure to the work: the hammers are of the largest kind, and weigh from fourteen to eighteen pounds, according to the strength of the workmen. In the Royal dock-yard great use is made of a stamping machine, which the workmen call Hercules; and which is very similar to the machine for driving piles. A heavy iron weight N, guided like the ram of the pile engine, is drawn up by the strength of several men, and let fall upon the anchor, to weld the bars, in the same manner as by a forge-hammer. The machine is erected on a large block of stone, which supports the anvil O; two square iron bars PP, are fixed on each side of the anvil in a vertical position, the angles of the bars being placed towards each other. These vertical bars are eight or nine feet high, and are fixed at the top to a beam in the roof of the building, in which the machine is placed; the ram N, which weighs 4½ cwt. is fitted to slide up and down between the bars P, having notches in its sides which receive the angles of the bars; it is drawn up by a rope passing over an iron pulley Q, mounted upon pivots above the top of the vertical bars; and the rope has eight or ten small ones R, spliced into it, for as many men to act together (which they do by a similar motion to that of ringing), to elevate the ram, and let it fall upon the iron, placed upon the anvil O. The Hercules is placed in the same sweep of the crane as the anvil K, so that the iron can be conveyed to either with equal ease.

The parts of the anchor are all made separately, and afterwards united together. The first step, in making the parts, is to assemble or faggot the bars. For the centre of the mass, which is to make the shank, four large bars are first laid together; then upon the flat sides of the square so formed, smaller bars are arranged to make it up to a circle. The number is various, but in large anchors six or eight bars are laid on every side; this circle is surrounded by a number of bars arranged like the staves of a cask; as many as thirty-six are often used, and form a complete case for the others. The ends are made up by short bars to a square figure; the faggot is finished by driving iron hoops upon it at sufficient distances; see W in the figure; and it is suspended from the crane in such a manner, that it can be moved and turned in any direction, by only one or two men, even when it weighs three tons. For this purpose, an iron pulley *k* is hooked to the iron loop *n* of the crane, and a short endless chain *l*, passed over the pulley, suspends the faggot in its loop: in this manner, the weight of the iron is in reality borne by the pivot of the pulley *k*, and the mass can be easily turned round upon its centre to bring any side upwards. To give a power to the man who guides it, one of the four central bars is double the length of the faggot, and projects, see *g*, to form a long lever by which it is steered; and two holes are made through the end of this bar to insert a cross lever *h*, by which the faggot is turned or rolled round upon its centre. As the faggot hangs very nearly on a balance in the loop of the chain *l*, the man, by weighing on the end of the long bar *g*, can easily raise up its end from the anvil K; and swinging the crane on its pivots, he can move it into the fire, which is made

up hollow like an oven. To effect this form, the fireman first spreads the coals evenly upon the hearth, and with his shovel or slice makes a flat surface about the level of the tue-hole; he then arranges some large cinders or cakes round in a circle upon this surface, and by other cinders builds it up like an oven or dome, leaving a mouth to introduce the iron. The oven is adapted in size to the magnitude of the mass of iron; and must be brought forwards upon the hearth, to leave a space between its interior cavity, and the orifice of the tue-iron; in which space a passage is made from the tue-hole to the fire, and filled up with large lighted coals, and then covered up by small coals. The blast from the bellows passes through these hot coals, in order that the cold air may not enter the fire at once, and blow on the iron, but be first converted into flame; which is urged forcibly into the oven, and is reverberated from the roof and sides upon the iron placed in the centre. As the floor of the oven is nearly upon a level with the tue-hole, the flame from the coals between it and the fire also plays upon the bottom, and thus heats the iron on all sides. The outside of the dome is covered over with a considerable thickness of small coals, which cake together, and, as the inside of the oven consumes, settle down into a dome again, which the smith aids by striking the outside with the flat of his slice. If the fire breaks out at any place in the roof, the smith immediately repairs the breach with fresh coals, and damps them with water, that they may not burn too fast; for if the inside of the oven burns very fierce, the flames will not be reverberated so forcibly as when it is in the state of burning cake. Care must likewise be taken to prevent the fire burning back to the tue-iron. The mouth of the oven should be made no larger than to admit the work, and that as little heat as possible may escape by the iron, the mouth is filled round it with coals. F is an iron screen hung on hinges, to swing before the mouth of the fire when the iron is withdrawn, that the workmen may not be scorched by the heat.

All the men unite to assist in blowing the bellows, which they work in the manner already described, from half an hour to an hour, according to the size of the anchor, until they have raised the iron to a good welding heat. The mouth of the fire is opened occasionally to inspect the process, and the faggot is turned in the fire, if it is not found to be heating equally in every part. Eight men, and sometimes more, are employed to forge an anchor; six of them strike with the hammers, one is stationed at the guide bar, and the eighth, who is master or foreman, directs the others, and occasionally assists to guide the anchor. When the whole of that part which is in the fire comes to a good welding heat, the workmen leave the bellows and take up their hammers; the coals are removed from the iron, which is swung out of the fire by the man who guides it, assisted by others, and the hot end placed on the anvil; during which time, one or two labourers with birch brooms sweep off the coals which adhere to it.

The smiths now begin hammering, one-half the number standing on one side and the other half on the other; they use large sledges, weighing from sixteen to eighteen pounds, and faced with steel, striking in regular order, one after the other, swinging the hammers at arms length, and all striking nearly at the same place: the foreman places himself near the man who guides, and with a long wand points out the part he wishes them to strike, and at the same time directs, and sometimes assists the guide to turn the faggot round, so as to bring that side uppermost which requires to be hammered. This is continued as long as the metal retains sufficient heat for welding. This process is exceedingly laborious for the workmen, and is much more effectually performed by means of the Hercules, which strikes such powerful blows upon the iron as to consolidate the bars much more than the strokes of small hammers can do, however long they may be continued. When the iron has lost so much of the heat, that it will no longer weld, the foreman takes a number of pins, made like very thick nails without heads; one of these he holds in the end of a cleft stick, places its point upon the iron, and two smiths, with their sledges, strike on it with all their force, to drive it through the bars; but this they must do quickly, or the pins will become hot and soft, so as not to penetrate the bar. These pins are intended to hold the whole together more firmly, and by swelling out the sides, to fill up any small spaces there may be between the bars. The iron is now returned to the fire; another mouth being opened on the opposite side of the oven, to admit the end or part which has been welded to come through, that a part further up the faggot may be heated; and when this is done, the welding is performed in the same manner as before. Thus, by repeated heatings, the faggot is made into one solid bar of the size and length intended; it is then hammered over again at welding heats to finish it, and make an even surface; and in this second operation, the workmen do not leave off hammering as soon as the iron loses its full welding heat, but continue till it turns almost black. This renders the surface solid and hard; and closes all small pores at which the sea-water might enter, and by corroding the bars, expand them, and, in time, split open the mass of iron.

The shank for an anchor is made larger at the lower end, where the arms are to be welded to it, and is of a square figure; a sort of rebate or scarf (*s*) is here formed on each side the square, in order that the arms may apply more properly for welding. This scarf is made in the original shape of the faggot, and finished by cutting away some of the metal with chisels whilst it is hot, and using sets or punches, properly formed to make a square angle to the shoulder of the scarf. The upper end of the shank is likewise square, and the length between these square parts is worked either to an octagon or round, tapering regularly from the lower to the upper end. The hole to receive the ring of the anchor is pierced through the square part at the upper end, first by a small punch, and then larger ones are used till it is sufficiently enlarged: the punch is made of steel, and, when it is observed to change colour by the heat, it is struck on the opposite end to drive it out, and is instantly dipped in water to cool it, and another driven in. The projecting pieces or nuts, which are

Anchor.

to keep the stock or wooden beam of the anchor, and its place on the shank are next welded on. To do this, the shank is heated, and, at the same time, a thick bar is heated in another forge; the end of this is laid across the shank; and the men hammer it down to weld it to the shank, then the piece is cut off by the chisel, and another piece welded on the opposite side.

Whilst this process of forging the shank is going on, the smiths of another forge, placed as near as convenient to the former, are employed in making the arms, which are made from faggots in the same manner as the shank, but of less size and shorter; they are made taper (see X), one end of each being smaller than the other; the larger ends are made square, and cut down with scarfs (*r*) to correspond with those (*s*) at the lower end of the shank. The middle parts of the arms are rounded, and the outer extremities are cut away as much as the thickness of the flukes or palms *m*, that the palms may be flush with the upper sides when they are welded on. The flukes are generally made at the iron forges in the country, by the forge hammer; but in some yards are made by faggoting small bars, leaving one long one for a handle; when finished they are welded to the arms, which have then the appearance of X.—The next business is to unite the arms to the end of the shank; and, in doing this, particular care is necessary; as the goodness of the anchor is entirely dependent upon its being effectually performed. In so large a weld, the outside is very liable to be welded, and make a good appearance while the middle part is not united; to guard against this, both surfaces of the scarfs should be rather convex, that they may be certain to touch in the middle first. When the other arm is welded, the anchor is complete except the ring, which is made from several small bars welded together, and drawn out into a round rod, then bent to a circle, put through the hole in the shank, and its ends welded together. If the shank or other part is crooked, it is set straight by heating it in the crooked part, and striking it over the anvil, or by the Hercules. After all this, the whole is heated, but not to a white heat, and the anchor hammered in every part, to finish and make its surface even: this is done by lighter hammers worked by both hands, but not swung over the head. This operation renders the surface of the metal hard and smooth; and if very effectually performed, the anchor will not rust materially by the action of the sea water. The hammering is continued till the iron is quite black and almost cold. It is common with some manufacturers, after they have made up the shank, to heat it again, and apply the end of a thin flat bar properly heated upon it; then by turning the large shank round, the bar is wound spirally upon it, so as to form a complete covering to the whole. This method admits of employing a kind of iron, which is less liable to corrosion, but we fear it is sometimes resorted to, to conceal the bad qualities of the iron of which the anchor is composed.

The iron from which anchors are made ought to be of the best quality; that kind of it which is called red short, will not bear sufficient hammering to weld the bars, and cold short, from its brittleness, is not to be depended upon when the anchor is in use. A good anchor should be formed of the toughest iron that can be procured. (R.)

Anderson.

We shall have some farther particulars to mention in regard to anchors, when we come to the article Dock-yards.

ANDERSON (Alexander), a very eminent Mathematician, who flourished in the early part of the seventeenth century. He was born at Aberdeen, but passed over to the Continent, and settled as a private teacher or Professor of Mathematics at Paris, where he published or edited, between the years 1612 and 1619, various Geometrical and Algebraical tracts, which are conspicuous for their ingenuity and elegance. It is doubtful whether he was ever acquainted with the famous Vieta, Master of Requests at Paris, who died in 1603; but his pure taste and skill in mathematical investigation, had pointed him out to the executors of that illustrious man, who had found leisure, in the intervals of a laborious profession, to cultivate and extend the ancient geometry, and by adopting a system of general symbols, to lay the foundation, and begin the superstructure of Algebraical science, as the person most proper for revising and publishing his valuable manuscripts. Anderson did not come forward, however, as a mere editor; he enriched the texts with learned comments, and gave neat demonstrations of those propositions which had been left imperfect. He afterwards produced a specimen of the application of Geometrical Analysis, which is distinguished by its clearness and classic elegance.

Of this able geometer, we are ignorant both of the time of his birth and of his death. His brother, David Anderson, a small proprietor in Aberdeenshire, but engaged in business, had likewise a strong turn for mathematics and mechanics, which, joined to great versatility of talent, made him be regarded by his neighbours at that period as a sort of oracle. The daughter of this clever and active burgess, was married to John Gregory, minister of Drumoak, in that county, father to the celebrated James Gregory, inventor of the reflecting telescope, and is supposed to have communicated to her children that taste for mathematical learning which afterwards shone forth so remarkably in the family of the Gregorys.

The works of Anderson amount to six thin quarto volumes, which are now very scarce. These are:

1. Supplementum Apollonii Redivivi; sive analysis problematis hactenus desiderati ad Apollonii Pergæi doctrinarum περι νευσεων, a Marino Ghetaldo Patritio Ragusino hujusque non ita pridem institutam. In quâ exhibetur mechanice æqualitatem tertii gradus sive solidarum, in quibus magnitudo omnino data æquatur homogeneæ sub altero tantum coefficiente ignoto. Huic subnexa est variorum problematum practice. Paris, 1612, in 4to.—This tract refers to the problem of *inclinations*, by which, in certain cases, the application of the curve called the *conchoid* is superseded.
2. Αιτιολογια: Pro Zetetico Apolloniani, problematis a se jam pridem edito in supplemento Apollonii Redivivi. Ad clarissimum et ornatissimum virum Marinum Ghetaldum Patritium Ragusinum. In qua ad ea quæ obiter mihi per strinxit Ghetaldus

ANDERSON (Dr James). The subject of this article, who has been brought into notice, principally from the more recent encouragement given to agriculture, and the versatility of his own genius, was born at the village of Hermandston, in the county of Edinburgh, in the year 1730. His parents were in humble life, and had possessed a farm for some generations, which he was destined to inherit and to cultivate. At that period improvement was in infancy, and the husbandman had to contend with a climate, whose uncertainty seemed to keep pace with the progress of his skill, and which too often disappointed him of the fruits of his industry. Anderson, while yet at an early age, lost his parents; however, his education was uninterrupted, and conceiving that an acquaintance with Chemistry would promote his profession, he attended a course of lectures on that science, then delivered by Dr Cullen. None of the other pupils besides himself took notes of his lectures, which being afterwards surreptitiously obtained from him, with the design of publication, he defeated the intended purpose, apprehensive that his preceptor's fame might be diminished by these imperfect transcripts. His own active occupations had already commenced, and along with the practice of husbandry, he prosecuted his original taste for literature.

Enlarging the sphere of his employments, Anderson forsook his first possession, for a farm of 1300 acres, which he rented in Aberdeenshire, though nearly in a state of nature, and where agriculture is still behind the southern districts. But, previous to this, he became known to men of letters, by some Essays on planting, which, under the signature Agricola, he ventured to commit to the world through the medium of the Edinburgh Weekly Magazine, in 1771. Soon embarking in a higher sphere of literature, he composed the article *Monsoon*, for the first edition of this *Encyclopædia*, in 1773, wherein he threw out some luminous ideas, and among other observations, predicted, from physical facts, and the state of geographical knowledge, that no polar continent would be found by the circumnavigators then employed by Government. In the year 1777, he published a considerable quarto volume, said to have been composed two years preceding, on the means of exerting a spirit of national industry, with regard to Agriculture, Commerce, Manufactures, and Fisheries; and in this, he enters into detailed views of many subjects of Political Economy. The interest of the Highlands and Islands of Scotland is in a particular manner considered, and the author maintains, that the only effectual means of increasing agriculture, is by promoting manufactures; as also, that the neglect which the agriculture of these parts of the kingdom experienced, resulted from the neglect of manufactures. Scotland, he affirms, is better adapted than England for the production of wool, and this, as well as other products, he thought, would be best encouraged by premiums. The advantages which might result from attending to the fisheries, he judged would be very great, and the shoals of herring frequenting the coast, could be converted to a source of national wealth under suitable establishments. Dr Anderson, who, soon after, had the degree of Doctor of Laws conferred on him by the University of Aberdeen, did not abandon these inquiries. He printed a tract regarding the fisheries, which was circulated among his friends; and, in consequence of being more widely diffused, he was appointed, by the Lords of the Treasury, to survey the western coast of Scotland, for the purpose of obtaining satisfactory information on the subject. This he did in 1784, and received the full approbation of his employers; and he published a brief account of the Hebrides, a chain of Islands then as little within the general acquaintance of the inhabitants of Great Britain, as if they had been under the dominion of another country. The principal obstacles to the fishery, Dr Anderson considered, were to be found in a duty on salt and coals, and he recommended the repeal of both. It is certain, that, from thenceforward, this great branch of national industry has received infinitely more patronage than before his report, and, while we only shared the labours of the Dutch for centuries, the fisheries on our own coast have since been monopolized by ourselves. Nothing can be more impolitic than to fetter the exertions of the industrious by exorbitant duties; or equally oppressive, with denying fuel to the poorer classes where it is scarce, by duties on its importation.

Dr Anderson had now withdrawn from his northern farm, where he resided above twenty years, and settled in the vicinity of Edinburgh. His agricultural speculations were still continued, and, when a Parliamentary grant was about to be proposed to Mr Elkington, for a particular mode of draining land, he reclaimed the practice as having been observed by himself many years anterior. Repeated examples, indeed, prove that the rewards granted by Parliament for improvement are attended with such slight investigations, that the merits of real invention are overlooked. Dr Anderson now projected a periodical publication, called the *Bee*, consisting of miscellaneous original matter, which attained the extent of eighteen volumes in octavo. It was published weekly, and a large proportion of it came from his own pen, which is seldom a prudent course in an Editor. The relation of Great Britain and her Colonies, and the political rights of man-

kind, — subjects which had excited strong interests throughout Europe,—also received some commentaries from Dr Anderson. He wrote a tract, called *The Interest of Great Britain with respect to her Colonies*, and commenced a correspondence with General Washington, which was afterwards published.

Towards the year 1797, he again removed to Islesworth, in the neighbourhood of London, where he undertook another periodical publication, appearing at more distant intervals than the former, entitled *Recreations in Agriculture, Natural History, Arts, and Miscellaneous Literature.* This work was prefaced by two copious dissertations, the one on Agriculture, the other on Natural History; and opened with a discussion regarding a very curious and important subject, namely, an inquiry into what are denominated varieties in plants and animals. Many useful and interesting remarks appear in the course of this publication, a portion of which was supplied by other contributors, and it is embellished by beautiful vignettes from engravings on wood. Owing to some difficulties attending the publication, it ceased in 1802, having subsisted three years. Though natural history is rather predominant, the rest of his leading subjects are not overlooked. Dr Anderson henceforward lived in a great measure in retirement, though occasionally reminding the world of his wonted inquiries, by the publication of tracts on unconnected subjects. He obtained a patent for an improved Hot-house, wherein no fuel was used; and employed himself in experiments regarding the degree of temperature and humidity most beneficial to plants. Likewise, having observed the uncommon depredations of wasps, he is said, after satisfying himself of their manner of increase, to have devised a plan for their absolute extermination. This was chiefly by the destruction of the females before founding their respective colonies by the depositation of innumerable eggs; and hand-bills were circulated under the auspices of an association formed by him, offering a reward for every female brought in dead within a specified time. It does not appear, however, that the breed was at all diminished by the proposed expedient.

Dr Anderson still remained in his retreat, enjoying the cultivation of his garden, and nothing of importance is known to have proceeded from his pen. After a gradual decline, partly occasioned by the over-exertion of the mental energies, he died in the year 1808, aged 69. He was twice married; first to Miss Seton of Mounie; secondly, to an English lady. By his first marriage he had thirteen children, six of whom survived him. One of his sons, who died a few years ago, made distinguished progress in the art of engraving on wood; and, if the vignettes of the *Recreations in Agriculture* are executed by him, they afford ample testimony of his abilities.

Dr Anderson was endowed with a vigorous understanding, which he chiefly displayed in treating of agricultural matters, and those connected with rural economy; but he was, at the same time, of a versatile talent, which could readily be occupied on transient facts and occurrences. Many of his works were of a fugitive nature, consisting of small impressions, which were not renewed, and hence are difficult to be obtained at present, if they have not totally disappeared. None of them soar to the more lofty regions of science; they are directed to practical views in useful projects, and, for the most part, relate to subjects of ordinary detail. Of this the reader will be enabled to judge by the subjoined list, which we believe is the most copious that has yet appeared. The industry of Dr Anderson was indefatigable, whether in personal exertion, or mental energy, and he possessed elevated sentiments of independence. During a period of overstrained political fervour, certain papers formed part of the periodical works already referred to, which were thought libellous on the Government. Although Dr Anderson's principles were noted for attachment to the existing administration, he was called upon to give up the author of the obnoxious compositions, which he steadily refused, and, even in the face of the civil magistrates, charged his printers not to violate their fidelity to him and the author in betraying his name. The business terminated here, until a factious individual insinuated to the same magistrates, that the compositions had proceeded from one of the Supreme Judges, whose party politics were avowedly hostile to those of Government. Dr Anderson having learned the reproach, hastened to relieve the object of it by divulging the name of the real author, who, to the universal surprise of the public, proved to be none other than the traducer himself.

1782. The Interest of Great Britain, with regard to her American Colonies, considered, 8vo.

1783. The True Interest of Great Britain considered, or a Proposal for Establishing the Northern British Fisheries, 12mo.

1785. An Account of the Present State of the Hebrides and Western Coasts of Scotland, being the Substance of a Report to the Lords of the Treasury, 8vo.

1789. Observations on Slavery, particularly with a View to its Effects on the British Colonies in the West Indies, 4to.

1790. Papers by Dr Anderson and Sir John Sinclair on Shetland Wool, 8vo.

1791. The Bee, 18 vols. 8vo.

1792. Observations on the Effects of the Coal Duty, 8vo.
1793. Thoughts on the Privileges and Powers of Juries, with Observations on the State of the Country with Regard to Credit, 8vo.
1793. Remarks on the Poor's Laws of Scotland, 4to.
1794. A Practical Treatise on Peat Moss, 8vo.
1794. A General View of the Agriculture and Rural Economy of the County of Aberdeen, and the Means of its Improvement, 8vo.
1794. An Account of the Different Kinds of Sheep found in the Russian Dominions, by Dr Pallas. With five Appendixes, by Dr Anderson, 8vo.
1795. Two Letters, to Dr Edward Home, on an Universal Character, in 8vo.
1797. A Practical Treatise on Draining Bogs and Swampy Grounds, with Cursory Remarks on the Originality of Elkington's Mode of Draining Lands, 8vo.
1799. Recreations in Agriculture, 6 volumes 8vo.
1800. Selections from Correspondence with General Washington, 8vo.
1801. A Calm Investigation of the Circumstances that have led to the Present Scarcity of Grain in Great Britain; suggesting the means of alleviating that evil, and of preventing the occurrence of such a calamity in future, 8vo.
1803. Description of a Patent Hot-house, which operates chiefly by the Heat of the Sun, and other Subjects, 8vo.

Dr Anderson besides wrote many papers in periodical publications, and an account of Ancient Fortifications in the Highlands, read to the Society of Scotish Antiquaries. (s.)

ANDES. The *Encyclopædia* contains such particulars relative to that amazing chain of mountains as could be gathered from the accounts of the early writers, and especially from the more precise descriptions given by the Academicians who were sent to Peru in 1736, to measure the length of a degree of the meridian under the Equator. But, since that period, Geography has made rapid advances, and Mineralogy, emerging from its obscurity, has risen to the rank of a science. The vast American Continent has been explored in different directions, by adventurous and intelligent travellers. Of these by far the most conspicuous for enterprise, accuracy of observation, and extent of scientific research, is the celebrated Humboldt, whose various discoveries in the regions of the New World have deservedly excited so much interest. The narrative, however, of this accomplished traveller is not yet completed, and we must content ourselves at present with combining the incidental sketches which occur in his other publications. We trust that we shall be enabled to give a fuller and more precise account of the Andes in the article MOUNTAINS.

The Andes are distinguished above all the known mountain-chains, by their immense extent and their prodigious altitude. They run almost parallel to the west coast of the southern Continent of America, at a mean distance of between 100 and 200 miles, rising in some places to the enormous height of 20,000 feet; and stretch from the mouth of the river Atrato, on the isthmus of Darien, in the latitude of 8 degrees north, as far as Cape Pilares, at the outlet of the Straits of Magellan, in the 53d degree of south latitude,—a range of at least 4200 miles. According to Humboldt, they send out, nearly at right angles to their colossal ridge, three dependent branches, called likewise *Cordilleras* by the Spaniards.

Of these secondary chains, the *first* and most northern is that of the coast of Venezuela, which is besides the highest and narrowest. With an irregular altitude, it bends eastwards from the Atrato, forming the Sierra of Abibé, the mountains of Cauca, and the high Savannahs of Folu, till it reaches the stream of Magdalena, in the province of St Martha. It contracts, as it approaches the Gulf of Mexico at Cape Vela; and thence extends to the mountain of Paria, or rather the Galley-Point in the island of Trinidad, where it terminates. This secondary chain attains its greatest known elevation where it rears the snowy summit, or Sierra Nevada, of St Martha and of Merida, the former being nearly 14,000, and the latter above 15,000 feet, in altitude. These insulated mountains, covered so near the equator with eternal snow, yet discharging boiling sulphureous water from their sides, are higher than the Peak of Teneriffe, and can be compared only with Montblanc. In their descent, they leave the Paramo or lofty desert of Rosa and of Mucachi; and on the west side of the lake Maracaybo, they form long and very narrow vales, running from south to north, and covered with forests. At Cape Vela, the mountain-chain divides into two parallel ridges, which form three confined vallies, ranging from east to west, and having all the appearance of being the beds of ancient lakes. These ridges, of which the northern is the continuation of the Sierra Nevada of St Martha, and the southern the extension of the snowy summits of Merida, are united again by two arms which seem to have been placed by the hand of nature, as dikes to confine the primeval collections of water. The three vallies thus enclosed are remarkable for their elevation above the sea, rising like steps one above another, the eastmost, or that of the Caraccas, being the highest. This plain was found by Humboldt to be elevated 2660 feet, while the basin of Aragua has only 1350 feet in height, and the Llanos, or reedy plains of Monai, spread within 500 or 600 feet above the level of the shore. The lake of the Caraccas appears to have forced a passage for itself through the *quebrada*, or cleft of Tipé, while that of Aragua has been gradually dissipated by a slow process of evaporation, leaving some vestiges of its former existence in pools charged with muriate of lime, and in the low islets called *Aparecidas*. The medium height of the Cordillera of the coast is about 4000 or 5000 feet; but its loftiest summit, next to the Sierra Nevada of Merida, is the *Silla* (or saddle) of the Caraccas, which was visited by Humboldt, and ascertained from barometrical measurement to have an elevation of 8420 feet. Farther to the eastward, the mountain-chain becomes suddenly depressed, especially its primitive rocks; the beds of gneiss and mica slate, meeting as they advance with accumulations of secondary calcareous substances, which envelope them completely, and rise to a great eleva-

tion. The incumbent mass of sandstone, with a calcareous base, extending from Capelluari, forms a detached range of mountains, in which no trace of primitive rock is found.

The *second* branch, which stretches from the Andes across the American Continent, and exhibits a chain of primitive mountains, is named by Humboldt the *Cordillera of the cataracts of Orinocco*. This very enterprising traveller surveyed it over an extent of upwards of 600 miles, from the Black River to the frontiers of the Great Bara; but the rest of the chain is very little known, running through unexplored wilds and regions almost inaccessible, occupied by fierce and independent tribes of savages. It leaves the great trunk between the 3d and 6th degree of southern latitude, and runs eastwards from the *Paramo*, or high desert of Tuquillo and St Martin, and the sources of the Guaviari, rearing the lofty summits of Umama and Canavami, and pouring forth the large rivers Meta, Zama, and Ymerida, which form the *roudals*, or tremendous rapids of Aturé and Maypuré, the only openings existing at present between the interior of the Continent and the plain of the Amazons. Beyond these cataracts, the chain of mountains again acquires greater elevation and breadth, occupying the vast tract enclosed between the rivers Caura, Cavony, and Padamo, and stretching southwards to the boundless forests where the Portuguese settlers gather that potent drug, the *sarsaparilla*. Farther eastwards this chain is not traced, no European or civilized Indian having ever explored the sources of the Orinocco; all access in that quarter being prevented by the ferocity of the Guaicas, a dwarfish but very fair and warlike race, and by the valour of the Guajaribos, a most desperate tribe of cannibals. Beyond these recesses, however, we are made acquainted with the continuation of the chain of the cataracts, by the astonishing journey performed by Don Antonio Santos, who, disguised like a savage, his body naked, and his skin stained of a copper colour, and speaking fluently the several Indian dialects, penetrated from the mouth of the Rio Caronis to the Lake of Parimé and the Amazons. The range of mountains sinks lower, and contracts its breadth to 200 miles, where it assumes the name of Serrania de Quimeropaca and Pacaraimo. A few degrees farther eastwards, it spreads out again, and bends south to the Canno Pirara along the Mao, near whose banks appears the Cerro or hill of Ueucuamo, consisting entirely of a very shining and yellow mica slate, which has therefore procured from the credulity of early travellers the magnificent appellation of *Dorado*, or Golden Mountain. East from the river Esquibo, this Cordillera stretches to meet the granitic or gneiss mountains of Dutch and French Guyana, inhabited by confederated bands of Negroes and Caribs, but giving birth to the commercial streams of Berbice, Surinam, and Marony.

The chain of the cataracts of Orinoeco, has only a mean height of about 4000 feet above the level of the sea. The greatest elevation occurs where the mountain of Duida rears its enormous mass from the midst of a luxuriant plain, clothed with the tropical productions of Palms and Ananas, and discharges from its steep sides, about the close of the rainy season, volumes of incessant flames. No one has yet had the resolution or perseverance to climb through the tangling and rampant bushes to its peak, which, measured trigonometrically, gives an altitude of 8465 feet above the sea. The whole mountain-group which forms this Cordillera, is distinguished by the abrupt descent of its south flank; nor is it less remarkable for containing no rock of secondary formation, or exhibiting any vestige of petrifactions and organic remains. It contains only granite, gneiss, mica slate, and hornblende, without any casing or admixture of sandstone or calcareous matter.

The *third* great branch sent out from the trunk of the Andes, is that of the *Chiquitos;* which province it traverses, making a sort of semicircular sweep between the parallels of 15 and 20 degrees south latitude, and appearing to connect the colossal heights of Peru and Chili, with the mountains of Brazil and Paraguay. It supplies the rivers that feed the Marānon on the one side, and the Plata on the other The structure and disposition, however, of the Cordillera of the Chiquitos still remain almost unknown.

These grand chains of mountains divide the southern Continent of America, from the latitude of 19 to that of 52 degrees, into three immense plains, which on the west side are shut up by the enormous ridge of the Andes, but are all open on the east, and towards the Atlantic Ocean. The most northern is the valley of the Orinocco, consisting of savannahs or level tracts covered with reedy herbage and scattered Palms. The next is the plain of the Marānon, which is entirely covered with dense impenetrable forests. The third and southmost valley is the Pampas; a dead flat of most prodigious expanse, clothed, like that of the Orinocco, with a coarse rank herbage, and abandoned to the occupation of countless herds of wild cattle.

Of these immense plains, the subsoil resembles the composition of the neighbouring mountains. In the valley of the Orinocco, the primitive rock is generally wrapt in a coat of sandstone with calcareous cement, or covered with calcareous concretions, which betray the vestiges of recent organic remains, but show none of the older impressions, such as the belemnites and ammonites so common in Europe. The woody plain of Marānon is distinguished by the thinness of its soil, and the total absence of any calcareous ingredients, the granite approaching close to the surface, which is in some places left quite bare over an extent of many furlongs. But the Pampas of Buenos Ayres are covered to a great depth with beds of alluvial deposites, in which the powers of vegetation, fomented by the rays of a burning sun, luxuriate in wanton profusion.

The disciple of Werner traces with delight, in the majestic features of the American Continent, the same order and succession of rocks which the sagacity of that illustrious Geologist had discovered in the mountains of Saxony. Granite appears still the oldest material of our globe: To it succeeds the laminated species, or gneiss; then mica slate containing garnets; next primitive slate, with beds of native alum; now slate mixed with hornblende; above this, greenstone, or primitive trap, followed by

amygdaloid; and last of the series, porphyry slate. Resting or flanked against those primary rocks, beds of the older limestone begin to appear, followed by a suite of minerals, bearing indications of organic remains—mica slate, hornblende, gypsum, and calcareous sandstone. The only formations which Humboldt did not meet with in his extensive travels, were those of chalk, rocstone, gray-wacke, topaz rock, and the compound of serpentine with granular limestone which occurs in Asia Minor. The grand ridge of the Andes is everywhere covered with porphyry, basalt, phonolite, and greenstone; which being often broken into columns, appear at a distance like ruined castles, and produce a very striking effect. Near the bottom of that enormous chain, two different sorts of limestone occur—one with a silicious base, enclosing sometimes cinnabar and coal—and another mostly calcareous, and cementing the secondary rocks. These formations are of enormous thickness and elevation. "Beds of coal are found in the neighbourhood of Santa Fé, 8650 feet above the level of the sea: and even at the height of 14,700, near Huanco in Peru. The plains of Bogota, although elevated 9000 feet, are covered with gypsum, sandstone, shell-limestone, and even in some parts with rock salt. Fossil shells, which, in the old Continent, have not been discovered higher than the summits of the Pyrennees, or 11,700 feet above the sea, were observed in Peru, near Micuipampa, at the height of 12,800 feet; and again at that of 14,120, beside Huancavelica, where sandstone also appears. The basalt of Pichincha, near the city of Quito, has an elevation of 15,500 feet; while the top of the Schneekoppe in Silesia is only 4225 feet above the sea; the highest point in Germany where that species of rock occurs. On the other hand, granite, which in Europe crowns the loftiest mountains, is not found in the American Continent above the height of 11,500 feet. It is scarcely known at all in the provinces of Quito and Peru. The frozen summits of Chimborazo, Cayambé, and Antisana, consist entirely of porphyry, which, on the flanks of the Andes, forms a mass of 10,000 or 12,000 feet in depth. The sandstone near Cuença, has a thickness of 5000 feet; and the stupendous mass of pure quartz, on the west of Caxamarca, measures perpendicularly 9600 feet. It is likewise a remarkable fact, that the porphyry of those mountains very frequently contains hornblende, but never quartz, and seldom mica."

"The central Andes are rich beyond conception in all the metals, lead only excepted. One of the most curious ones in the bowels of those mountains is the *pacos*, a compound of clay, oxyd of iron, and the muriate of silver with native silver. The mines of Mexico and Peru, so long the objects of envy and admiration, far from being yet exhausted, promise, under a liberal and improved system, to become more productive than ever. But nature has blended with those hidden treasures the active elements of destruction. The whole chain of the Andes is subject to the most terrible earthquakes. From Cotopaxi to the South Sea, no fewer than forty volcanos are constantly burning; some of them, especially the lower ones, ejecting lava, and others discharging the muriate of ammonia, scorified basalt, and porphyry, enormous quantities of water, and especially *moya*, or clay mixed with sulphur and carbonaceous matter. Eternal snow invests their sides, and forms a barrier to the animal and vegetable kingdoms. Near that confine, the torpor of vegetation is marked by dreary wastes." (*Edin. Review*, Vol. XV. p. 233.)

We may subjoin, that, near Quito, the liquid mud ejected by the volcanos often involves myriads of small dead fish. In some parts, the mountains, like the fabled cave of Æolus, seem at times to let out their imprisoned air, and produce such furious gusts of wind as to sweep everything before them to a vast distance. In other districts, the efforts of the contending elements are betrayed, especially during the rainy season, by a doleful moaning noise, or hollow and portentous groans, enough to cast a darker shade on the gloom of superstition, and to fill the imagination of the remotest settler with secret awe and dread.

A person who, for the first time, climbs the mountains of Switzerland, is astonished to witness, in the space perhaps of a few hours, so rapid a change of climate, and such a wide range of vegetable productions. He may begin his ascent from the midst of warm vineyards, and pass through a succession of Chesnuts, Oaks, and Beeches, till he gains the elevation of the hardy Pines and stunted Birches, or treads on Alpine pastures, extending to the border of perpetual snow. But within the tropics everything is formed on a grander scale. The boundary of permanent congelation is 7500 feet higher at the equator than at the mean latitude of 45 degrees. Under a burning sun, Ananas and Plantains grow profusely near the shore; Oranges and Limes occur a little higher; then succeed fields of maize and luxuriant wheat; and the traveller has actually reached the high plain of Mexico, or the still loftier vale of Quito, before he finds a climate analogous to that of Bourdeaux or of Geneva. Now only commences the series of plants which inhabit the central parts of Europe.

But the very magnitude of the Andes appears to have the effect of diminishing the impressions of awe and wonder, which the sight of them so powerfully excites. The country on which they rest, is heaved to such a vast altitude above the sea, that the relative elevation of their summits becomes diminished in comparison with that of the surrounding amphitheatre. The majestic forms of Chimborazo, Cotopaxi, and Antisana, though 6000 feet higher than Montblanc, and clothed, like it, with eternal snow, seem to a traveller scarcely more sublime from the plains of Riobomba and Quito, than this celebrated mountain when viewed from the vale of Chamouni. It requires some time for his imagination to expand itself to the new scale of grandeur.

The central Andes, with all their magnificence, want a feature which, in the higher latitudes, contributes so much to the beauty and sublimity of the Alpine scenery. They have no vestige whatever of *Glaciers*, those icy belts dropping from the limits of congelation, and spreading in concrete sheets, or hanging in disjointed columns fantastically thrown, which occur alike in the heart of Switzerland and on the northern shores of Norway and Lapland. This defect is evidently owing to the almost uniform temperature which prevails near the equator. In

those torrid regions, the days are constantly of the same length, and the sun shines through the whole year with very nearly equal force. The limit of perpetual congelation is hence marked on the sides of the mountains of Quito with singular precision. The temperature decreases regularly in proportion as one ascends them, till at a certain altitude it comes to the point of freezing, where the permanent field of snow begins to appear, defined with an almost unvarying border. But in the higher latitudes, the sun remains, during the summer, so long above the horizon, and shines with such augmented force, that the heat of the atmosphere, and consequently of the surface of the ground, suffers a wide alteration in the different seasons. To the general investure of snow, is therefore annexed every winter, a zone of considerable breadth, which again softens and partly melts away during the continuance of the summer months. This alternate thawing and freezing, occasions the production of glaciers, by converting successively the lower detached masses of snow in the precipitous flanks of the mountains, into a collection of broken and intermingled pillars of translucid ice.

For the same reason the Andes, though torn by flaming volcanos, and convulsed by frequent and terrible earthquakes, are exempt from those *avalanches* and *eboulements* which, in Switzerland and other mountainous parts of Europe, often bury the helpless traveller in a torrent of snow, and batter down whole villages by the sudden discharge of a shower of rocks. Under the equator, the variation of temperature throughout the year is so small, as not to disturb the solidity of the vast collections of snow. But on the flanks of the Alps or Pyrennees, as the heat of the summer increases, portions of the upper field of snow become loosened, and, sliding down, put other masses likewise in motion, till spreading wider, and gaining accelerated force, the whole tide precipitates itself to the plain, sweeping all before it. Such is the accident of an *avalanche ;* but the occurrence of an *eboulement*, though less frequent, is more tremendous. When the alternation of frost and thaw detaches a mass of rock, it rolls down the side of the mountain with resistless fury, shivering into fragments and tearing everything opposed to it, overwhelming men, cattle, and houses, in one common heap of ruins.

But the Andes are distinguished from the chains of the European mountains, by frightful *quebradas* or perpendicular rents, which form very narrow vales of immense depth, whose terrific walls, fringed below with luxuriant trees and shrubs, seem to lift their naked and barren heads to the distant skies. The noted crevices of Chota and Cutaco are nearly a mile deep, the former measuring 4950, and the latter 4300 feet, in a vertical descent. The task of crossing such tremendous gullies, is often a work of infinite toil and extreme danger. In those mountainous countries, travellers are accustomed to perform their journies sitting in chairs fastened to the backs of men, called *cargueros* or *carriers*. These porters are Mulattos, and sometimes Whites, of great bodily strength and action, who will climb along the face of precipices, bearing loads of twelve and fourteen, or even eighteen stone. These *cargueros* lead a vagabond life, exposed to incredible fatigue, but recommended to them by its irregular course. Often those wretched men toil over mountains for the space of eight or nine hours every day, till, like beasts of burthen, they have their backs chafed, and made quite raw with the load. In this deplorable condition, they are not unfrequently abandoned by unfeeling travellers, and left alone to sicken, pine, or die in the forests. Yet their earnings would appear inadequate to such violent and overpowering exertions, since they receive scarcely three guineas for performing the journey from Ibague to Carthago, which requires fifteen, and perhaps twenty-five or thirty days.

The Icononzo, remarkable for its natural bridges, is a small *quebrada* or cleft of the mountains, through which flows the river of the Summa Paz, descending from the highest upland desert. The rocks consist of two different kinds of sandstone, the one extremely compact, and the other of a slaty texture, divided into their horizontal strata. The rent was probably caused by an earthquake, which the harder portion of the stony mass had resisted, and now connects the upper part of the chasm. This natural arch is 50 feet long, 40 broad, and 8 feet thick at the middle. Its height is about 300 feet above the surface of the torrent, which has a medium depth of twenty feet. About 60 feet below the natural bridge, another smaller arch occurs, composed of three slanting blocks of stone wedged together, which had probably fallen from the roof at the same instant of time, and struck against the sides of the crevice in their descent.

The natural bridge of Icononzo has perhaps no counter-part in the old world; but the writer of this article had the pleasure of seeing, in early life, a similar phenomenon, scarcely inferior to it, in the United States of America. We allude to the famous arch, described by Mr Jefferson, which crosses the Cedar Creek in Rockbridge county, about an hundred miles beyond the Blue Ridge, in the higher district of Virginia. The divided rock is a pure limestone, leaving a chasm about 90 feet wide, of which the walls are 230 feet high, sprinkled with verdant bushes, and enamelled with gay flowers, among which the *aquilegia* is conspicuous. This bridge, viewed from a little distance below, has all the appearance of a Gothic arch ; and is of such solidity, that loaded waggons used formerly to pass along it, till a more convenient line of road was formed.

In some places, the natives of Peru connect the clefts of their mountains by pendulous bridges thrown fearlessly across, and suspended from both sides of a gap. They are formed of ropes made of the tough fibres of the *agavé*, hanging in a gentle parallel curve, and covered with reeds or canes, with occasionally a narrow border of basket-work. The intrepid Indian, regardless of the horrors of the unfathomed abyss which yawns from below, commits himself to his frail and floating arch, and swiftly glides along its bending curvature, till he gains the opposite bank.

The Andes likewise give rise to waterfalls of immense height and amazing force. The cataract of Tequendama, considered in all its circumstances, exceeds any other in the known world. The basin

which feeds its streams is the vast plain of Bogota, 7465 feet above the level of the sea, encircled completely with lofty mountains, except where the water, aided probably by the concussion of an earthquake, has cut for itself a narrow passage. The river Funcha, swelled by numerous feeders, gradually contracts its channel to the breadth of about 40 feet, and then gathering augmented force, dashes at two bounds from a perpendicular height of near 600 feet, into a dark gulf. Owing to the excessive rapidity and depth of its current, it must discharge a prodigious volume of water, which quite stuns the ear by the roar of its crash; while it raises enormous clouds of thick spray and vapour, that continually bedew, and perhaps quicken the vegetation of the adjacent grounds. Everything conspires to exalt the beauty and grandeur of the scenery. "Independent of the height and mass of the column of water," says Humboldt, "the figure of the landscape, and the aspect of the rocks, it is the luxuriant form of the trees and herbaceous plants, their distribution into thickets, the contrast of those craggy precipices, and the freshness of vegetation, which stamp a peculiar character on these great scenes of nature." The transition from a temperate to a warm climate is rapid and surprising. The plain of Bogota bears rich crops of wheat, then succeed Oaks and Elms, intermingled with Aralias, Begonias, and the Yellow-bark trees; but, immediately below the cataract, a few Palms appear, as if it were to mark the advance to a sultry soil.

A lively idea of the character and grand features of the Andes may be conceived from the account which the celebrated Humboldt has given of his journey across that majestic chain. Our readers will be glad to peruse it in the author's own words:

"The mountain of Quindiu, in the latitude of 4° 36′, is considered as the most difficult passage in the Cordilleras of the Andes. It is a thick uninhabited forest, which, in the finest season, cannot be traversed in less than ten or twelve days. Not even a hut is to be seen, nor can any means of subsistence be found. Travellers, at all times of the year, furnish themselves with a month's provision, since it often happens, that, by the melting of the snows, and the sudden swell of the torrents, they find themselves so circumstanced, that they can descend neither on the side of Carthago, nor that of Ibague. The highest point of the road, the Garito del Paramo, is 11,500 feet above the level of the sea. As the foot of the mountain, towards the banks of the Cauca, is only 3150 feet, the climate there is generally mild and temperate. The pathway, which forms the passage of the Cordilleras, is only 12 or 15 inches in breadth, and has the appearance, in several places, of a gallery dug, and left open to the sky. In this part of the Andes, as almost in every other, the rock is covered with a thick stratum of clay. The streamlets which flow down the mountains have hollowed out gullies about 20 feet deep. Along these crevices, which are full of mud, the traveller is forced to grope his passage; the darkness of which is increased by the thick vegetation that covers the opening above. The oxen, which are the beasts of burden commonly used in this country, can scarcely force their way through these galleries, some of which are more than a mile in length; and if, perchance, the traveller meets them in one of these passages, he finds no means of avoiding them, but by turning back, and climbing the earthen wall which borders the crevice, and keeping himself suspended, by laying hold of the roots which penetrate to this depth from the surface of the ground."

"We traversed the mountain of Quindiu in the month of October 1801, on foot, followed by twelve oxen, which carried our collections and instruments, amidst a deluge of rain, to which we were exposed during the last three or four days, in our descent on the western side of the Cordilleras. The road passes through a country full of bogs, and covered with Bamboos. Our shoes were so torn by the prickles which shoot out from the roots of these gigantic gramina, that we were forced, like all other travellers who dislike being carried on men's backs, to go barefooted. This circumstance, the continual humidity, the length of the passage, the muscular force required to tread in a thick and muddy clay, the necessity of fording deep torrents of icy water, render this journey extremely fatiguing; but however painful, it is accompanied by none of those dangers with which the credulity of the people alarm travellers. The road is narrow, but the places where it skirts the precipices are very rare."

"When travellers reach Ibague, and prepare to cross the forests of Quindiu, they pluck in the neighbouring mountains, several hundred leaves of the Vijao, a plant of the family of the Bananas, which forms a genus approaching to the Thalia, and which must not be confounded with the *Heliconia Bibai*. These leaves, which are membranous and silky, like those of the *Musa*, are of an oval form, two feet long and 16 inches broad. Their lower surface is a silvery white, and covered with a farinaceous substance which falls off in scales. This peculiar varnish enables them to resist the rain during a long time. In gathering these leaves, an incision is made in the middle rib, which is the continuation of the foot-stalk; and this serves as a hook to suspend them, when the moveable roof is formed. On taking it down, they are spread out, and carefully rolled up in a cylindrical bundle. It requires about an hundred weight of leaves to cover a hut large enough to hold six or eight persons. When the travellers reach a spot in the midst of the forests where the ground is dry, and where they propose to pass the night, the cargueros lop a few branches from the trees, with which they make a tent. In a few minutes, this slight timber work is divided into squares, by the stalks of some climbing plant, or the threads of the agave placed in parallel lines, 12 or 13 inches from each other. The Vijao leaves meanwhile have been unrolled, and are now spread over the above work, so as to cover it like the tiles of a house. These huts, thus hastily built, are cool and commodious. If, during the night, the traveller feels the rain, he points out the spot where it enters, and a leaf is sufficient to obviate the inconvenience. We passed several days in the valley of Boquia, under one of those leafy tents, which was perfectly dry, amidst violent and incessant rains."

For farther information relative to the structure of the Andes, see the various sketches given by Humboldt, and particularly an abstract of his Geological Observations inserted in the *Journal de Physique*, Vol. LIII. for 1801. (D.)

ANDREWS (JAMES PETTIT), a late English historian and miscellaneous writer, was the younger son of Joseph Andrews, Esq. of Shaw-house, near Newbury, Berks, where he was born in the year 1737. He was educated privately, and is said to have discovered an early taste for literature and the fine arts. He joined the Berkshire militia when they were first called out, being then about 18 or 19; and held the rank of lieutenant in that regiment, until it was disbanded. On the institution of the new system of London Police, he was appointed one of the Commissioners for the district of Queen's Square and St Margaret's, Westminster, and discharged the duties of that office, with great industry and integrity, until his death, which took place at his house in London, on the 6th of August 1797, in the 60th year of his age. He married Miss Anne Penrose, daughter of the Reverend Mr Penrose, late rector of Newbury, by whom he had two sons and a daughter. He seems to have possessed a cheerful and social disposition, and enjoyed the conversation of a large circle of literary acquaintance, who frequently met at his house and experienced his hospitality.

Mr Andrews appears to have devoted a considerable portion of his time to literary pursuits; and he is the author of several works which are not undeserving of notice. The first publication upon which we find him employed, is an edition of the poems of his friend and relation, Penrose, in 1781; to which he prefixed an introduction, containing a short account of the life and character of the author. His first original production, so far as we have been able to ascertain, was a pamphlet in behalf of the chimney-sweepers' apprentices, in 1788; which is said to have led to the act of Parliament, passed not long afterwards, for the purpose of ameliorating the condition of that unfortunate class of beings. In 1789, he published *Anecdotes, ancient and modern*, 8vo; a work of pleasantry, in the composition of which, he acknowledged having received assistance from the late Laureat, Mr Pye, the facetious antiquary, Captain Grose, and others. To this volume he added a supplement, in 1790.

The most extensive work undertaken by Mr Andrews, was his *History of Great Britain, connected with the Chronology of Europe; with Notes*, &c. The first volume, which commences with Cæsar's invasion, and ends with the deposition and death of Richard II. was published in 1794, in 4to. A second volume, in which the history is continued from the deposition and death of Richard II. to the accession of Edward VI. appeared in 1795. The plan of this work is new, and in some respects singular; a certain portion of the history of England is given on one page, and a corresponding portion of the contemporaneous history of Europe on the one opposite. The notes consist of a variety of curious and amusing particulars, not immediately connected with the main story. Appendixes are also added, at proper intervals, containing an account of the state of literature, science, religion, government, manners, &c. at different periods. The author, however, did not live to complete this curious and extensive work; no more of it having appeared than the two volumes above mentioned. In 1796, he published a continuation of Henry's *History of Britain*, in one volume 4to, and two volumes 8vo.

The other productions of this author are, *An Account of Saxon Coins found in Kintbury Church-yard, Berks*, printed in the 7th volume of the *Archæologia*; the *Account of Shaw*, in Mr Mores's Berkshire collections; *The Savages of Europe*, a popular French novel, which he translated, and illustrated by prints from his own designs. Mr Andrews was also a frequent contributor to the *Gentleman's Magazine*. See the *Gen. Biog. Dict.* by Chalmers; *Introduction to "Poems by the Rev. Thomas Penrose,"* 1781; *Gent. Mag.* for 1797 and 1801; and Lysons' *Supplement to Environs of London*. 1811. (H)

ANEMOMETER, ANEMOSCOPE. See these Articles in the *Encyclopædia*, and WIND-GAGE in this Supplement.

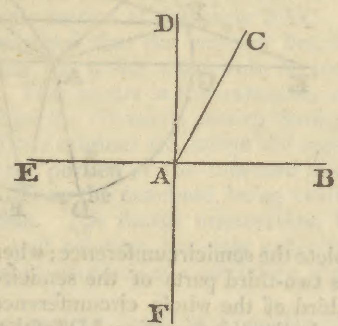
ANGLE. This term is, owing to the poverty of language, employed to signify very different things. In Plane Geometry, it means the opening or separation of two straight lines which meet in a point; but in Solid Geometry, it variously denotes the deviation of a straight line from a plane, the divergencies of one plane from another at their line of junction, or even a cluster of plane angles terminating in a common summit. This diversified application of the same word is not likely, however, among mathematicians, to occasion any misconception. But it would be more perspicuous, and certainly more philosophical, to imitate the practice of naturalists in framing a set of cognate words to express the several transitions of meaning.

The word *angle* was drawn from common discourse into the vocabulary of science. Its primitive sense in all the languages in which it can be traced, is merely a *nook* or *corner*; but it has acquired a more precise and extensive application in its transfer to geometry. In its simplest form, it now denotes generally the *divergence* or difference of direction between two concurring straight lines. Yet a learner still experiences some difficulty in seizing the correct idea of its nature, which has always baffled the attempts of authors to reduce to the terms of a strict definition. Apollonius, at once the most elegant and inventive of the Greek geometers, was satisfied with representing an angle as a *collection of space about a point*; a description which is not only extremely loose, but which intimates quite a different conception. Euclid, the great compiler of the *Elements*, has defined an angle to be the κλισις, *or mutual inclination of two straight lines that meet*. But, in strict language, this definition should apply only to the acute angle, in which one of the sides leans towards the other, and deflects from the perpendicular. Without an extension of the meaning of the term *inclination*, it will not include the obtuse angle, and far less comprehend angles in general; which, since they are capable of repeated additions, must evidently, as much as lines themselves, be susceptible of all degrees of magnitude.

Nature of.

It is indeed impossible, by any combination of words, to express completely and accurately, the primary notions which form the ground of geometrical science. The more profitable task is to trace the process by which the mind, refining on external observation, comes to acquire such abstract ideas. We seem to get the idea of *length* or of *linear extension,* by viewing progressive motion; and the enlarged conception of *angles* or of *angular magnitude* is easily attained, from the contemplation of revolving motion. In opening, for instance, the legs of a pair of compasses, we perceive that their difference in direction gradually increases, keeping pace with the turning at the joint. The quantity of this opening properly constitutes the measure of an angle; and an entire revolution, which brings the moving side of the angle back to its first position, furnishes a standard of reference. The revolution bisected, marks the divergence of a directly opposite position, or that of two segments of a straight line at their point of separation; and the half of this again, or the divergence of a line proceeding from the same point, and turned equally aside from both segments, is the right angle, which, therefore, being constant, serves to measure all the rest.

Suppose an inflexible straight line AB to turn from right to left, about the point or vertex A. It first comes to the position AC, then to AD, next to AE, now it reaches AF, and lastly it gains its original site AB.

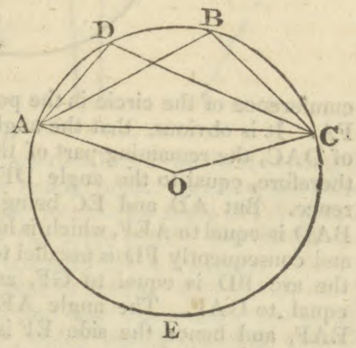


The angles thus formed at the point A, arise from the combination of successive openings. The angle BAD is composed of BAC and CAD, the angle BAE, or that of direct opposition, is compounded of BAC, CAD, and DAE, and the entire circuit is made up of the accumulated angle BAC, CAD, DAE, EAF, and FAB. This circuit being quartered by the straight lines BE and DF, is divided at the vertex A into four right angles. By comparison, therefore, the angle BAC is acute, and CAE obtuse.

But the side AB can attain the direction AC, either by moving onwards, or by turning backwards through the points F, E, and D. The angle compounded of the openings BAF, FAE, EAD, and DHC, may hence be termed appropriately the *reverse* of BAC. The defect of an angle from a right angle is called its *complement*, the defect from two right angles its *supplement*, and the defect from four right angles or the entire circuit, might be conveniently named its *explement*. Thus, CAD is the *complement* of the angle BAC, CAE is its *supplement*, and the reverse angle BAC its *explement*.

If we consider attentively the formation of angles about a point, we shall be convinced that two concurring straight lines do not contain merely a single angle, but involve an indefinite multitude of angles; in short, that they comprehend all the revolutions and parts of a revolution by which the one line would successively attain the direction of the other. Hence AB will, after describing repeated revolutions, always return into the same position AC. Thus, if A represent the measure of an angle, and C that of a whole circuit or four right angles; then the primary angle will include likewise A+C, A+2C, A+3C, A+4C continued for ever. Of those successive angles, A, A+C, A+2C, A+3C, A+4C, &c. &c. the sines, tangents, and secants, are severally the same; and so are the versed sines, the cosines, cotangents and cosecants. This extension of the doctrine of angles, is of the greatest importance in the higher branches of geometry, in the application of trigonometrical formulæ, and in algebraical analysis.

Euclid, in the course of his reasoning, has frequent occasion to combine angles together; and yet he never ventures beyond the consideration of those angles which are less than two right angles. Had he composed his *Elements* after the science of trigonometry came to be cultivated, he could not have failed to take more enlarged views of angular magnitude. In consequence of his narrow conception of the constitution of angles, the Greek geometer is not a little cramped sometimes, and obliged to adopt a circuitous mode of demonstration. For instance, in the 20th prop. of his third book—that "the angles at the circumference are the halves of those at the centre standing on the same arc,"—he quite overlooks the case of obtuse angles at the circumference. But, in the annexed figure, the angle ABC is clearly the half of the *reverse* angle AOC at the centre, which is subtended by the large arc AEC. It hence follows that the obtuse angles ABC and ADC contained in the same segment must be equal, since they are both of them halves of the *reverse* angle AOC. Yet, in demonstrating this very obvious corollary, Euclid is constrained to divide the obtuse angles into portions which are shown to be the halves of corresponding angles at the centre. For the same reason, he finds it necessary to give a distinct demonstration of the celebrated proposition that "the angle contained in a semicircle is a right angle." But this property ought likewise to be considered as a simple corollary, for if radii OA and OC were supposed to extend in one straight line, and thus form the diameter of the circle, their angle AOC would become equal to two right angles, and consequently ABC its half would be one right angle. See *Leslie's Geometry.* (D.)



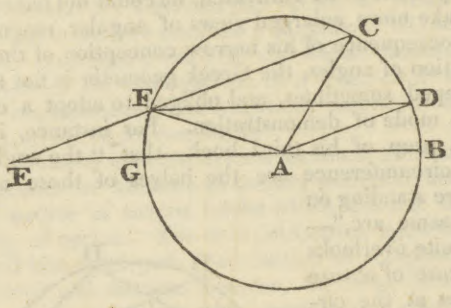
ANGLE (Trisection of). The attempts of the Greek mathematicians to *Double a Cube* and to *Trisect an Angle,* were their first steps beyond the limits

Trisection of.

of Elementary Geometry. They soon perceived that such problems cannot be solved by any combination of mere straight lines or circles. To this conclusion they were led directly by the application of *Geometrical Analysis*, a beautiful instrument of discovery which Plato had recently invented or improved. Their investigations pointed at some curves of a higher order than the circle, and opened to them a wide and interesting field of research.

The analysis of the trisection of an angle, conducted in two different ways, terminates in the construction of the *Conchoid*, a complex curve which was first proposed by Nicomedes. As the subject is very curious, and throws great light on the theory of angular magnitude, we shall here not only give both the ancient methods of investigation, but subjoin a third which is due to the sagacity of Newton.

1. Let it be required to trisect the angle BAC or the arc BC. Suppose the thing already done, and the angle BAD to be the third part of the given angle. From the point CE draw CE parallel to AD, meeting the extended diameter in E, and cutting the cir-

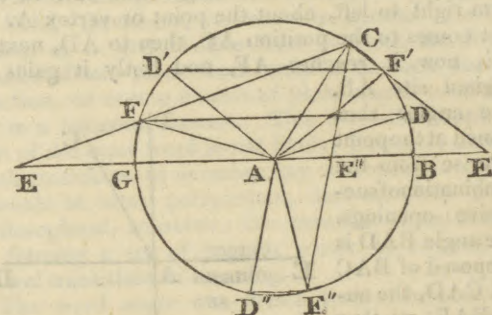


cumference of the circle in the point F; join FD and FA. It is obvious, that the angle BAD is the half of DAC, the remaining part of the whole angle, and therefore, equal to the angle DFC at the circumference. But AD and EC being parallel, the angle BAD is equal to AEF, which is hence equal to DFC; and consequently FD is parallel to EB. Wherefore, the arc BD is equal to GF, and the angle BAD equal to GAF. The angle AEF is thus equal to EAF, and hence the side EF is equal to AF, the radius of the circle.

To solve the problem, therefore, it would be requisite to inflect from C a straight line CFE, such that the portion FE, intercepted between the circumference and the diameter or its extension, should be equal to the radius of the circle. The radius AD, drawn parallel to this inflected line, CE would cut off an angle BAD, which is the third part of the given angle BAC.

But it is clear, that Elementary Geometry will not furnish the means of inflecting CE, according to the required conditions. This must be done either tentatively, that is, by repeated trials, or by the application of a curve, so constituted, that every straight line drawn from the *pole* C, to the *directrix* BG, shall have the portion EF, intercepted by the curve equal to AB. This curve is, from its general shape or resemblance to a *conch* or shell, named the *Conchoid;* consists of two branches, one above the directrix called the *interior conchoid*, and the other below it, called the *exterior conchoid*. The conchoid being described, will, by its intersection with the circumference of the circle, give the point F, and consequently the position of trisecting line AD′. But such a complex curve must cut the circumference in more points than one, and consequently the problem of angular trisection, viewed in its generality, admits of several answers. In fact, there are always *three* distinct positions of the inflected line CE, which will fulfil the conditions of the problem

It is curious to examine these different positions of the inflected line. Draw AD′ parallel to the *second* position CE′, and join D′F′, AD′, and AF′. Because AF′ is equal to E′F′, the angle E′AF′ is equal to AE′F′; and, consequently, the exterior angle AFC is the double of either of these. But CAF′ being an isosceles triangle, AF′C is equal to ACF′, which again is equal to the alternate angle CAD′; wherefore, CAD′ is the double of the angle AE′F′; and being likewise the double of CF′D′ at the circumference, the angles CF′D′ and AE′F′ are equal; and, consequently, F′D′ and E′A parallel. Now the angle CAD′ being double of E′AF′ or D′AG, and the angle CAD double of DAB, the arc DCD′ is double of the arcs D′G and DB, which serve to com-



plete the semicircumference; wherefore, this arc DCD′ is two-third parts of the semicircumference, or one-third of the whole circumference.

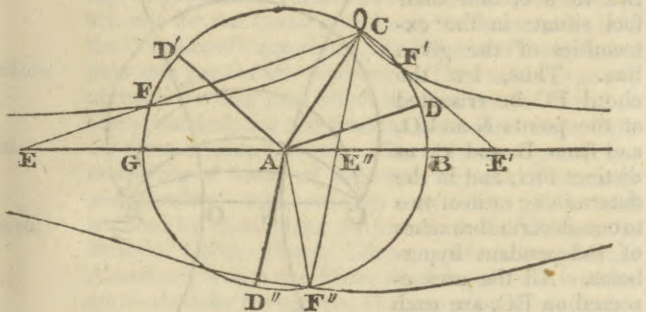
In the *third* position AD″ of the trisecting line, draw CF″ parallel to it, and join AF″ and D″F″. The isosceles triangles D″AF″ and AF″E″ have equal vertical angles; and, consequently, the angles at their base are likewise equal; wherefore, AF″D″ is equal to the alternate angle F″AE″, and the chord D″F″ parallel to the diameter BG. But the reverse angle CAD″, standing on the arc CD′D″, is double of the angle CF″D″ at the circumference, and, therefore, double of BE″F″ or of BAD″; and the angle CAD being, by the first construction, likewise double of BAD, the reverse angle CAD″, together with CAD, must be double of BAD″ and BAD, or the arc CD′GD″ is double of DBD″, which completes the circumference. Hence the arc DD′D″ is two-thirds of the circumference.

It thus appears that the construction of the problem assumes three different aspects, and that the trisecting lines, to which a close analogy conducts us, mutually divide the whole circuit into equal portions. These results are perfectly conformable with the theory of angular magnitude. For if A denote the arc BC, and C the whole circumference, this arc

Trisection of.

will be generally expressed by A, A+C, A+2C, &c.; consequently, the third part will be expressed by $\frac{1}{3}$A, $\frac{1}{3}$A+$\frac{1}{3}$C, $\frac{1}{3}$A+$\frac{2}{3}$C, &c., which evidently correspond to BD, BD′ and BD″. But any farther extension of this progression only brings the trisecting line back into its former positions.

To solve completely, therefore, the problem of the trisection of an angle, from the pole C, on either side of the directrix BG, with a measure equal to the radius of the circle, describe the exterior and the interior or nodated conchoid; draw CF, CF′ and CF″ to the three points of intersection with the circumference,

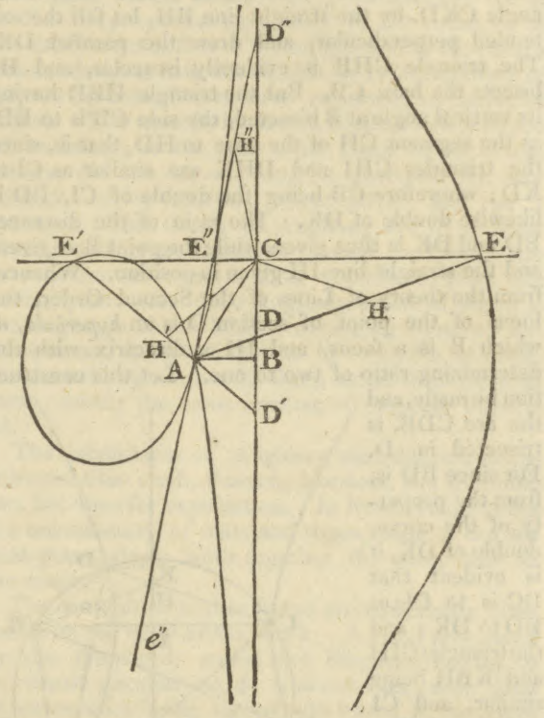


and the radii AD, AD′, and AD″, parallel to these will mark the triple section of the angle BAC.

It may be perceived that the exterior branch of the conchoid cuts the under semicircle in another point besides F. This occurs in the extension of the radius CA, or where the diameter, passing through C, the extremity of the original arc, meets the opposite circumference; the portion of the inflected line, intercepted below BG by the conchoid, being evidently equal to the radius. The fourth intersection, however, affords no real solution, but only exhibits the amount of repeated division, as completing the arc itself.

2. But another analysis leads to a similar result. Let the angle BAD as before be third part of BAC; draw BC perpendicular to AB and CE parallel to it, meeting AD produced in E. The right angle DCE would be contained in a semicircle having DE for its diameter; join C with the centre H, and the triangle CHE being isosceles, the exterior angle CHA is double of CEH, or of the alternate angle BAD: and, therefore, equal to the remaining portion CAD of the divided angle BAC. Whence the triangle ACH is isosceles, and the side CH equal to HC, or the diameter DE must be double of AC.

The construction of the problem is thus reduced to the drawing from the vertex to the given angle, a straight line, ADE, such that the part DE intercepted between the perpendiculars BC and CE, shall be equal to the double of AC. This can only be done by describing a conchoid from the pole A to the directrix BC, and with the double of AC as the measure; the intersection of the curve with the perpendicular CE, will determine the position of the trisecting line ADE. The exterior branch of the conchoid, will cut the perpendicular in the point E, and the interior or nodated branch will meet and cross it at the two points E′ and E″. The radiating lines AE, AE′, and AE″, or its extension A$e$″, will indicate the complete trisection of the angle BAC. These lines will be found, as in the first construction, to make angles with each other that are equal to the thirds of an entire circuit. It may be worth while to examine the several cases.



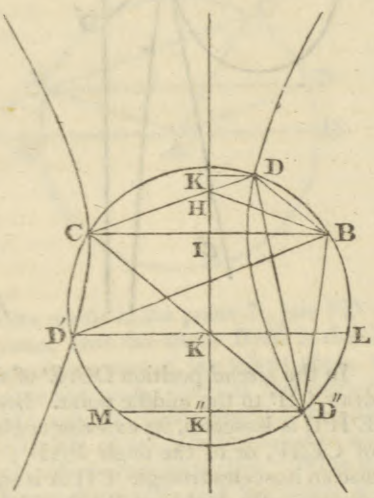
In the *second* position D′AE′ of the trisecting line, draw CH′ to the middle point. Because the triangle E′H′C is isosceles, its exterior angle CH′A is double of CE′H′, or of the angle BAD′; but H′CA being also an isosceles triangle, CH′A is equal to CAH, and consequently double of BAD. Add CAD, which is double of BAD, and the compound angle DAE′ is double of DAD′, which would complete two right angles; whence DAE′ is two-thirds of two right angles, or one-third of a whole circuit.

In the *third* position, AE″D″ of the trisecting line, or rather its extension A$e$″, draw CH″ to bisect E″D″. The triangles CH″D and ACH″ are then isosceles, and consequently the angle CAD″ or CH″A is double of CD″A; but CAE is likewise double of CEA, and therefore the combined angle D″HE is double of the angles CD″A and CEA. Now this angle D″HE, together with the two angles CD″A and CEH, is evidently equal to the exterior angle DC″E or a right angle. Whence D″AE is two-thirds of a right angle, or one-third of two right angles, and therefore the adjacent angle DAE″ is two-thirds of two right angles, or one-third of a whole circuit.

3. The simplest and most elegant solution of the trisection of an arc is due to modern science, and first appeared in Newton's *Universal Arithmetic*.

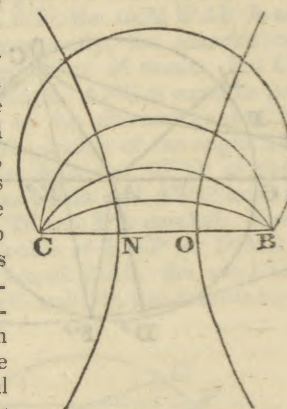
Trisection of.

The problem is there reduced to the combination of the circle with a certain kind of hyperbola. But the general property of the directrix, which belongs to all the conic sections, or the lines of the second order, affords the readiest mode of investigation. Let the arc BD be the third part of BDC. Complete the circle, and draw the chords BD, BC, and CD. The arc CD is evidently double of BD, and therefore, the angle CBD is double of BCD. Bisect the angle CKD, by the straight line BH, let fall the extended perpendicular, and draw the parallel DK. The triangle CHB is evidently isosceles, and HI bisects the base CB. But the triangle HBD having its vertical angle at B bisected, the side CB is to BD, as the segment CH of the base to HD, that is, since the triangles CHI and DHK are similar as CI to KD; wherefore CB being the double of CI, BD is likewise double of DK. The ratio of the distances BD and DK is thus given, while the point B is given, and the straight line IH given in position. Whence, from the theory of Lines of the Second Order, the locus of the point of section D is an *hyperbola*, of which B is a focus, and IH a directrix, with the determining ratio of two to one. Let this construction be made, and the arc CDB, is trisected in D. For since BD is, from the property of the curve, double of DK, it is evident that BC is to CI as BD to DK; and the triangles CIH and KBH being similar, and CI to CH, as DK to DH, it follows that BC is to CH as BD to DH, or alternately BC is to BD as CH to DK. Wherefore the vertical angle CBD is bisected by BH, or the angle CBD is double of CBH or of BCD; and consequently the arc CD is double of BD, or BD itself is the third part of the whole arc CDB.

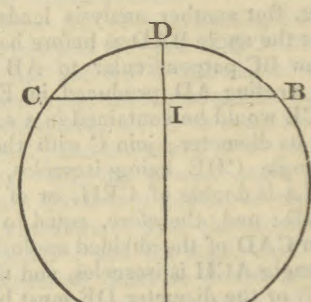


But the opposite branch of the hyperbola, which passes through C, also comes into play; and the intersection of these two branches with the circle, assigns three different positions of the point D, separated from each other by intervals equal to the third of the whole circumference. Thus, in the *second* position D′, produce the perpendicular D′K′ to the opposite circumference L; and since BD′ is double of D′K, it must be equal to the chord D′L, and consequently the arc BDCD′ is equal to D″MD′. Wherefore the double of BDCD′, together with the interval BL or CD, is equal to the whole circumference; that is, the double of DCD′ with the double of BD and CB′ is equal to the whole circumference; and since the double of BD is DC, the triple of the arc DCD′ must complete the circumference. In the *third* position D″, produce the perpendicular DK″ as before; the double of this or the chord BD″ is hence equal to D″M, and the arc BLD″ equal to DM. Consequently the double of BLD″, with the compound arc, BDCM completes the circumference; but D″M, being parallel to BC, the arc BLD″ is equal to CD′M, and therefore three times the arc BLD″ with the arc BDC, or the triple of BD will fill up the circumference, or the arc DBD″ is a third part of it.

The trisection of innumerable arcs described on the same chord is rendered very conspicuous, by combining the separate branches of two hyperbolas that have the determining ratio of two to one, and their foci situate in the extremities of the given line. Thus, let the chord BC be trisected at the points N and O, and from B and C, as distinct foci, and in the determining ratio of two to one, describe branches of independent hyperbolas. All the arcs erected on BC, are each of them divided by those curves into three equal portions. These arcs, as they flatten, approach to the trisected chord CNOB, on the one hand; and as they become enlarged, they constantly tend, on the other, to the complete circumference which the asymptotes of the hyperbola, making angles on each side of the axis equal to two-thirds of a right angle, would themselves trisect.



It may be observed in general, that the section of an arc or angle admits of as many different answers as the number of divisions proposed. Thus, the quadrisection would give four distinct results, and a quinsection would involve no fewer than five separate products. Nay, the bisection itself of an arc, though within the limits of the most elementary geometry, yet brings out a double result. Thus, the arc CDB is bisected by perpendicular or diameter DID′, which not only gives BD for the half of that arc, but also BDCD′, or the same half arc augmented by a semicircumference.



These conclusions agree with the results derived from the general theory of functions. The expression for the sine of a multiple arc, is always an equation of corresponding dimensions; which therefore admits of as many distinct roots as the index contains units.

(D.)

Anglesey.

Extent and Divisions.

ANGLESEY, the Mona of Tacitus, and Tir-mon of the Welsh, is of an irregular form, and indented on three of its sides with numerous small bays and creeks; its length from Carnets point to Bangor ferry is 20 miles, and its greatest breadth from Llanddwyn Abbey to Penmon Priory, 17 miles; its area, by the most recent and accurate survey, comprises 173,000 acres. At the time when Wales was divided into six Counties by Henry VIII. this Island, which formed one of them, was subdivided into three Hundreds; at present it contains six Hundreds. In it there are four market towns, Beaumaris (the County town), Newborough, Llanerchymedd, and Holyhead; and 74 parishes. It returns two members to Parliament, viz. one for the County, and one for Beaumaris; is in the Province of Canterbury, and Diocese of Bangor, and pays one part of the land-tax. The surface is gently undulated; that part which borders on the Menai is finely wooded, but the interior is a naked tract without trees or even hedges. The soil is nearly uniform, consisting of loam of different degrees of tenacity and fertility, with scarcely any clay. It is well watered by 12 rivulets, the principal of which are the Braink, Cefni, Ffraw, Llivon, and Allon. Near Aberffraw, where the Ffraw discharges itself into the sea, is the lake Llyngoron, about two miles in circumference, abounding in trout, gwyniaid, and other fish. There is undoubted evidence of the encroachment of the sea on the shore of this Island: the Lavan sands, in the bay of Beaumaris, formed a habitable Hundred in the sixth century, when they were suddenly overwhelmed by the sea. There are five ferries across the Menai Straits, of which Port-hamel, or the Gloomy ferry (so called from the dense woods which in former times overshaded its banks), is celebrated as the place, where Suetonius landed, when he exterminated the Druids. Off the eastern point is the steep, rocky islet of Priest-holme, or Puffin's island: it is a noted resort, during the summer, of various birds of passage; the Puffin, whence it derives one of its appellations, breeds there in immense numbers. At the northern point of Anglesey, is the isle of Seals; its sides are frequented by vast shoals of fish, and Seals which prey upon them.

Surface.

Soil.

Rivers.

Minerals.

Anglesey is rich in minerals, particularly in copper. Of the mines of this metal in the Parys mountain, a particular account is given in the body of the work, on the authority of Mr Pennant; since that account was written, the produce of these mines has declined considerably; the number of men employed having been reduced, from 1500 to 600. Besides common limestone, white marble, and blue-veined grey marble, sulphat of barytes, an earth yielding $\frac{2}{7}$ of pure magnesia, steatite, serpentine, fullers earth, and native sulphur, are found in this Island. Hitherto, coal has not been wrought with any profit, though the depth of coal, in proportion to the whole depth sunk, appears favourable, being $3\frac{1}{2}$ feet in 77 feet. An uncommon appearance in the natural history of this fossil is met with in Anglesey, viz. podicles of loose coal of several tons weight. This Island is celebrated for the variety of its shell-fish; Bingley, in his tour, gives a list of thirty-eight of the principal of these productions; the oysters in particular are highly esteemed. The botany of Anglesey presents nothing very peculiar or remarkable.

Anglesey || Annealing.

Agriculture.

Of the 173,000 acres contained in Anglesey, it is computed that there are 12,600 acres of waste land; and that no more than the eleventh part of the remainder is under tillage, in the following proportions; oats 7953 acres; barley 6107; wheat 520; rye 2. In the *Encyclopædia*, apparently on the authority of the anonymous author of the supplement to Rowland's *Mona Antiqua*, it is stated, that in 1770, upwards of 90,000 bushels of corn were exported, exclusive of wheat. This must be incorrect, as the whole produce of the Island, in the year 1795, taken by an actual survey, did not exceed 59,770 quarters; viz. oats 35,485; barley 22,700; wheat 1578; and rye 7 quarters. The Cattle of Anglesey are of a good breed; and great attention is paid to them; the average annual export is about 8000 head, from one to four years old. The Anglesey breed of sheep is the largest in North Wales; averaging about 15 lbs. the quarter, and yielding from $1\frac{3}{4}$ to $2\frac{1}{2}$ lbs. of wool: the annual exportation of sheep varies from 5000 to 7000; nearly the same number of hogs are exported.

Manufactures.

The inhabitants of Anglesey manufacture deep-coloured blue cloth, flannels, blankets, &c. for home use, but none for exportation. In Newborough there is a manufacture of mats and ropes, made of the sea reed-grass, which binds together the sandy hills on the coast.

Antiquities.

The antiquities of this Island are sufficiently illustrated in the body of the work. A rural pipe, used by the Shepherd, called the Pibgorn, is said to be almost peculiar to it; it derives its name from its extremities being tipped with horn; it has seven holes, besides the aperture in which the reed is concealed; and its tone is between the flute and the clarionet.

Population.

From the population returns of 1801, it appears that there were then in Anglesey 6679 houses, inhabited by 7058 families; and 127 uninhabited houses; 9776 *persons* chiefly employed in agriculture: 2614 in manufactures and trade; and 19,228 not comprised in these two classes: the number of males was 15,775; and of females 18,031. By the returns in 1811, there were 7183 houses, inhabited by 7706 families; 72 houses building; 108 uninhabited; 5376 *families* chiefly employed in agriculture; 1453 in manufactures; and 877 not comprised in these two classes: the number of males was 17,444; and of females 19,601. It will be remarked, that, according to both returns, the number of females exceeds that of males; this disproportion is not, however, peculiar to Anglesey, but extends over all Wales.

The reader, who is desirous of farther information, in regard to this Island, may consult Davie's *General View of the Agriculture of North Wales.*—Bingley's *Tour in North Wales.*—A. Aiken's *Tour in Wales.* (c.)

ANNEALING. The nature and use of this process in Glass-making, has been already explained in

Annealing. the body of the work; it remains to add some details in regard to its application to metals. In the manufactures, in which the malleable metals are employed, annealing is used to soften a metal after it has been rendered hard by the hammer, and also to soften cast-iron, which is rendered very hard and brittle by rapid cooling.

In the manufacture of steel goods, which are first formed by the hammer, and require to be filed or otherwise treated, and in which softness and flexibility are essential to the change, annealing is absolutely necessary. This is particularly the case in making files and scissors; that the metal may be left sufficiently soft for cutting the teeth, and for filing off those parts which cannot be ground. Annealing is not less necessary in the drawing of wire, whether iron, copper, brass, silver, or gold. The operation of drawing soon gives the wire a degree of hardness and elasticity, which, if not removed from time to time by annealing, would prevent the extension of the wire, and render it extremely brittle. The same operation is also necessary in rolling or flatting those metals which are in a cold state, such as brass, silver, gold, &c. The Brazier who forms vessels of copper and brass by the hammer, can work upon it only for a little time, before he is obliged to anneal it.

The common methods employed for annealing iron and steel are very injudicious, and materially injure the latter, when it is used for making cutting instruments. After they have been formed by the hammer, they are generally piled up in an *open* fire, slowly raised to red heat, and then allowed as gradually to cool. By this method, the surface of the steel will be found considerably scaled, from the action of the oxygen of the atmosphere. When it is remembered, that steel consists of iron joined to carbon, it will be evident, that the steel immediately under the scaly oxyd will be deprived of its carbon, which has been carried off by the attraction of the oxygen; and in consequence, will lose the property, of acquiring that degree of hardness necessary to a cutting instrument.

Nothing, therefore, can be more obvious, than that steel particularly should be annealed in close vessels, to prevent that effect. For this purpose, the goods should be placed in a trough or recess made of fire-stone, or fire-brick, and stratified with ashes, or clean sand, and finally covered with a thick stratum of the same; but if the size of the vessel be small, it may have a cover of its own materials. This oven or trough must now be heated by the flame of a furnace passing under and round it till the whole is of a red heat. It must then be suffered to cool, without letting in the air. The goods so treated, will be much softer than by the common method. The surface, instead of becoming scaled, will have acquired a metallic whiteness, from the presence of a small quantity of carbonaceous matter contained in the ashes in which they were imbedded. They will become so flexible also, as to allow them to bend considerably without breaking, which is very far from being the case before the operation. The fracture, before annealing, will be smooth and short; but afterwards it will be rough, exhibiting bright parts of a crystalline appearance. Wire, especially that of iron and steel, should be treated in a similar way, when it is annealed. The wire used for some purposes, requires to be soft, and is sold in that state. If the wire after finishing, when it is bright and clean, were to be annealed in contact with oxygen, it would not only lose all its lustre and smoothness, but much of its tenacity. The process above-mentioned will therefore be particularly necessary in annealing finished wire, as well as in softening it from time to time during the drawing.

Copper and brass suffer much less than iron and steel from annealing in the open air, and do not require to be heated above a low red heat. If, however, the lustre is to be preserved, a close vessel would be desirable. The latter metals, after annealing, although much discoloured by the oxygen of the atmosphere, may be cleansed, by immersion in a hot liquor composed of water and a small quantity of sulphuric or nitric acid. Very small brass or copper wire is frequently annealed, by exposing it to the flame of hay or straw. In casting minute pieces of pig-iron, which is generally done in wet sand, the metal possesses the property of steel to such a degree, as to assume, by the rapid cooling, a degree of hardness equal to hardened steel; at the same time, that the articles are so brittle as to break by falling on the ground. When, however, these goods are treated in the way above directed, they acquire a degree of softness which renders them penetrable by the file, and at the same time capable of bending. In this state, they are much less tenacious than steel, but still so much so, as to have been sold in the form of cutlery for steel.

The change which metals undergo by annealing, is not yet thoroughly understood. Most of the malleable metals are susceptible of two distinct forms, one called the crystalline form, which they assume by slow cooling; and the other, the fibrous, which is acquired by hammering or rolling. When this, however, is carried beyond a certain point, the metal becomes so hard, that it is not capable of being bent far without breaking. All the malleable metals in the ingot or in their cast state are brittle, and exhibit a crystalline fracture. By hammering or rolling, they become more tenacious, and break with difficulty, exhibiting what is called a fibrous fracture. At the same time, they become stiffer and more elastic. They lose the latter properties by annealing, but become more malleable. If the annealing, however, be long continued, the malleability diminishes, and they again have a crystalline fracture. Zinc by wire-drawing becomes very flexible, and possesses a degree of tenacity not inferior to that of copper. But, if it be kept in boiling water for a length of time, it will resume its original brittleness, and show a crystalline appearance when broken. This proves that the particles of metals can change their arrangement, without losing their solid form;—which is still more strongly confirmed by the fact, that brass wire loses its tenacity by exposure to the fumes of acids, and even by the presence of a damp atmosphere. This is not caused by the moisture, but by the action

of air upon the moistened surface. The manufacturers of common pins are obliged to keep their wire in a dry atmosphere, or immerged in water. If the wire be first moistened, and then exposed to the air, it will assume the brittle state much sooner. In this condition it breaks with a crystalline fracture, similar to that exhibited by an ingot. When a steel plate, such as a watch-spring, has been once tempered, the operation of simply rubbing it bright, will render it soft and elastic. The same change is brought about by slightly hammering it. It, however, resumes its elastic state, by being carefully heated till it becomes of a blue colour. If the heat be continued to redness, particularly in a close vessel, it becomes perfectly annealed. (T.)

# ANNUITIES.

Annuities have been treated of in the body of the work, but in such a manner as to render it necessary, that so useful a branch of knowledge should form the subject of an entirely new article in this place.

History. The doctrine of Compound Interest and Annuities-certain, is too simple ever to have occupied much of the attention of Mathematicians: inquiries into the values of interests dependent upon the continuance or the failure of human life, being more interesting and difficult, have occupied them more, but yet not so much as their importance would seem to demand; the discoveries, both in pure Mathematics and Physics, especially those of Newton, which distinguished the close of the seventeenth century, having provided them with ample employment of a more interesting kind, ever since the subjects of this article were submitted to calculation.

Fermat, Pascal, and Huygens, by laying the foundation of the doctrine of Probabilities about the middle of that century, first opened the way to the solution of problems of this kind. The earliest mathematical publication on Probabilities, the little tract of Huygens, *De ratiociniis in ludo aleæ*, appeared in 1658; and in 1671, his celebrated countryman, John De Witt, published a treatise on Life-annuities, in Dutch. (*Montucla, Hist. des Math.* Tom. III. p. 407.) This, however, appears to have been very little known, or read, and to have had no sensible influence on the subsequent progress of the science; the origin of which may be properly dated from the publication of Dr Halley's paper on the subject, in the *Philosophical Transactions* for the year 1693 (No. 196.) That celebrated Mathematician there first gave a table of mortality, which he had constructed from observations made at Breslaw, and showed how the probabilities of life and death, and the values of annuities and assurances on lives, might be determined by such tables; which, he informs us, had, till then, been only done by an imaginary valuation. Besides his algebraical reasonings, he illustrated the subject by the properties of parallelograms, and parallelopipedons: there are, perhaps, no other mathematical inquiries, in the prosecution of which, algebra is entitled to so decided a preference to the elementary geometry as in these, and this example of the application of geometry has not been followed by any of the succeeding writers.

In the year 1724, Mr De Moivre published the first edition of his tract, entitled, *Annuities on Lives*. In order to shorten the calculation of the values of such annuities, he assumed the annual decrements of life to be equal; that is, that out of a given number of persons living at any age, an equal number dies every year until they are all extinct; and, upon that hypothesis, he gave a general theorem, by which the values of annuities on single lives might be easily determined: this approximation, when the utmost limit of life was supposed to be 86 years, agreed very well with the true values between 30 and 70 years of age, as deduced from Dr Halley's table, and the method was of great use at the time; as no tables of the true values of annuities had then been calculated, except a very contracted one inserted by Dr Halley in the paper mentioned above. But, upon the whole, this hypothesis of De Moivre has probably contributed to retard the progress of the science, by turning the attention of Mathematicians from the investigation of the true law of mortality, and the best methods of constructing tables of the real values of annuities.

The same distinguished Analyst also endeavoured to approximate the values of joint lives; but it has since been found, that the formulæ he gave for that purpose are too incorrect for use. Mr Thomas Simpson published his *Doctrine of Annuities and Reversions* in the year 1742, in which the subject is treated in a manner much more general and perspicuous than it had been previously; his formulæ are adapted to any table of mortality, and, in the 7th corollary to his first problem, he gave the theorem demonstrated in the 149th number of this article, to which we owe all the best tables of the values of life-annuities that have since been published.

In the same work, he also gave a table of mortality deduced from the London observations, and four others calculated from it, of the values of annuities on lives, each at three rates of interest; the first for single lives, the three others for two and three equal joint lives, and for the longest of two or of three lives.

These were the first tables of the values of joint lives that had been calculated; for although Dr Halley had shown, half a century before, how such tables might be computed, and had taken considerable pains to facilitate the work; the necessary calculations, by the known methods, previous to the publication of Mr Simpson's Treatise, were so very labo-

History.

rious, that no one had had the courage to undertake them. And, unfortunately, the mortality, according to the London table, was so much above the common average, that the values of annuities in Mr Simpson's tables were much too small for general use.

In the year 1746, M. Deparcieux published his *Essai sur les probabilités de la durée de la vie humaine*, in which he gave several valuable tables of mortality deduced from the mortuary registers of different religious houses, and from the lists of the Nominees in the French Tontines; also a table of the values of annuities on single lives, at three rates of interest, calculated from his table of mortality for the tontine annuitants. These tables were a great acquisition to the science, as, before their publication, there were only two extant that gave tolerably exact representations of the true law of mortality;—Dr Halley's for Breslaw, and one constructed but a short time before by M. Kerseboom, principally from registers of Dutch annuitants. Those of M. Deparcieux for the Monks and Nuns, were the first ever constructed for the two sexes separately; and by them, the greater longevity of females was made evident.

The work commences with an algebraical theory of Annuities-certain; but the principal essay, *On the Probabilities of the Duration of Human Life*, is perfectly intelligible to those who have not studied Mathematics; it is written with great judgment and perspicuity, but contains very little more than the explanation of the construction of his tables, some of which relate to Tontines; and he did not avail himself to the extent he might have done, of the excellent tract of Thomas Simpson.

This work, however, appears to have been more read upon the Continent, and to have contributed more to the diffusion of this kind of information there, than all the other writings on the subject. The article *Rentes viageres* in the *Encyclopédie*, is acknowledged to have been taken entirely from it, as was also the article Vie, *durée de la ;* and these are proofs, among many others that might be produced, how little M. D'Alembert and the principal Mathematicians, his contemporaries, attended to the subject.

In the year 1752, Mr Simpson published, in his *Select Exercises*, a supplement to his Doctrine of Annuities; wherein he gave new tables of the values of annuities on two joint lives, and on the survivor of two lives, much more copious than those he had inserted in the principal work; but these also were calculated from his London table of mortality.

The celebrated Euler, in a paper inserted in the Memoirs of the Royal Academy of Sciences at Berlin for the year 1760, gave a formula by which the value of an annuity on a single life of any age, may be derived from that of an annuity on a life one year older; which formula was included in that given by Mr Simpson eighteen years before, for effecting the same purpose in the case of any number of joint lives; and by this compendious method, M. Euler calculated a table of the values of single lives from M. Kerseboom's table of mortality.

The first edition of Dr Price's *Observations on Reversionary Payments* was published in 1769; and its chief object was, to give information to persons desirous of forming themselves into societies for the purpose of making provision for themselves in old age, or for their widows. When tables of the values of single lives, and of two joint lives are given, the methods of determining the terms on which such provisions can be made with safety to all the parties concerned, are very simple, and were, at that time, well understood in theory, by the Mathematicians who had studied the subject; but, for want of the requisite tables, the algebraical formulæ had, till then, been of little practical utility.

History.

In the prosecution of this laudable design, Dr Price was obliged to have recourse to approximations. He informs us, that by following M. De Moivre too implicitly in his rules for determining the value of two joint lives, he was led into difficulties which convinced him that they were not only useless, but dangerous; he therefore calculated a table of these values upon M. De Moivre's hypothesis of the decrements of life being equal, and its utmost limit 86 years, from a correct formula given by Mr Simpson in his Doctrine of Annuities (Cor. 5. Prob. I.); by this, and a table of the values of single lives, calculated by Mr Dodson on M. De Moivre's hypothesis, he was enabled to give answers tolerably near the truth, to some of the most interesting questions of this kind, and to show that the plans of several of the societies then recently established, were quite inadequate; and instead of the benefits they promised, could only, in the end, produce disappointment and distress, unless they either dissolved or reformed themselves.

The work also contained instructive dissertations on the probabilities and expectations of life, and on the mean duration of marriage and of widowhood; besides accounts of some of the principal societies which had then been formed for the benefit of old age, and of widows; with observations on the method of forming tables of mortality for towns, and two new tables of that kind, constructed from registers kept at Norwich and Northampton. Mr Morgan's *Doctrine of Annuities and Assurances* was published in 1779, containing tables of the values of single lives, of two equal joint lives, and of two lives differing in age by 60 years. calculated from the Northampton table of mortality. And in the same year, M. De Saint-Cyran published his *Calcul des Rentes viageres sur une et sur plusieurs têtes*, wherein the valuation of annuities on lives is treated algebraically, but in a manner much inferior in all respects to that of Mr Simpson; and six tables are given of the values of annuities,—on single lives, on the survivor of two lives, and on the last survivor of three, calculated from M. Kerseboom's table of mortality. Although the values in the cases of two, and of three lives, were only determined by approximation, these tables were, just then, a valuable acquisition to the science; but their use was entirely superseded only four years after, by the publication of others much more valuable.

The fourth edition of Dr Price's *Observations on Reversionary Payments* appeared in 1783. One of the best effects of the preceding editions on the pro-

gress of the science, had been, to direct the public attention to these inquiries, by showing their important uses in the affairs of life; and to procure the requisite *data* for forming tables of mortality, that should illustrate the laws according to which human life wastes under different circumstances, by exciting the curiosity of intelligent men who had the necessary leisure and means of information. The ingenious author had, accordingly, been furnished with the necessary abstracts of mortuary registers which had been kept with these views, by Dr Haygarth at Chester, Dr Aikin at Warrington, and the Rev. Mr Gorsuch at Holy-Cross, near Shrewsbury, since the publication of the first edition; also by Mr Wargentin, with the mean numbers both of the living, and the annual deaths in all Sweden and Finland, for twenty-one successive years, in all of which the sexes were distinguished; and from these *data*, he constructed tables of mortality that threw great light on the subject. He also inserted in this edition, an improved table of mortality for Northampton; and, what had been so long wanted, a complete set of tables of the values of annuities on single lives, at six rates of interest, and on two joint lives at four, all calculated from the new Northampton table. The combinations of joint lives were sufficiently numerous to admit of all the values not included being easily interpolated. Besides these, he also gave tables of the values of annuities on single lives from the Swedish observations, both with and without distinction of the sexes, and on two joint lives without that distinction.

The values given in these tables are too low for the general average of lives, at all ages under 60; but in the treatise of Mr Baron Maseres on *the Principles of the Doctrine of Life-Annuities*, which was published in the same year (1783), others were given, calculated from the table of mortality which M. Deparcieux constructed from the lists of the Nominees in the French Tontines. The tables for single lives are calculated at twelve different rates of interest from 2 to 10 *per cent.*; but those for joint lives, only at $3\frac{1}{2}$ and $4\frac{1}{2}$ *per cent.*; and the combinations they include are only those of ages that are equal, or that differ by 5 or 10 years, and the multiples of 10.

There is reason to believe that the values in these tables, at all ages under 75 or 80 years, are nearer the truth, for the average of this country, than any others then extant; but certainly for the average of lives on which annuities and reversions depend. After that period of life, however, they are too small; and, in most cases, it is difficult to derive the values of joint lives from them with sufficient accuracy, on account of the contracted scale they have been calculated upon.

It was not Dr Price's object to deliver the elements of the science systematically; but he treated most parts of it with great judgment, enriched it with a vast collection of valuable facts and observations, and corrected several errors into which some of the most eminent writers upon it had fallen. The mathematical demonstrations (which are given in the notes) are much inferior to the rest of the work.

The values of reversionary sums and annuities, which depend upon some of the lives involved failing according to assigned orders of precedency, had been approximated by Mr Simpson in his *Select Exercises*, and by Mr Morgan in his *Doctrine of Annuities;* but the latter gentleman first gave accurate solutions of problems of this kind, in the *Philosophical Transactions* for the years 1788, 1789, 1791, 1794, and 1800.

Except by the solution of these problems, the science had not been materially advanced, during a period of more than thirty years that had elapsed since the appearance of the fourth edition of Dr Price's work, when Mr Milne published his *Treatise on the Valuation of Annuities and Assurances, on Lives and Survivorships*, in the beginning of last year (1815).

The work consists of two volumes; the first is mathematical, the second entirely popular, except the notes, and a few of the tables. The algebraical part of this article is merely a short abstract of the first volume, and may serve as a specimen of the manner in which the subject has been treated there; but the construction of tables of mortality, which forms the subject of the third chapter, has not been noticed here; neither is the valuation of reversionary sums or annuities depending upon assigned orders of survivorship, treated in the present article; and these are parts of the work, which will not be found the least interesting to mathematicians.

The second volume contains upwards of fifty new tables, with a few others that had been published before, but have been reprinted either on account of their value, or scarcity, or both. Four of the new ones are tables of mortality constructed by the author, from registers kept at Carlisle and Montpellier, and in all Sweden and Finland, since the period of the observations Dr Price made use of; the sexes are distinguished in the tables for Sweden and Montpellier, but not in that for Carlisle. This last is the only table, besides those for Sweden and Finland, that has been formed from the necessary *data*,—enumerations of the living, as well as registers of the deaths in every interval of age.

Twenty-one of these tables, being the seventeenth to the thirty-seventh inclusive, in the collection at the end of the work, render it easy to apply the algebraical formulæ to practical purposes, and numerous examples of such applications are given. They have all been calculated from the Carlisle table of mortality; those of the values of life-annuities on the same extensive scale, with those which Dr Price derived from the Northampton table. It is the author's opinion that the values of interests dependent upon the continuance or the failure of life, may be derived from them more correctly than from any others extant, and he has taken considerable pains to assist his readers in judging of this for themselves.

Besides the tables, the principal contents of the second volume, are explanations of their construction and uses; many of them relate to the progress of population,—the comparative mortality of different diseases—of different seasons,—and of the two sexes at every age—the proportion of the sexes at birth—and that of the born alive to the still-born of each sex.

History.

It will be found that the author has been furnished with facts and observations of great value, and that he has endeavoured to present the information they afford, in the forms best calculated for the further prosecution of these inquiries.

Plan of this Article.

In treating of annuities, we think that it may be useful in a work of this kind, to address ourselves as well to those readers who have not, as to those who have, an acquaintance with *Algebra*; and we shall, accordingly, divide what follows into two Parts, corresponding to these two views of the subject.

## PART I.

We shall, in this Part, demonstrate all that is most useful and important in the doctrine of Annuities and Assurances on lives, without using Algebra, or introducing the idea of probability; but the reader is, of course, supposed to understand common Arithmetic. In the first 30 numbers of this Part, *Compound Interest* and *Annuities-certain* are treated of; from the 31st to the 76th, the doctrine of *Annuities on Lives* is delivered; and that of *Assurances* on Lives, from thence to the 108th, where the popular view terminates.

What is demonstrated in this Part, will be sufficient to give the reader clear and scientific views of the subjects treated; and, with the assistance of the necessary tables, will enable him to solve the more common and simple problems respecting the values of Annuities and Assurances. He will also understand clearly the general principles on which problems of greater difficulty are resolved; but these he cannot undertake with propriety, when the object is, to make a fair valuation of any claims or interests, with a view to an equitable distribution of property, unless he has studied the subject carefully, with the assistance of Algebra; for intricate problems of this kind can hardly be solved without it; and those who are not much exercised in such inquiries, often think they have arrived at a complete solution, when they have overlooked some circumstance or event, or some possible combination of events or circumstances, which materially affect the value sought. Eminent Mathematicians have, in this way, fallen into considerable errors, and it can hardly be doubted, that those who are not mathematicians, must (*cæteris paribus*) be more liable to them.

### I. ON ANNUITIES-CERTAIN.

No. 1. When the rate is 5 *per cent.*, L.1 improved at simple interest during one year, will amount to L. 1·05; which, improved in the same manner during the second year, will be augmented in the same ratio of 1 to 1·05; the amount then, will therefore be $1{\cdot}05 \times 1{\cdot}05$, or $(1{\cdot}05)^2 = 1{\cdot}1025$.

In the same manner it appears, that this last amount, improved at interest during the third year, will be increased to $(1{\cdot}05)^3 = 1{\cdot}157625$; at the end of the fourth year, it will be $(1{\cdot}05)^4$; at the end of the fifth $(1{\cdot}05)^5$, and so on; the amount at the end of any number of years being always determined, by raising the number which expresses the amount at the end of the first year, to the power of which the exponent is the number of years. So that when the rate of interest is 5 *per cent.*, L.1 improved at compound interest, will, in seven years, amount to $(1{\cdot}05)^7$, and in 21 years, to $(1{\cdot}05)^{21}$.

But if the rate of interest were only 3 *per cent.*, these amounts would only be $(1{\cdot}03)^7$, and $(1{\cdot}03)^{21}$ respectively.

2. The present value of L.1 to be received certainly at the end of any assigned term, is such a less sum, as, being improved at compound interest during the term, will just amount to one pound. It must therefore be less than L.1, in the same ratio as L.1 is less than its amount in that time; but in three years, at 5 *per cent.*, L.1 will amount to L. $(1{\cdot}05)^3$ (1). And $(1{\cdot}05)^3 : 1 :: 1 : \frac{1}{(1.05)^3}$, so that $\frac{1}{(1{\cdot}05)^3} = \frac{1}{1{\cdot}157625} = 0{\cdot}863838$ is the present value of L.1 to be received at the expiration of three years.

In the same manner it appears that, at 4 *per cent.* interest, the present value of L.1 to be received at the end of a year, is $\frac{1}{1{\cdot}04} = 0{\cdot}961538$; and if it were not to be received until the expiration of 21 years, its present value would be $\frac{1}{(1{\cdot}04)^{21}} = (0{\cdot}961538)^{21} = 0{\cdot}438834$.

Hence it appears, that if unity be divided by the amount of L.1, improved at compound interest during any number of years, the quotient will be the present value of L.1 to be received at the expiration of the term: which may also be obtained by raising the number which expresses the present value of L.1 receivable at the expiration of a year, to the power of which the exponent is the number of years in the term.

3. When a certain sum of money is receivable annually, it is called an Annuity, and its *quantum* is expressed by saying it is an annuity of so much; thus, according as the annual payment is L.1, L.10, or L.100; it is called an annuity of L.1, of L.10, or of L.100.

4. When the annual payment does not depend upon any contingent event, but is to be made certainly, either in perpetuity or during an assigned term, it is called an *Annuity-certain*.

5. In calculating the value of an annuity, the first payment is always considered to be made at the end of the first year from the time of the valuation, unless the contrary be expressly stated.

6. The whole number, and part or parts of one annual payment of an annuity, which all the future payments are worth in present money, is called *the number of years purchase* the annuity is worth; and,

being the sum of the present values of all the future payments, is also the sum which, being put out and improved at compound interest, will just suffice for the payment of the annuity (2).

7. Hence it follows, that when the annuity is L. 1, the number of years purchase and parts of a year, is the same as the number of pounds and parts of a pound in its present value.

And throughout this article, whenever the *quantum* of an annuity is not mentioned, it is to be understood to be L. 1.

8. The sum of which the simple interest for one year is L. 1, is evidently that which, being put out at interest, will just suffice for the payment of L. 1 at the end of every year, without any augmentation or diminution of the principal; and, being equivalent to the title to L. 1 *per annum* for ever, is called the *value of the perpetuity*, or the number of years purchase the perpetuity is worth.

But, while the rate remains the same, the annual interests produced by any two sums, are to each other as the principals which produce them; therefore, since $5 : 1 :: 100 : \frac{100}{5} = 20$, when the rate of interest is 5 *per cent.*, the value of the perpetuity is 20 years purchase. In the same manner it appears, that according as the rate may be 3 or 6 *per cent.* the value of the perpetuity will be $\frac{100}{3} = 33\frac{1}{3}$, or $\frac{100}{6} = 16\frac{2}{3}$ years purchase; and may be found in every case, by dividing any sum by its interest for a year.

9. All the most common and useful questions in the doctrines of compound interest and annuities-certain, may be easily resolved by means of the first four tables at the end of this article. Their construction may be explained by the following specimen, rate of interest 5 *per cent.*

| Construction of | | | | | |
|---|---|---|---|---|---|
| | Table IV. | Table III. | Table I. | Table II. | |
| | Amount of L. 1 *per annum*. | Amount of L. 1. | Present value of L. 1 to be received at | Present value of L. 1 *per annum*, to be received until | |
| Term. | improved at Interest until | | | | Term. |
| | the Expiration of the Term. | | | | |
| 1 Yr. | 1·000000 | 1·050000 | ·952381 | 0·952381 | 1 Yr. |
| 2 Yrs. | 2·050000 | 1·102500 | ·907029 | 1·859410 | 2 Yrs. |
| 3 | 3·152500 | 1·157625 | ·863838 | 2·723248 | 3 |
| 4 | 4·310125 | 1·215506 | ·822702 | 3·545950 | 4 |
| 5 | 5·525631 | 1·276282 | ·783526 | 4·329476 | 5 |
| 6 | 6·801913 | 1·340096 | ·746215 | 5·075691 | 6 |
| 7 | 8·142009 | 1·407100 | ·710681 | 5·786372 | 7 |

10. The calculation must begin with Table III., the first number in which should evidently be 1·05, the amount of L. 1 improved at interest during one year; which, being multiplied by 1·05, the product is 1·025, the second number; this second number being multiplied by 1·05, the product is 1·157625, the amount at the end of three years. And so the calculation proceeds throughout the whole of the column; each number after the first, being the product of the multiplication of the preceding number, by the amount of L. 1 in a year (1).

11. The number against any year in Table I. is found by dividing unity by the number against the same year in Table III. (2); thus, the number against the term of six years in Table I. is $\frac{1}{1·340096} = ·746215$. All the numbers in that table after the first, may also be found, by multiplying that first number continually into itself (2).

12. The number against any year in Table II. being the sum of the numbers against that and all the preceding years in Table I.; is found by adding the number against that year in Table I. to the number against the preceding year in Table II.; thus, the number against 4 years in Table II., being

the sum of 0·822702
and 2·723248

is 3·545950.

13. If each payment of an annuity of L. 1 be put out as it becomes due, and improved at compound interest during the remainder of the term, it is evident that at the expiration of the term, the payment then due will be but L. 1, having received no improvement at interest. That received one year before will be augmented to the amount of L. 1 in a-year; that received two years before will be augmented to the amount of L. 1 in two years; that received three years before to the amount of L. 1 in three years, and so on until the first payment, which will be augmented to the amount of L. 1 in a term one year less than that of the annuity.

Hence, it is manifest, that the number against any year in Table IV. will be unity added to the sum of all those against the preceding years in Table III.

And, therefore, that the number against any year in Table IV. is the sum of those in Tables III. and IV. against the next preceding year.

Thus, the number against seven years in Table IV., being

the sum of 1·340096
and 6·801913

is 8·142009.

14. The method of construction is obviously the same at any other rate of interest.

15. All the amounts and values which are the objects of this inquiry, evidently depend upon the improvement of money at compound interest; it is, therefore, that the first, second, and fourth tables, all depend upon the third.

But every pound, and every part of a pound, when put out at interest, is improved in the same manner as any single pound considered separately. Whence, it is obvious, that while the term and the rate of interest remain the same, both the amount and the present value, either of any sum, or of any annuity, will be the same multiple, and part or parts of the amount or the present value found against the same term, and under the same rate of interest in these tables, as the sum or the annuity proposed is of L. 1.

So that to find the amount or the present value of

any sum or annuity for a given term and rate of interest, we have only to multiply the corresponding tabular value by the sum or the annuity proposed; the product will be the amount or the value sought, according as the case may be.

16. *Example* 1. To what sum will L. 100 amount, when improved at compound interest during 20 years? the rate of interest being 4 *per cent. per annum.*

By Table III., it appears, that L. 1 so improved, would, at the expiration of the term, amount to L. 2·191123, therefore L. 100 would amount to 100 times as much, that is, to L. 219·1123, or L. 219, 2s. 3d.

17. *Ex.* 2. What is the present value of L. 400, which is not to be received until the expiration of 14 years, when the rate of interest is 5 *per cent.?*

The present value of L. 1 to be received then, will be found by Table I. to be L. 0·505068 : L. 400 to be received at the same time, will therefore be worth, in present money, 400 times as much, or L. 202·0272, that is, L. 202, 0s. $6\frac{1}{2}$d.

18. *Ex.* 3. Required the present value of an annuity of L. 50 for 21 years, when the rate of interest is 5 *per cent.*

Table II. shows the value of an annuity of L. 1 for the same term to be L. 12·8212 ; the required value must therefore be 50 times as much, or L. 641·06, that is, L. 641, 1s. $2\frac{1}{2}$d.

19. *Ex.* 4. What will an annuity of L. 10, 10s. or L. 10·5, for thirty years, amount to, when each payment is put out as it becomes due, and improved at compound interest until the end of the term? The rate of interest being 4 *per cent.*

The amount of an annuity of L. 1 so improved, would be L. 56·084938, as appears by Table IV., the amount required will therefore be 10·5 times this, or L. 588·89185, that is, L. 588, 17s. 10d.

20. When the interval between the time of the purchase of an annuity and the first payment thereof, exceeds that which is interposed between each two immediately successive payments; such annuity is said to be *deferred* for a time equal to that excess, and to be *entered upon* at the expiration of that time.

21. If two persons, *A* and *B*, purchase an annuity between them, which *A* is to enter upon immediately, and to enjoy during a certain part of the term, and B, or his heirs, or assigns, for the remainder of it ; the present value of *B's* interest will evidently be, the excess of the value of the annuity for the whole of the term from this time, above the value of the interest of *A*.

So that when the entrance on an annuity is deferred for a certain term, its present value will be the excess of the value of the annuity for the term of delay and continuance together, above the value of an equal annuity for the term of delay only.

22. *Example* 1. Required the value of a perpetual annuity of L. 120, which is not to be entered upon until the expiration of 14 years from this time, reckoning interest at 3 *per cent.*

The perpetuity, with immediate possession, would be worth $33\frac{1}{3}$ years' purchase (8) ; and an annuity for the term of delay is worth 11·2961 (Table II.)

| | |
|---|---|
| From | 33·3333 |
| subtract | 11·2961, and multiply |
| the remainder | 22·0372 |
| by - | 120 |
| the product | 2644·464 = L. 2644, 9s. $3\frac{1}{4}$d. |

is the required value.

23. *Ex.* 2. Allowing interest at 5 *per cent.* what sum should be paid down now for the renewal of 14 years lapsed, in a lease for 21 years of an estate producing L. 300 *per annum*, clear of all deductions?

This is the price of an annuity for 14 years, to be entered upon 7 years hence ; the term of delay, therefore, is 7 years, and that of the delay and continuance together 21 years.

By Table II. it appears, that the present value of an annuity

| | | |
|---|---|---|
| for 21 years, is - - | 12·8212 | years' purchase. |
| for 7 years, - - | 5·7864 | |
| Value of the deferred annuity, | 7·0348 | |
| Multiply by - - | 300 | |
| The product - | L. 2110·44, or L. 2110, | |

8s. $9\frac{1}{2}$d. is the price required.

24. Hitherto we have proceeded upon the supposition of the annuity being payable, and the interest convertible into principal, which shall reproduce interest, only once a-year.

But annuities are generally payable half-yearly, and sometimes quarterly ; and the same circumstances that render it desirable for an annuitant to receive his annual sum in equal half-yearly or quarterly portions, also give occasion to the interest of money being paid in the same manner.

But whatever has been advanced above, concerning the present value or the amount of an annuity, when both that and the interest of money were only payable once a-year, will evidently be true when applied to half the annuity, and half the interest paid twice as often, on the supposition of half-yearly payments ; or to a quarter of the annuity, and a quarter of the interest, paid four times as often, when the payments are made quarterly.

25. Half-yearly payments are, however, by far the most common, and these four tables will also enable us to answer the most useful questions concerning them.

For we have only to extract the present value, or the amount, from the table, against twice the number of years in the term, at half the annual rate of interest, and, in the case of an annuity, to multiply the number so extracted, by half the annuity proposed.

26. *Ex.* 1. To what sum will L. 100 amount in 20 years, when the interest at the rate of 4 *per cent. per annum*, is convertible into principal half-yearly?

This being the amount in 40 half years at 2 *per cent.* interest for every half year, will be the same as the amount in 40 years at 2 *per cent. per annum*, which, by Table III. will be found to be 220·804, or L. 220, 16s. 1d. ; and is only L. 1, 13s. 10d. more than it would amount to if the interest were not convertible more than once a-year (16).

27. *Ex.* 2. What is the present value of an annuity of L. 50 for 21 years, receivable in equal half-yearly payments, when money yields an interest of $2\frac{1}{2}$ *per cent.* every half year?

By Table II. it appears, that an annuity of L. 1 for 42 years, when the interest of money is $2\frac{1}{2}$ *per cent. per annum*, will be worth L. 25·8206 (25); 25 times this sum, or L. 645, 10s. $3\frac{1}{2}$d. is therefore, the required value, and exceeds the value when the interest and the annuity are only payable once a-year by L. 4, 9s. 1d. (18).

28. The excess of an annuity-certain above the interest of the purchase-money, is the sum which, being put out at the time of each payment becoming due, and improved at compound interest until the expiration of the term, will just amount to the purchase-money originally paid.

But, while everything else remains the same, the longer the term of the annuity is, the less must its excess above the interest of the purchase-money be, because a less annuity will suffice for raising the same sum within the term. Therefore, the proportion of that excess to the annual interest of the purchase-money, continually diminishes as the term is extended; and when the annuity is a perpetuity, there is no such excess (8).

29. The reason why the value of an annuity is increased by that and the interest being both payable more than once in the year, is, that the grantor loses, and the purchaser gains, the interest produced by that part of each payment, which is in excess above the interest then due upon the purchase-money, from the time of such payment being made, until the expiration of the year.

Hence it is obvious, that the less this excess is, that is, the longer the term of the annuity is (28), the less must the increase of value be.

And when the annuity is a perpetuity, its value will be the same, whether it and the interest of money be both payable several times in the year, or once only.

30. When the annuity is not payable at the same intervals at which the interest is convertible into principal, its value will depend upon the frequencies both of payment and conversion; but its investigation without algebra, would be too long, and of too little use, to be worth prosecuting here.

## II. OF ANNUITIES ON LIVES.

31. When the payment of an annuity depends upon the existence of some life or lives, it is called a *Life-annuity*.

32. The values of such annuities are calculated by means of tables of mortality, which show, out of a considerable number of individuals born, how many upon an average have lived to complete each year of their age; and, consequently, what proportion of those who attained to any one age, have survived any greater age.

The fifth Table at the end of this article is one of that kind, which has been taken from Mr Milne's *Treatise on Annuities*, and was constructed from accurate observations made at Carlisle by Dr Heysham, during a period of 9 years, ending with 1787.

33. By this table it appears, that during the period in which these observations were made; out of 10,000 children born, 3203 died under 5 years of age, and the remaining 6797 completed their fifth year. Also, that out of 6797 children who attained to 5 years of age, 6460 survived their 10th year.

But the mortality under 10 years of age, has been greatly reduced since then, by the practice of vaccination.

This table also shows, that of 6460 individuals who attained to 10 years of age, 6047 survived 21. And that of 5075 who attained to 40, only 3643 survived their 60th year.

34. There is good reason to believe (as has been shown in another place), that the general law of mortality, that is, the average proportion of persons attaining to any one age, who survive any greater age, remains much the same now among the entire mass of the people throughout England, as it was found to be at Carlisle during the period of these observations; except among children under 10 years of age, as was noticed above (33).

If this be so, it will follow, that of 6460 children now 10 years of age, just 6047 will attain to 21; or rather, that if any great number be taken in several instances, this $\left(\frac{6047}{6460}\right)$ will be the average proportion of them that will survive the period.

And if 6460 children were to be taken indiscriminately from the general mass of the population at 10 years of age, and an office or company were to engage to pay L. 1, eleven years hence, for each of them that might then be living; this engagement would be equivalent to that which should bind them to pay L. 6047 certainly, at the expiration of the term. Therefore, the office, in order that it might neither gain nor lose by the engagement, should, upon entering into it, be paid for the whole, the present value of L. 6047, to be received at the expiration of 11 years; and for each life, the $\frac{1}{6460}$th part of it; that is, the $\frac{6047}{6460}$th part of the present value of L. 1 to be received then.

But when the rate of interest is 5 *per cent.* the present value of L. 1, to be received at the expiration of 11 years, is L. 0·584679; therefore, at that rate of interest, there should be paid for each life $\frac{6047 \times 0{\cdot}584679}{6460} =$ L. 0·5473.

And the present value of L. 100, to be received upon a life now 10 years of age attaining to 21, will be L. 54·73, or L. 54, 14s. 7d.

In the same manner it will be found, that reckoning interest at 4 *per cent.* the value would be L. 60, 16s. 1d.

35. This is the method of calculating the present values of endowments for children of given ages; and the values of annuities on lives may be computed in the same manner.

For, from the above reasoning it is manifest, that if the present value of L. 1, to be received certainly at the expiration of a given term, be multiplied by the number in the table of mortality against the

Popular View.

age, greater than that of any proposed life by the number of years in the term, and the product be divided by the number in the same table, against the present age of that life; the quotient will be the present value of L. 1, to be received at the expiration of the term, provided that the life survive it.

And if, in this manner, the value be determined of L. 1, to be received upon any proposed life, surviving each of the years in its greatest possible continuance, according to the table of mortality adapted to it; that is, according to the Carlisle table, upon its surviving every age greater than its present, to that of 104 years inclusive; then, the sum of all these values will evidently be the present value of an annuity on the proposed life.

36. If 5642 lives at 30 years of age be proposed, and 5075 at the age of 40; since each of the 5642 younger lives may be combined with every one of the 5075 that are 10 years older, the number of different pairs, or different combinations of two lives differing in age by 10 years, that may be formed out of the proposed lives, is 5642 times 5075.

But at the expiration of 15 years, the survivors of the lives now 30 and 40 years of age, being then of the respective ages of 45 and 55, will be reduced to the numbers of 4727 and 4073 respectively; and the number of pairs, or combinations of two, differing in age by 10 years, that can be formed out of them, will be reduced from $5642 \times 5075$ to $4727 \times 4073$.

So that L. 1 to be paid at the expiration of 15 years for each of these $5642 \times 5075$ pairs or combinations of two, now existing, which may survive the term, will be of the same value in present money, as 4727 times L. 4073, to be received certainly at the same time.

Now let A be any one of these lives of 30 years of age, and B any one of those aged 40; and from what has been advanced it will be evident, that the present value of L. 1 to be received upon the two lives in this particular combination jointly surviving the term, will be the same as that of the sum L. $\frac{4727 \times 4073}{5642 \times 5075}$ to be then received certainly.

But, when the rate of interest is 5 *per cent.* L. 1 to be received certainly at the expiration of 15 years, is equivalent to L. 0·481017 in present money (Table I).

Therefore, at that rate of interest, and according to the Carlisle table of mortality; the present value of L. 1 to be received upon A and B now aged 30 and 40 years respectively, jointly surviving the term of 15 years, will be $\frac{4727 \times 4073 \times \text{L. } 0{\cdot}481017.}{5642 \times 5075.}$

37. Hence it is sufficiently evident, how the present value of L. 1 to be received upon the same two lives jointly surviving any other year may be found. And if that value for each year from this time until the eldest life attain to the limit of the table of mortality be calculated, the sum of all these will be the present value of an annuity of L. 1 dependent upon their joint continuance.

In this manner, it is obvious that the value of an annuity on the joint continuance of any other two lives might be determined.

38. If, besides the 5642 lives at 30 years of age, and the 5075 at 40 (mentioned in No. 36), there be also proposed 3643 at 60 years of age; each of these 3643 at 60, may be combined with every one of the $5642 \times 5075$ different combinations of a life of 30, with one of 40 years of age; and, therefore, out of these three classes of lives $5642 \times 5075 \times 3643$ different combinations may be formed; each containing a life of 30 years of age, another of 40, and a third of 60.

Popular View.

But at the expiration of 15 years, the numbers of lives in these three classes will, according to the table of mortality, be reduced to 4727, 4073, and 1675 respectively; the respective ages of the survivors in the several classes being then 45, 55, and 75 years; and the number of different combinations of three lives (each of a different class from either of the other two), that can be formed out of them, will be reduced to $4727 \times 4073 \times 1675$.

Hence, by reasoning as in No. 36, it will be found, that if A, B, and C be three such lives, now aged 30, 40, and 60 years, the present value of L. 1 to be received upon these three jointly surviving the term of 15 years from this time, will be $\frac{4727 \times 4073 \times 1675}{5642 \times 5075 \times 3643} \times \text{L. } 0{\cdot}481017$: interest being reckoned at 5 *per cent.*

Thus it is shown, how the present value of an annuity dependent upon the joint continuance of these three lives might be calculated, that being the sum of the present values thus determined, of the rents for all the years which, according to the table of mortality, the eldest life can survive.

39. But it is easy to see, that the same method of reasoning may be used in the case of four, five, or six lives, and so on without limit. Whence, this inference is obvious.

The present value of L. 1, to be received at the expiration of a given term, provided that any given number of lives all survive it, may be found by multiplying the present value of L. 1 to be received certainly at the end of the term, by the continual product of the numbers in the table of mortality against the ages greater respectively by the number of years in the term, than the ages of the lives proposed; and dividing the last result of these operations, by the continual product of the numbers in the table of mortality against the present ages of the proposed lives.

And by a series of similar operations, the present value of an annuity on the joint continuance of all these lives might be determined.

But it should be observed, that, in calculating the value of a life-annuity in this way, the denominator of the fractions expressing the values of the several years rents, that is, the divisor used in each of the operations, remains always the same; the division should, therefore, be left till the sum of the numerators is determined, and one operation of that kind will suffice.

40. Enough has been said to show that these methods of constructing tables of the values of annuities on lives are practicable, though excessively laborious, and, in fact, all the early tables of this kind were constructed in that manner. We proceed now

Popular View.

to show how such tables may be calculated with much greater facility.

41. By the method of No. 34, it will be found that, reckoning interest at 5 *per cent.*, the present value of L. 1 to be received at the expiration of a year, provided that a life, now 89 years of age, survived till then, is $\frac{142 \times 0{\cdot}95238}{181}$. But the age of that life will then be 90 years, and the proprietor of an annuity of L. 1 now depending upon it, will, in that event, receive his annual payment of L. 1 then due; therefore, if the value then of all the subsequent payments, that is, the value of an annuity on a life of 90 be 2·339 years' purchase, the present value of what the title to this annuity may produce to the proprietor, at the end of the year, will be the same as that of L. 3·339, to be received then, if the life be still subsisting, or $\frac{142 \times 0{\cdot}952381}{181} \times$ L. $3{\cdot}339 =$ L. 2·495; which, therefore, will be the present value of an annuity of L. 1 on a life of 89 years of age. That is to say, an annuity on that life will now be worth 2·495 years' purchase (7).

42. In the same manner it appears generally, that, if unity be added to the number of years' purchase that an annuity on any life is worth, and the sum be multiplied by the present value of L. 1, to be received at the end of a year, provided that a life one year younger survive till then, the product will be the number of years' purchase an annuity on that younger life is worth in present money.

43. But according to the table of mortality, an annuity on the eldest life in it is worth nothing; therefore, the present value of L. 1 to be received at the end of a year, provided that the eldest life but one in the table survive till then, is the total present value of an annuity of L. 1 on that life. Which, being obtained, the value of an annuity on a life one year younger than it may be found by the preceding number; and so on for every younger life successively.

Exemplification.

Rate of Interest 5 *per cent.*

| Age of Life. | Value of an Annuity on that Life, increased by Unity. | Which, being multiplied by 0·952381, and the Product by | Produces the value of an Annuity on the next younger Life | Its Age being |
|---|---|---|---|---|
| 104 | 1·000 | $\frac{1}{5}$ | 0·317 | 103 |
| 103 | 1·317 | $\frac{3}{5}$ | 0·753 | 102 |
| 102 | 1·753 | $\frac{5}{7}$ | 1·192 | 101 |
| 101 | 2·192 | $\frac{7}{9}$ | 1·624 | 100 |
| 100 | 2·624 | $\frac{9}{11}$ | 2·045 | 99 |
| 99 | 3·045 | $\frac{11}{14}$ | 2·278 | 98 |
| 98 | 3·278 | $\frac{14}{18}$ | 2·428 | 97 |
| 97 | 3·428 | $\frac{18}{23}$ | 2·555 | 96 |
| 96 | 3·555 | $\frac{23}{30}$ | 2·596 | 95 |
| 95 | 3·596 | $\frac{30}{40}$ | 2·569 | 94 |

44. Proceeding as in No. 36, it will be found, that at 5 *per cent.* interest, and according to the Carlisle table of mortality, the present value of L. 1 to be received at the expiration of a year, provided that a person now 89 years of age, and another now 99, be then living, is $\frac{142 \times 9 \times \text{L. } 0{\cdot}952381}{181 \times 11}$: therefore, if the present value of an annuity of L. 1 on the joint continuance of two lives, now aged 90 and 100 years respectively, be L. 0·950; by reasoning as in No. 41, it will be found that the present value of an annuity on the joint continuance of two lives, of the respective ages of 89 and 99 years, will be worth $\frac{142 \times 9 \times 0{\cdot}952381}{181 \times 11} \times 1{\cdot}950 = 1{\cdot}192$ years' purchase.

45. In this manner, commencing with the two oldest lives in the table that differ in age by ten years, and proceeding according to No. 43, the values of annuities on all the other combinations of two lives of the same difference of age, may be determined.

The method is exemplified in the following specimen:

| Ages of two Lives. | Value of an Annuity on their joint continuance, increased by Unity. | Which, being multiplied by 0·952381, and the Product by | Produces the value of an Annuity on the two joint Lives one year younger respectively, | their Ages being |
|---|---|---|---|---|
| 94 & 104 | 1·000 | $\frac{1 \times 40}{3 \times 54}$ | 0·235 | 93 & 103 |
| 93 & 103 | 1·235 | $\frac{3 \times 54}{5 \times 75}$ | 0·508 | 92 & 102 |
| 92 & 102 | 1·508 | $\frac{5 \times 75}{7 \times 105}$ | 0·733 | 91 & 101 |
| 91 & 101 | 1·733 | $\frac{7 \times 105}{9 \times 142}$ | 0·950 | 90 & 100 |
| 90 & 100 | 1·950 | $\frac{9 \times 142}{11 \times 181}$ | 1·192 | 89 & 99 |
| 89 & 99 | 2·192 | $\frac{11 \times 181}{14 \times 232}$ | 1·280 | 88 & 98 |

46. Hence, and by what has been advanced in the 39th number of this article, it is sufficiently evident, how a table may be computed of the values of annuities on the joint continuance of the lives in every combination of three, or any greater number; the differences between the ages of the lives in each combination remaining always the same in the same series of operations, while the calculation proceeds back from the combination in which the oldest life is the oldest in the table, to that in which the youngest is a child just born.

47. But, when there are more than two lives in each combination, the calculations are so very laborious, on account, principally, of the great number

of combinations, that no tables of that kind have yet been published, except three or four for three lives.

And, in the books that contain tables of the values of two joint lives, methods are given of approximating towards the values of such combinations of two and of three lives, as have not yet been calculated.

Therefore, assuming the values of annuities on single lives, and on the joint continuance of two or of three lives, to be given; we have next to show how the most useful problems respecting the values of any interests that depend upon the continuance or the failure of life, may be resolved by them.

48. *Proposition* 1. The value of an annuity on the survivor of two lives, *A* and *B*, is equal to the excess of the sum of the valnes of annuities on the two single lives, above the value of an annuity on their joint continuance.

49. *Demonstration.* If annuities on each of the two lives were granted to *P*, during their joint continuance, he would have two annuities; but if *P* were only to receive these upon condition that, during the joint lives of *A* and *B*, he should pay one annuity to *Q*; then, there would only remain one to be enjoyed by him, or his heirs or assigns, until the lives both of *A* and *B* were extinct; whence the truth of the proposition is manifest.

50. *Prop.* 2. The value of an annuity on the joint continuance of the two last survivors out of three lives, *A*, *B*, and *C*, is equal to the excess of the sum of the values of annuities on the three combinations of two lives (*A* with *B*, *A* with *C*, and *B* with *C*) that can be formed out of them, above twice the value of an annuity on the joint continuance of all the three lives.

51. *Demons.* If one annuity were granted to *P* on the joint continuance of the two lives *A* and *B*, another on the joint continuance of *A* and *C*, and a third, on the joint continuance of *B* and *C*; during the joint continuance of all the lives he would have three annuities.

But if he were only to receive these upon condition that he should pay two annuities to *Q*, during the joint continuance of all the three lives; then, there would only remain to himself one annuity during the joint existence of the last two survivors out of the three lives. And the truth of the proposition is manifest.

52. *Prop.* 3. The value of an annuity on the last survivor of three lives, *A*, *B*, and *C*, is equal to the excess of the sum of the values of annuities on each of the three single lives, together with the value of an annuity on the joint continuance of all the three, above the sum of the values of three other annuities; the first dependent upon the joint continuance of *A* and *B*, the second, on that of *A* and *C*, and the third, on *B* and *C*.

53. *Demons.* If annuities on each of the three single lives were granted to *R*; during the joint continuance of all the three, he would have three annuities, and from the time of the extinction of the first life that failed, till the extinction of the second, he would have two.

So that he would have two annuities during the joint existence of the two last survivors out of the three lives; and besides these, a third annuity during the joint continuance of all the three.

Therefore, if out of these, *R* were to pay one annuity to *P* during the joint continuance of the last two survivors out of the three lives, and another to *Q* during the joint continuance of all the three; he would only have left one annuity, which would be receivable during the life of the last survivor of the three.

But in the demonstration of the last proposition (51) it was shown, that the value of what he paid to *P*, would fall short of the sum of the values of annuities dependent respectively on the joint continuance of *A* and *B*, of *A* and *C*, and of *B* and *C*, by two annuities on the joint continuance of all the three lives. Whence it is evident, that the value of the annuities he paid both to *P* and *Q*, would fall short of the sum of these three values of joint lives, only by the value of one annuity on the joint continuance of all the three lives.

Wherefore, if from the sum of the values of all the three single lives, the sum of the values of the three combinations of two that can be formed out of them were taken; there would remain less than the value of an annuity on the last survivor, by that of an annuity on the joint continuance of the three lives.

But if, to the sum of the values of the three single lives *A*, *B*, and *C*, there be added that of an annuity on the joint continuance of the three, and from the sum of these four values, the sum of the values of the three combinations, *A* with *B*, *A* with *C*, and *B* with *C* be subtracted; then, the remainder will be the value of an annuity on the last survivor of the three lives. Which was to be demonstrated.

54. *Prop.* 4. *Problem.* The law of mortality and the values of single lives at all ages being given; to determine the present value of an annuity on any proposed life, deferred for any assigned term.

55. *Solution.* Find the present value of an annuity on a life older than the proposed, by the number of years during which the other annuity is deferred; multiply this by the present value of L. 1 to be received upon the proposed life surviving the term, and the product will be the value sought.

56. *Demons.* Upon the proposed life surviving the term, the annuity dependent upon it will be worth the same sum, that an annuity on a life so much older is now worth; therefore, it is evident, that the deferred annuity is of the same present value as that sum to be received at the expiration of the term, provided the life survive it.

57. *Corollary.* In the same manner it appears, that the present value of an annuity on the joint continuance of any number of lives, deferred for a given term, may be found by multiplying the present value of an annuity on the joint continuance of the same number of lives, older respectively than the proposed, by the number of years in the term; by the present value of L. 1 to be received, upon the proposed lives all surviving it.

58. A *Temporary Annuity* on any single life, or on the joint continuance of any number of lives, that is, an annuity which is to be paid during a certain term, provided that the single life or the other lives jointly subsist so long; together with an annuity on the same life or lives *deferred* for the same term, are evidently equivalent to an annuity on the whole duration of the same life or lives.

So that the value of an annuity on any life or on the joint continuance of any number of lives for an assigned term, is equal to the excess of the value of an annuity on their whole duration, with immediate possession, above the value of an annuity on them deferred for the term.

59. Whatever has been advanced from No. 48. to 53. inclusive, respecting the values of annuities for the whole duration of the lives whereon they depend, will apply equally to those which are either deferred or temporary; and, therefore, to determine the value of any deferred or temporary annuity, dependent upon the last survivor of two or of three lives; or, upon the joint continuance of the last two survivors out of three lives; we have only to substitute temporary or deferred annuities, as the case may require, for annuities on the whole duration of the lives; and the result will, accordingly, be the value of a temporary or deferred annuity on the life of the last survivor, or on the joint lives of the two last survivors.

60. *Prop.* 5. *A* and *B* being any two proposed lives now in existence, the present value of an annuity to be payable only while A survives B, is equal to the excess of the value of an annuity on the life of A, above that of an annuity on the joint existence of both the lives.

61. *Demons.* If an annuity on the life of *A*, and to be entered upon immediately, were now granted to *P*, upon condition that he should pay it to *B* during the joint lives of *A* and *B*; it is evident that there would only remain to *P*, an annuity on the life of *A* after the decease of *B*: whence the truth of the proposition is manifest.

62. When any thing is affirmed or demonstrated of *any life or lives*, it is to be understood as applying equally to any proposed single life, or to the joint continuance of the whole of any number of lives that may be proposed together, or to that of any assigned number of the last survivors of them, or to the last surviving life of the whole.

63. *Prop.* 6. The present value of the reversion of a perpetual annuity after the failure of any life or lives, is equal to the excess of the present value of the perpetuity with immediate possession, above the present value of an annuity on the same life or lives.

64. *Demons.* If a perpetual annuity with immediate possession were granted to *P*, upon condition that he should pay the annual produce to another individual, during the existence of the life or lives proposed; it is evident that there would only remain to *P*, the reversion after the failure of such life or lives; and the present value of that reversion would manifestly be as stated above.

65. The 6th, 7th, and 8th tables at the end of this article, which have been extracted from the 19th, 21st, and 22d, respectively, in Mr Milne's *Treatise on Annuities*, will serve to illustrate the application of these propositions to the solution of questions in numbers.

In all the following examples, we suppose the lives to be such, as the general average of those the Carlisle table of mortality was constructed from, and the rate of interest to be *5 per cent*.

66. *Ex.* 1. What is the present value of an annuity on the joint lives, and the life of the survivor of two persons now aged 40 and 50 years respectively?

According to No. 48, the process is as follows:

| | | | |
|---|---|---|---|
| Value of a single life of | 40 | 13·390 | by Table VI. |
| | 50 | 11·660 | |
| | sum | 25·050 | |
| Subtract the value of their joint lives, | | 9·984 | (Table VIII.) |
| | remains | 15·066 | years' purchase, |

the required value.

And if the annuity be L. 200, its present value will be L. 3013·2, or L. 3013, 4s.

67. *Ex.* 2. The lives *A*, *B*, and *C*, being now aged 50, 55, and 60 years respectively, an annuity on the joint continuance of all the three, is worth 6·289 years purchase; What is the value of an annuity on the joint existence of the last two survivors of them?

According to No. 50, the process is thus:

| Ages. | Values. | |
|---|---|---|
| 50 & 55 | 8·528 | Table VII. |
| 55 & 60 | 7·106 | |
| 50 & 60 | 7·601 | Table VIII. |

sum 23·235

Subtract $2 \times 6{\cdot}289 = 12{\cdot}578$

remains 10·657 years' purchase, the required value.

Therefore, if the annuity were L. 300, it would be worth L. 3197, 2s. in present money.

68. *Ex.* 3. Required the value of an annuity on the last survivor of the three lives in the last example.

Proceeding according to No. 52, we have

| Ages. | Values. | |
|---|---|---|
| 50 | 11·660 | Tab. VI. |
| 55 | 10·347 | |
| 60 | 8·940 | |
| 50, 55, & 60 | 6·289 | (No. 67). |
| sum | 37·236 | |
| Subtract the sum of the values of annuities on the three combinations of two lives, | 23·235 | (No. 67.) |
| remains | 14·001 | years' purchase, |

the required value. And if the annuity were L. 300, it would now be worth L. 4200, 6s.

69. *Ex.* 4. What is the present value of an annuity on a life now 45 years of age, which is not to be entered upon until the expiration of ten years; the first payment thereof being to be made at the expiration of eleven years from this time, if the life survive till then?

*Solution.*

The present value of an annuity on a life of 55 is 10·347 (Table VI.), and the present value of L. 1 to be received upon the proposed life attaining to the

Popular View.

age of 55, is $\frac{4073}{4727} \times 0{\cdot}613913$; therefore, by No. 55, the required value is $\frac{4073 \times 0{\cdot}613913 \times 10{\cdot}347}{4727}$ $= 5{\cdot}473$ years purchase; so that if the annuity were L. 200, its present value would be L. 1094, 12s.

70. *Ex.* 5. Required the present value of an annuity to be received for the next ten years, provided that a person now 45 years of age, shall so long live.

*Solution.*

The present value of an annuity on a life of 45, to be entered upon immediately, is 12·648 (Table VI.)

| | |
|---|---|
| Subtract that of an annuity on the same life deferred 10 years, | 5·473 (69). |
| the remainder, | 7·175 |

is the required number of years purchase. And, if the annuity were L. 200, its present value would be L. 1435.

71. *Ex.* 6. An annuity on a life of 45, deferred 10 years, was shown in No. 69, to be worth 5·473 years purchase in present money; let it be required to determine the equivalent annual payment for the same, to be made at the end of each of the next 10 years, but subject to failure upon the life failing in the term.

*Solution.*

The present value of L. 1 *per annum* on the proposed life for the next 10 years, has just been shown to be L. 7·175, and this, multiplied by the required annual payment, must produce L. 5·473; that payment must, therefore, be $\frac{5{\cdot}473}{7{\cdot}175} = 0{\cdot}76279$. And, since the annual payment for the deferred annuity of L. 1 *per annum* would be L. 0·76279, that for an annuity of L. 200 must be L. 152, 11s. 2d.

72. *Ex.* 7. Let the present value be required of an annuity on a life now 40 years of age, to be payable only while that life survives another now of the age of 50 years.

| | |
|---|---|
| From the present value of a life of 40, | 13·390 (Table VI.) |
| Subtract that of the two joint lives, | 9·984 (Table VIII.) |
| the remainder, | 3·406 |

years purchase is the required value (60).

Therefore, if the annuity were L. 100, it would be worth L. 340, 12s. in present money.

73. If the annuity in the last example were to be paid for by a constant annual premium at the end of each year while both the lives survived; by reasoning as in No. 71, it will be found, that such annual premium for an annuity of L. 1 should be $\frac{3{\cdot}406}{9{\cdot}984} =$ L. 0·341146; for an annuity of L. 100 it should therefore be L. 34, 2s. 3½d.

74. But if one of the equal premiums for this annuity is to be paid down now, and another at the end of each year while both the lives survive; the number of years purchase the whole of these premiums are worth, will evidently be increased by unity, on account of the payment made now, it will, therefore, be 10·984; and each premium for an annuity of L. 1 must, in this case, be $\frac{3{\cdot}406}{10{\cdot}984} =$ L. 0·310087; for an annuity of L. 100 it should, therefore, be L. 31, 0s. 2d.

Popular View.

75. *Ex.* 8. Let it be required to determine the present value of the reversion of a perpetual annuity after the failure of a life now 50 years of age.

*Solution.*

The value of the perpetuity is 20 years purchase (8.)

| | |
|---|---|
| Subtract that of an annuity on the life of 50, | 11·660 (Table VI.) |
| | Remains 8·34 years purchase, the required value of the reversion (63.) |

So that if the annuity were L. 300, its present value would be L. 2502.

76. In the same manner it will be found, by the 68th number and those referred to in the last example, that the reversion of a perpetuity, after the failure of the last survivor of three lives, now aged 50, 55, and 60 years respectively, is worth 5·999 years purchase in present money; therefore, if it were L. 100 *per annum*, its present value would be L. 599, 18s.

## III. OF ASSURANCES ON LIVES.

77. An assurance upon a life, or lives, is a contract by which the Office or Underwriter, in consideration of a stipulated premium, engages to pay a certain sum upon such life or lives failing within the term for which the assurance is effected.

78. If the term of the assurance be the whole duration of the life or lives assured, the sum must necessarily be paid whenever the failure happens; and, in what follows, that payment is always supposed to be made at the end of the year in which the event assured against takes place. The anniversary of the assurance, or the day of the date of the policy, being accounted the beginning of each year.

79. At the end of the year in which any proposed life or lives may fail, the proprietor of the reversion of a perpetual annuity of L. 1 after their failure, will receive the pound then due, and will, at the same time, enter upon the perpetuity; therefore, the present value of the reversion is the same as that of L. 1 added to the money a perpetual annuity of L. 1 would cost, supposing this sum not to be receivable until the expiration of the year in which the failure of the life or lives might happen.

80. Hence we have this proportion. As the value of a perpetuity increased by unity is to L. 1, so is the present value of the reversion of a perpetual annuity of L. 1, after the failure of any life or lives, to the present value of L. 1, receivable at the end of the year in which such failure shall take place.

81. Therefore, *if the value of an annuity of one pound on any life or lives, be subtracted from that of the perpetuity, and the remainder be divided by the value of the perpetuity increased by unity; the quo-*

Popular View.

*tient will be the value, in present money, of the assurance of one pound on the same life or lives.* (63)

82. *Ex.* 1. What is the present value of L. 1, to be received at the end of the year, in which a life now 50 years of age may fail?

The rate of interest being 5 *per cent.* the value of the perpetuity is 20 years purchase, and that of the life 11·66; the answer therefore is $\frac{20-11{\cdot}66}{20+1}=\frac{8{\cdot}34}{21}=$ L. 0·397143. And if the sum assured were L. 1000, the present value of the assurance would be L. 397, 2s. 10d.

83. When the term of a life assurance exceeds one year, its whole value is hardly ever paid down at the time that the contract is entered into, but, in the instrument (called a Policy) whereby the assurance is effected, an equivalent annual premium is stipulated for, payable at the *commencement* of each year during the term, but subject to failure with the life or lives assured.

84. But by reasoning as in No. 74, it will be found, that an annual premium payable at the *commencement* of each year in the whole duration of the life or lives assured, will be worth one year's purchase more, than an annuity on them payable at the *end* of each year; and, consequently, that if the value in present money of an assurance on any life or lives, be divided by the number of years purchase an annuity on the same life or lives is worth, increased by unity, the quotient will be the equivalent annual premium for the same assurance.

85. *Ex.* 2. Required the annual premium for the assurance of L. 1, on a life of 50 years of age.

In No. 82, the single premium for that assurance was shown to be 0·397143, and the value of an annuity on the life is 11·66, therefore, by the preceding number, the required annual premium will be $\frac{0{\cdot}397143}{12{\cdot}66}=$ ·0313699 for the assurance of L. 1; and for the assurance of L. 1000, it will be L. 31, 7s. 5d.

86. *Ex.* 3. Let both the single payment in present money, and the equivalent annual premium be required for the assurance of L. 1, on the joint continuance of two lives of the respective ages of 45 and 50 years.

The value of an annuity of L. 1 on the joint continuance of these two lives, appears by Table VII. to be L. 9·737, therefore $\frac{20-9{\cdot}737}{20+1}=\frac{10{\cdot}263}{21}=$ L. 0·488714 is the single premium, and $\frac{0{\cdot}488714}{10{\cdot}737}=$ L. 0·0455168, the equivalent annual one for the assurance of L. 1 to be paid at the end of the year, in which that life becomes extinct which may happen to fail the first of the two.

Therefore, if the sum assured were L. 500, the total present value of the assurance would be L. 244, 7s. 2d. and the equivalent annual premium L. 22, 15s. 2d.

87. *Ex.* 4. Let both the single and the equivalent annual premium be required for the assurance of L. 1, on the life of the survivor of two persons now aged 40 and 50 years respectively.

The value of an annuity on the survivor of these two lives was shown in No. 66, to be 15·066, therefore, by No. 81, the single premium will be $\frac{20-15{\cdot}066}{20+1}=\frac{4{\cdot}934}{21}=$ L. 0·234952; and by No. 84, the annual one will be $\frac{\text{L. } 0.234952}{16{\cdot}066}=$ L. 0·0146242.

Popular View.

That is, for the assurance of L. 1 to be received at the end of the year, in which the last surviving life of the two becomes extinct.

Therefore, for the assurance of L. 5000, the single premium will be L. 1174, 15s. 2d. the equivalent annual one L. 73, 2s. 5d.

88. *Ex.* 5. What should the single and equivalent annual premiums be for an assurance on the last survivor of three lives, of the respective ages of 50, 55, and 60 years.

The value of an annuity on the last survivor of them, was shown in No. 68, to be 14·001, the single premium should therefore be $\frac{20-14{\cdot}001}{20+1}=\frac{5{\cdot}999}{21}$ = L. 0·285666, and the annual $\frac{\text{L. } 0{\cdot}285666}{15{\cdot}001}=$ L. 0·0190431, for the assurance of L. 1, to be received at the end of the year, in which the last surviving life of the three may fail.

For the assurance of L. 2000, the single premium would therefore be L. 571, 6s. 8d. the annual one L. 38, 1s. 9d.

89. *Lemma.* If an annuity be payable at the *commencement* of each year, which some assigned life or lives may *enter upon* in a given term; the number of years purchase in its present value, will exceed by unity the number of years purchase, in the present value of an annuity on the same life or lives for one year less than the given term, but payable as annuities generally are, at the *end* of each year.

*Demonstration.* Since the proposed life or lives can only enter upon any year after the first, by surviving the year that precedes it; the receipt of each of the payments after the first, that are to be made at the commencement of the year, will take place at the same time, and upon the same conditions as that of the rent for the year then expired of the life-annuity, for a term one year less than the term proposed: this last mentioned annuity, will therefore, be worth in present money, just the same number of years' purchase as all the payments subsequent to the first, which may be made at the commencements of the several years.

And, since the first of these is to be made immediately, the present value of the whole of them, will evidently exceed the number of years purchase last mentioned, by unity, which was to be demonstrated.

90. If, while the rest remains the same, the payment of the annuity which depends upon the assigned life or lives *entering upon* any year, is not to be made until the end of that year; as the condition upon which every payment is to be made, will remain the same, but each of them will be one year later; the only alteration in the value of the whole, will arise from this increase in the remoteness of payment, by which it will be reduced in the ratio of L. 1, to the present value of L. 1, receivable at the end of a year (2).

Popular View.

91. When the value of an annuity on any proposed life or lives for an assigned term is given, it is evident that the value of an annuity on the same life or lives for one year less may be found, by subtracting from the given value, the present value, of the rent to be received upon the proposed life or lives surviving the term assigned.

92. *Proposition.* The present value of an assurance on any proposed life or lives for a given term, is equal to the excess of the value of an annuity to be paid at the end of each year, which the life or lives proposed may *enter upon* in the term, above the value of an annuity on them for the same term, but dependent, as usual, upon their surviving each year.

*Demonstration.* If an annuity payable at the end of each year, which the proposed life or lives may enter upon during the given term, be granted to $P$, upon condition that he shall pay over what he receives to $Q$, at the end of each year which the same life or lives may survive; it is manifest that there will only remain to $P$, the rent for the year in which the proposed life or lives may fail; that is, the assurance of that sum thereon for the given term (77). Which was to be demonstrated.

93. From the last four numbers (89—92) we derive the following

Rule

for determining the present value of an assurance on any life or lives for a given term.

*Add unity to the value of an annuity on the proposed life or lives for the given term, and from the sum subtract the present value of one pound, to be received upon the same life or lives surviving the term; multiply the remainder by the present value of L. 1, to be received certainly at the end of a year, and from the product subtract the present value of an annuity on the proposed life or lives for the term.*

This last remainder will be the value in present money of the assurance of L. 1 during the same term, on the life or lives proposed.

94. It has been shown above (34—39), how the present value of L. 1, receivable upon any single or joint lives surviving an assigned term, may be found. And all that was demonstrated from No. 48. to 53. inclusive, respecting annuities on the last survivor of two, or of three lives, or on the joint continuance of the two last survivors out of three lives, is equally true of any particular year's rent of those annuities. Hence it is evident, how the present value of L. 1, to be received upon the last survivor of two, or of three lives, or upon the last two survivors out of three lives, surviving any assigned term, may be found.

95. *Example.* Required the present value of L. 1, to be received at the end of the year, in which a life, now forty-five years of age, may fail, provided that such failure happens before the expiration of ten years.

Here the present value of L. 1, to be received upon the life surviving the term, will be found to be L. 0·528976, and the value of an annuity on the proposed life for the term, is 7·175 (70.)

From 8·175
subtract 0·528976

the remainder 7·646024
being multiplied by 0·952381

produces 7·28193
from this subtract 7·17500

remains L. 0·10693, the required value of the assurance; and if the sum assured were L. 3000, the value of the assurance in present money would be L. 320, 15s. 7d.

96. By numbers 89, 91, and 95, it appears, that an annuity, payable at the commencement of each of the next ten years that a life of 45 enters upon, is worth 7·646 years purchase: therefore, $\frac{0\cdot10693}{7\cdot646} =$ L. 0·013985 will be the annual premium for the assurance of L. 1 for ten years on that life. For the assurance of L. 3000, it will therefore be L. 41, 19s. 1d.

97. When the term of the assurance is the whole duration of the life or lives assured, L. 1 to be received upon their surviving the term is worth nothing; and an annuity on the lives for the term, is also for their whole duration.

Therefore, from No. 93. we derive the following

Rule

for determining the present value of an assurance on any life or lives.

*Add unity to the value of an annuity on the proposed life or lives; multiply the sum by the present value of L. 1, to be received certainly at the end of a year; and from the product, subtract the value of an annuity on the same life or lives.*

The remainder will be the value of the assurance in present money.

98. *Example.* Required the present value of L. 1, to be received at the end of the year, in which the survivor of two lives may fail, their ages now being 40 and 50 years respectively.

The value of an annuity on these lives was shown in No. 66. to be 15·066.

Multiply 15·066 by 0·952381, from the product 15·3009, subtract 15·066, the remainder L. 0·2349 is the required value, agreeably to No. 87.

And, in all other cases, the values determined by the rule in the preceding number, will be found to agree with those obtained by the method of No. 81.

99. When an assurance on any life or lives has been effected at a constant annual premium, and kept up for some time, by the regular payment of that premium; the annual premium required for a new assurance of the same sum on the same life or lives, will, on account of the increase of age, be greater than that at which the first assurance was effected: Therefore, the present value of all these greater annual premiums, that is, the total present value of the new assurance, will exceed the present value of all the premiums that may hereafter be received under the existing policy. And the excess

will evidently be the value of the policy, supposing the life or lives to be still insurable; that being the only advantage that can now be derived from the premiums already paid.

So that, if the present value of all the future annual premiums to be paid under an existing policy for the assurance of a certain sum upon any life or lives, be subtracted from the present value of the assurance of the same sum on the same life or lives; the remainder will be the value of the policy.

100. *Example.* L. 1000 has been assured some years, on a life now 50 years of age, for its whole duration, at the annual premium of L. 20, one of which has just now been paid: What is the value of the policy?

The present value of the assurance of L. 1000 on that life, has been shown in No. 82. to be L. 397, 2s. 10d.; and an annuity on the life, being worth 11·66 years purchase (Table VI.), the present value of all the premiums to be paid in future under the existing policy, is $11{\cdot}66 \times$ L. $20 =$ L. 233, 4s. 0d.; the value of the policy, therefore, is L. 163, 18s. 10d.

Immediately before the payment of the premium, the value of the policy would evidently have been less by the premium then due.

101. In our investigations of the values of annuities on lives, we have hitherto assumed, that no part of the rent is to be received for the year in which the life wherewith the annuity may terminate fails.

But if a part of the annuity is to be received at the end of that year, proportional to the part of the year which may have elapsed at the time of such failure; as, in a great number of such cases, some of the lives wherewith the annuity terminates will fail in every part of the year, and as many, or very nearly so, in any one part of it as in any other: we may assume, that, upon an average, half a year's rent will be received at the end of the year in which such failure happens; and, therefore, that by the title to what may be received after the failure of the life or lives whereon the annuity depends, the present value of that annuity will be increased by the present value of the assurance of half a year's rent on the same life or lives.

102. Thus, for example: the present value of the assurance of L. 1 on a life of 50 years of age, having in No. 82. been shown to be L. 0·397143, the value of an annuity of L. 1 on that life, when payable, till the last moment of its existence, will exceed L. 11·66, its value, if only payable, until the expiration of the last year it survives, by $\left(\frac{\text{L. } 0{\cdot}397143}{2} =\right)$ L. 0·199; it will therefore be L. 11·859.

103. If, at the end of the year in which an assigned life $A$ may fail, $Q$ or his heirs are to receive L. 1; and are, at the same time, to enter upon an annuity of L. 1, to be enjoyed during another life $P$, to be then fixed upon: the present value of $Q$'s interest will evidently be the same as that of the assurance on the life of $A$, of a number of pounds, exceeding by unity the number of years purchase in the value of an annuity on the life of $P$, at the time of nomination.

104. What is the present value of the next presentation to a living of the clear annual value of L. 500; $A$, the present incumbent, being now 50 years of age; supposing the age of the clerk presented to be 25, at the end of the year in which the present incumbent dies; also, that he takes the whole produce of the living for that year?

By Table VI. it will be found, that the value of an annuity of L. 1 on a life of 25, is L. 15·303; and in No. 82. it has been shown, that the present value of the assurance of L. 1 on a life of 50, is L. 0·397143. Hence, and by the last number, it appears, that if the annual produce of the living were but L. 1, the present value of the next presentation would be L. $16{\cdot}303 \times 0{\cdot}397143 =$ L. 6·47467. The required value, therefore, is L. 3237, 6s. 9d.

105. If, to the value of the succeeding life, determined according to No. 103, the value of the present be added, the sum of these will evidently be the present value of both the lives in succession; and, in the case of the preceding number, will be $6{\cdot}475 + 11{\cdot}66 = 18{\cdot}135$ years' purchase.

106. In No. 103, we proceeded upon the supposition that the annuity on the present life is only payable up to the expiration of the last year it survives; and, consequently, that the succeeding life takes the whole rent for the year in which the present fails.

But, if the succeeding life is only to take a part of that rent, in the same proportion to the whole, as the portion of the year which intervenes between the failure of the present life and the end of the year, is to the whole year, then, by reasoning as in No. 101, it will be found, that the portion of that rent which the succeeding life will receive, may be properly assumed to be one half. And, instead of increasing the number of years' purchase the annuity on the succeeding life will be worth at the end of the year in which the other fails, by unity, we must only add one half to that number, in order that the present value of the assurance of the sum on the existing life, may be the number of years' purchase, which all that may be received during the succeeding life, is now worth.

107. The value of the succeeding life, in the case of No. 104, will, upon this hypothesis, be $15{\cdot}803 \times 0{\cdot}397143 = 6{\cdot}27605$ years' purchase.

And this appears to be the most correct way of calculating the value of an annuity on a succeeding life; although that of No. 103. proceeds upon the principle on which life interests are generally valued.

108. But the value of two lives in succession, will be the same on both hypotheses. The rent for the year in which the first may fail, being, in the one case, given entirely to the successor; and, in the other, divided equally between the two.

This is also true of any greater number of successive lives.

## PART II.

109. We now proceed to treat the subject of Annuities *Algebraically*.

### I. ON ANNUITIES CERTAIN.

Let $r$ denote the *simple interest* of L. 1 for one year.
$s$, any *sum* put out at interest.
$n$, the *number of years* for which it is lent.
$m$, its *amount* in that time.
$a$, an *annuity* for the same time (3 and 4.)
M, the *amount* to which that *annuity* will increase, when each payment is laid up as it becomes due, and improved at compound interest until the end of the term.
V, the *present value* of the same annuity (6.)

110. Then, reasoning as in the first number of this article, it will be found that $m = s(1+r)^n$. And by No. 2. it appears, that the present value of $s$ pounds to be received certainly at the expiration of $n$ years, is $s\frac{1}{(1+r)^n}$, or $s(1+r)^{-n}$.

111. The amount of L. 1 in $n$ years being $(1+r)^n$, its increase in that time will be $(1+r)^n-1$, and when it is considered that this increase arises entirely from the simple interest ($r$) of L. 1 being laid up at the end of each year, and improved at compound interest during the remainder of the term; it must be obvious that $(1+r)^n-1$ is the amount of an annuity of $r$ pounds in that time, but $r : a :: (1+r)^n-1 : \frac{a}{r}\left[(1+r)^n-1\right]$, which, therefore, is equal to M, the amount of an annuity of $a$ pounds in $n$ years.

112. Reasoning as in No. 8. it will be found, that since $r : 1 :: a : \frac{a}{r}$, the present value of a perpetual annuity of $a$ pounds is $\frac{a}{r}$.

113. If two persons, $A$ and $B$, purchase a perpetuity of $a$ pounds between them, which $A$ and his heirs or assigns are to enjoy during the first $n$ years, and $B$, and his heirs and assigns, for ever after. Since the value of the perpetuity to be entered upon immediately, has just been shown to be $\frac{a}{r}$, the present value of $B$'s share, that is, the present value of the same perpetuity when the entrance thereon is deferred until the expiration of $n$ years, will be $\frac{a}{r}(r+1)^{-n}$, (110); and the value of the share of $A$ will be thus much less than that of the whole perpetuity (21), and therefore equal to $\frac{a}{r}\left[1-(1+r)^{-n}\right] = \text{V}$, the present value of an annuity of $a$ pounds for the term of $n$ years certain.

114. If the annuity is not to be entered upon until the expiration of $d$ years, but is then to continue $n$ years, its value at the time of entering upon it will be $\frac{a}{r}\left[1-(1+r)^{-n}\right]$, as has just been shown; therefore its present value will be

$$\frac{a}{r}\left[(1+r)^{-d}-(1+r)^{-(d+n)}\right] = \text{V}, \ (110.)$$

115. In the same manner, it appears that, when the entrance on a perpetuity of $a$ pounds is deferred $d$ years, its present value will be $\frac{a}{r}(1+r)^{-d}$ (110 and 112.)

116. $q$ being any number whatever, whole, fractional, or mixed, let $\lambda q$ denote its logarithm, and $\kappa q$ the arithmetical complement of that logarithm; so that these equations may obtain, $\lambda\frac{1}{q} = -\lambda q = \kappa q$.

Then, for the resolution of the principal questions of this kind by logarithms, we shall have these formulæ.

1. *Amount of a sum improved at interest.*
$$\lambda m = n\lambda(1+r) + \lambda s, \ (110.)$$

2. *Amount of an annuity when each payment is laid up as it becomes due, and improved at interest until the expiration of the term.*
$$\lambda \text{M} = \lambda\left[(1+r)^n-1\right] + \lambda a + \kappa r, \ (111.)$$

3. *Value of a lease or an annuity.*
$$\lambda \text{V} = \lambda\left[1-(1+r)^{-n}\right] + \lambda a + \kappa r \ (113.)$$

4. *Value of a deferred annuity, or the renewal of any number of years lapsed in the term of a lease.*
$$\lambda \text{V} = \lambda\left[(1+r)^{-d}-(1+r)^{-(d+n)}\right] + \lambda a + \kappa r, (114.)$$

5. *Value of a deferred perpetuity, or the reversion of an estate in fee simple, after an assigned term.*
$$\lambda \text{V} = \lambda a + \kappa r + d\kappa(1+r), \ (115).$$

By means of each of these equations, it is manifest that any one of the quantities involved in it may be found, when the rest are given.

117. If the interest be convertible into principal $\nu$ times in the year, at $\nu$ equal intervals, since the interest of L. 1 for one of these intervals will be $\frac{r}{\nu}$, (109), and the number of conversions of interest into principal in $n$ years $\nu n$; to adapt the formula in No. 110. to this case, we have only to substitute $\frac{r}{\nu}$ for $r$, and $\nu n$ for $n$, in the equation $m = s(1+r)^n$ there given, whereby it will be tranformed to this, $m = s\left(1+\frac{r}{\nu}\right)^{\nu n}$.

118. According as $\nu$ is equal to 1, 2, 4, or is infinite; that is, according as the interest is convertible into principal yearly, half-yearly, quarterly, or continually, let $m$ be equal to Y, H, Q, or C; so shall

$$Y = s(1+r)^n,$$

$$H = s\left(1+\frac{r}{2}\right)^{2n},$$

$$Q = s\left(1+\frac{r}{4}\right)^{4n},$$

and $C = s \cdot N$

N being the number whereof $nr$ is the hyperbolic logarithm, and $nr \times 0{\cdot}43429448$ its logarithm in Briggs' *System*, and the common tables.

119. From No. 117 and 110, it follows, that the present value of $s$ pounds to be received at the end of $n$ years, when the interest is convertible into principal at $\nu$ equal intervals in each year, is $s\left(1+\frac{r}{\nu}\right)^{-\nu n}$.

120. When the present values and the amounts of annuities are desired, let the interest be convertible into principal at $\nu$ equal intervals in the year, while the annuity is payable at $\pi$ intervals therein, the amount of each payment being $\frac{a}{\pi}$.

121. *Case* I. $\mu$ being any whole number not greater than $\nu$, let $\frac{1}{\pi}=\frac{\mu}{\nu}$, so that the interest may be convertible into principal $\mu$ times in each of the intervals between the payments of the annuity.

Then will the amount of L. 1, at the expiration of the period $\frac{1}{\pi}$ be $\left(1+\frac{r}{\nu}\right)^{\mu}$ (117), and the interest of L. 1 for the same time will be $\left(1+\frac{r}{\nu}\right)^{\mu}-1$; whence the present value of the perpetuity will be $\dfrac{\frac{1}{\pi}a}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}$ (8), and the value of the same deferred $n$ years, will be $\frac{a}{\pi}\cdot\dfrac{\left(1+\frac{r}{\nu}\right)^{-\nu n}}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}$ (119), therefore the present value of the annuity to be entered upon immediately, and to continue $n$ years, will be

$$\frac{a}{\pi}\cdot\frac{1-\left(1+\frac{r}{\nu}\right)^{-\nu n}}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}=\text{V}.$$

122. *Case* 2. $\mu$ being any whole number greater than $\pi$, let $\frac{1}{\nu}=\frac{\mu}{\pi}$, so that the annuity may be payable $\mu$ times in each of the intervals between the payments of interest, or the conversion thereof into principal.

Then, at the expiration of the $\frac{1}{\nu}$th of a year, when the interest on the purchase-money is first payable or convertible, the interest on all the $\mu-1$ payments of the annuity previously made, will be

$$\frac{ar}{\pi\pi}\left[(\mu-1)+(\mu-2)+(\mu-3)+\ldots\ldots+3+2+1\right]$$

$=\frac{a}{\pi}\cdot\frac{r\mu(\mu-1)}{2\pi}$; to which, adding the $\mu$ payments of $\frac{a}{\pi}$ each (including the one only then due), the sum, $\frac{a}{\pi}\left[\mu+\frac{r\mu(\mu-1)}{2\pi}\right]$, is the simple interest which the value of the perpetuity should yield at the expiration of each $\nu$th part of a year, in order to supply the deficiency (both of principal and interest) that would be occasioned during each of those periods, in any fund out of which the several payments of the annuity might be taken, as they respectively became due; and since $\frac{r}{\nu}:\frac{a}{\pi}\left[\mu+\frac{r\mu(\mu-1)}{2\pi}\right]::1:\frac{a\nu}{r\pi}\left[\mu+\frac{r\mu(\mu-1)}{2\pi}\right]=a\left(\frac{1}{r}+\frac{\mu-1}{2\pi}\right)$, this last expression will be the value of such perpetuity with immediate possession (8); the value of the same deferred $n$ years, will therefore be $a\left(\frac{1}{r}+\frac{\mu-1}{2\pi}\right)\times\left(1+\frac{r}{\nu}\right)^{-\nu n}$ (119). Whence it appears, that the present value of the annuity to be entered upon immediately, and to continue $n$ years, will be

$$a\left(\frac{1}{r}+\frac{\mu-1}{2\pi}\right)\cdot\left[1-\left(1+\frac{r}{\nu}\right)^{-\nu n}\right]=\text{V}.$$

123. *Case* 3. When, in consequence of the annuity being always payable at the same time that the interest is convertible, $\nu=\pi$.

Since the interest of L. 1 at the expiration of the period $\frac{1}{\pi}$ will be $\frac{r}{\pi}$, the value of the perpetuity will be $\dfrac{\frac{1}{\pi}a}{\frac{1}{\pi}r}=\frac{a}{r}$ (8), whence, proceeding as before, we obtain the present value of the annuity,

$\frac{a}{r}\left[1-\left(1+\frac{r}{\nu}\right)^{-\nu n}\right]=\text{V}$. When $\nu=\pi$, and consequently $\mu=1$, the values of V, given in the two preceding cases, will be found to coincide with this.

124. According as $\nu$ and $\pi$ are each equal to 1, 2, 4, or are infinite; that is, according as the interest and the annuity are each payable yearly, half-yearly, quarterly, or continually, let V be equal to $y$, $h$, $q$, or $c$, then will

$$y=\frac{a}{r}\left[1-(1+r)^{-n}\right],$$

$$h=\frac{a}{r}\left[1-\left(1+\frac{r}{2}\right)^{-2n}\right],$$

$$q=\frac{a}{r}\left[1-\left(1+\frac{r}{4}\right)^{-4n}\right],$$

and $c=\frac{a}{r}\left[1-\frac{1}{\text{N}}\right]$, N being as in No. 118.

125. The amount of an annuity is equal to the sum to which the purchase money would amount, if it were put out and improved at interest during the whole term.

For, from the time of the purchase of the annuity, whatever part of the money that was paid for it may be in the hands of the grantor, he must improve thus to provide for the payments thereof; and if the purchaser also improve in the same manner all he receives, the original purchase money must evident-

Algebraical View.

ly receive the same improvement during the term, as if it had been laid up at interest at its commencement.

126. The periods of conversion of interest into principal, and of the payment of the annuity being still designated as in No. 120; since in $n$ years, the number of periods of conversion will be $\nu n$, in the

1*st Case*, Where the interest is convertible $\mu$ times in each of the intervals between the payments of the annuity, we have $\left(1+\frac{r}{\nu}\right)^{\nu n}\text{v}=\frac{a}{\pi}\cdot\frac{\left(1+\frac{r}{\nu}\right)^{\nu n}-1}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}$ $=\text{M}$, (117, 121, and 125). In the 2*d Case*, when the annuity is payable $\mu$ times, in each interval between the conversions of interest,

$$\left(1+\frac{r}{\nu}\right)^{\nu n}\text{v}=a\left[\frac{1}{r}+\frac{\mu-1}{2\pi}\right]\cdot\left[\left(1+\frac{r}{\nu}\right)^{\nu n}-1\right]$$

$=\text{M}$, (117, 122, and 125).

And, in the 3*d Case*, when the annuity is always payable at the same time that the interest is convertible, $\left(1+\frac{r}{\nu}\right)^{\nu n}\text{v}=\frac{a}{r}\left[\left(1+\frac{r}{\nu}\right)^{\nu n}-1\right]=\text{M}$,(117, 123, and 125).

127. According as $\nu$ and $\pi$ are each equal to 1, 2, 4, or are infinite; that is, according as the interest and the annuity are each payable yearly, half-yearly, quarterly, or continually, let M be denoted by $y'$, $h'$, $q'$, or $c'$;

then will $\quad y'=\frac{a}{r}\left[(1+r)^{n}-1\right]$,

$$h'=\frac{a}{r}\left[\left(1+\frac{r}{2}\right)^{2n}-1\right],$$

$$q'=\frac{a}{r}\left[\left(1+\frac{r}{4}\right)^{4n}-1\right],$$

and $c'=\frac{a}{r}(\text{N}-1)$; N being as in No. 118.

128. *Example* 1. What will L.320 amount to, when improved at compound interest during 40 years; the rate of interest being 4 *per cent. per annum?*

By the first formula in No. 116, the operation will be as follows:

$$\begin{aligned} 1+r&=1{\cdot}04\ \lambda\ 0{\cdot}01703334\\ &\qquad\times n=40\\ (1+r)^n&\ \lambda\ 0{\cdot}6813336\\ s&=320\ \lambda\ 2{\cdot}5051500\\ m&=1536{\cdot}327\ \lambda\ 3{\cdot}1864836 \end{aligned}$$

And the answer is L.1536, 6s. 6½d.

129. *Ex.* 2. If the interest were convertible into principal every half-year, the operation, according to No. 117, would be thus:

$$\begin{aligned} 1+\frac{r}{2}&=1{\cdot}02\ \lambda\ 0{\cdot}00860017\\ &\qquad\times \nu n=80\\ &\quad 0{\cdot}6880136\\ s&=320\ \lambda\ 2{\cdot}5051500\\ m&=1560.14\ \lambda\ 3{\cdot}1931636 \end{aligned}$$

So that in this case the amount would be L.1560, 2s. 9½d.

130. *Ex.* 3. Required the present value of an annuity of L.250 for 30 years, reckoning interest at 5 *per cent.*

By the third formula in No. 116, the operation will be thus:

$$\begin{aligned} \lambda\ (1+r)^{-1}&=\kappa\ 1{\cdot}05=\bar{1}{\cdot}9788107\\ &\qquad\times n=30\\ (1+r)^{-n}&={\cdot}23137704\ \lambda\ \bar{1}{\cdot}3643210\\ 1-(1+r)^{-n}&={\cdot}76862296\ \lambda\ \bar{1}{\cdot}8857133\\ a&=250\ \lambda\ 2{\cdot}3979400\\ r&={\cdot}05\ \kappa\ 1{\cdot}3010300\\ \text{v}&=3843{\cdot}114\ \lambda\ 3{\cdot}5846833 \end{aligned}$$

And the required value is L.3843, 2s. 3¼d.

131. *Ex.* 4. The rest being still the same, if the annuity in the last example be payable half-yearly, in the formula of No. 122, $\nu$ will be equal to 1, $\pi=2$, and $\mu=2$; that formula will therefore become $a\left(\frac{1}{r}+\frac{1}{4}\right)\cdot\left[1-(1+r)^{-n}\right]=\text{v}$; and the operation will be thus:

$$\begin{aligned} \left.\begin{aligned}1-(1+r)^{-n}&\ \lambda\ \bar{1}{\cdot}8857133\\ a=250&\ \lambda\ 2{\cdot}3979400\end{aligned}\right\}&\ \text{No. 130.}\\ \frac{1}{r}+\frac{1}{4}&=20{\cdot}25\ \lambda\ 1{\cdot}3064250\\ \text{v}&=3891{\cdot}15\ \lambda\ 3{\cdot}5900783 \end{aligned}$$

The value of the annuity will, therefore, in this case, be L. 3891, 3s.

132. *Ex.* 5. To what sum will an annuity of L. 120 for 20 years amount, when each payment is improved at compound interest, from the time of its becoming due until the expiration of the term; the rate of interest being 6 *per cent.?*

The operation by the second formula in No. 116 is thus:

$$\begin{aligned} 1+r&=1{\cdot}06\ \lambda\ 0{\cdot}025305865\\ &\qquad\times n=20\\ (1+r)^n&=3{\cdot}207135\ \lambda\ 0{\cdot}5061173\\ (1+r)^n-1&=2{\cdot}207135\ \lambda\ 0{\cdot}3438289\\ a&=120\ \lambda\ 2{\cdot}0791812\\ r&={\cdot}06\ \kappa\ 1{\cdot}2218487\\ \text{M}&=4414{\cdot}27\ \lambda\ 3{\cdot}6448588 \end{aligned}$$

And the amount required is L. 4414, 5s. 5d.

133. *Ex.* 6. The rest being the same as in the last example; if both the interest and the annuity be payable half-yearly, the amount will be determined by the second of the formulæ given in No. 127; which, in this case, will become $\frac{120}{0{\cdot}6}\left[(1{\cdot}03)^{40}-1\right]$, and the operation will be as follows:

$$1{\cdot}03 \ \lambda \ 0{\cdot}01283723$$
$$\times \ 40$$

$$(1{\cdot}03)^{40} = 3{\cdot}26204 \ \lambda \ 0{\cdot}5134892$$

$$(1{\cdot}03)^{40} - 1 = 2{\cdot}26204 \ \lambda \ 0{\cdot}3545003$$
$$120 \ \lambda \ 2{\cdot}0791812$$
$$\cdot 06 \ \kappa \ 1{\cdot}2218487$$

$$\text{M} = 4524{\cdot}08 \ \lambda \ 3{\cdot}6555302$$

So that the amount in this case, would be L. 4524, 1s. 7¼d.

## II. ON THE PROBABILITIES OF LIFE.

134. Any persons $A$, $B$, $C$, &c. being proposed, let the numbers which tables of mortality (32) adapted to them, represent to attain to their respective ages, be denoted by the symbols $a$, $b$, $c$, &c.; while lives $n$ years older than those respectively, are denoted thus: ${}^nA$, ${}^nB$, ${}^nC$, &c. and the numbers that attain to their ages, by the symbols ${}^na$, ${}^nb$, ${}^nc$, &c.; also let lives $n$ years younger than $A$, $B$, $C$, &c. be denoted thus: $A_n$, $B_n$, $C_n$, &c., while the numbers which the tables show to attain to those younger ages, are designated by the symbols $a_n$, $b_n$, $c_n$, &c.

Then, if $A$ be 21 years of age, and we use the Carlisle Table, we shall have $a = 6047$, and ${}^{14}a = 5362$, the number that attain to the age of thirty-five, or that live to be fourteen years older than $A$.

Hence the number that are represented by the table to die in $n$ years from the age of $A$, will be $a - {}^na$, that is in 14 years, $a - {}^{14}a$; and by the Carlisle Table, n 14 years from the age of 21, that is, between 21 and 35, it will be $6047 - 5362 = 685$.

135. *Problem.* To determine the probability that a proposed life $A$, will survive $n$ years.

*Solution.* $a$ being the number of lives in the table of mortality, that attain to the age of that which is proposed, conceive that number of lives to be so selected, (of which $A$ must be one,) that they may each have the same prospect with regard to longevity, as the proposed life and those in the table, or the average of those from which it was constructed; then will the number of them that survive the term be ${}^na$ (134).

So that the number of ways all equally probable, or the number of equal chances for the happening of the event in question is ${}^na$; and the whole number for its either happening or failing is $a$; therefore, according to the first principles of the doctrine of probabilities, the probability of the event happening, that is, of $A$ surviving the term, is $\frac{{}^na}{a}$.

If the age of $A$ be 14, the probability of that life surviving 7 years, or the age of 21, will, according to the Carlisle Table, be $\frac{{}^7a}{a} = \frac{6047}{6335}$, or 0·95454.

136. Since the number that die in $n$ years from the age of $A$ is $a - {}^na$ (134), it appears, in the same manner, that the probability of that life failing in $n$ years will be $\frac{a - {}^na}{a} = 1 - \frac{{}^na}{a}$ which probability, when the life, term, and table of mortality, are the same as in the last No. will be 0·04546.

137. If two lives $A$ and $B$ be proposed, since the probability of $A$ surviving $n$ years will be $\frac{{}^na}{a}$, and that of $B$ surviving the same term will be $\frac{{}^nb}{b}$; it appears from the doctrine of probabilities that $\frac{{}^na}{a} \cdot \frac{{}^nb}{b}$ or $\frac{{}^n(ab)}{ab}$ will be the measure of the probability that these lives will both survive $n$ years.

In the same manner it may be shown, that the probability of the three lives $A$, $B$, and $C$ all surviving $n$ years, will be measured by $\frac{{}^na}{a} \cdot \frac{{}^nb}{b} \cdot \frac{{}^nc}{c}$, or $\frac{{}^n(abc)}{abc}$. And, universally, that any number of lives $A$, $B$, $C$, &c. will jointly survive $n$ years, the probability is $\frac{{}^n(abc, \&c.)}{abc, \&c.}$

138. Let $\frac{{}^na}{a} = {}_na$, $\frac{{}^nb}{b} = {}_nb$, $\frac{{}^nc}{c} = {}_nc$, &c.; also let $\frac{{}^n(abc,\&c.)}{abc,\&c.} = {}_n(abc, \&c.)$; so that the probabilities of $A$, $B$, $C$, &c. surviving $n$ years may be denoted by ${}_na$, ${}_nb$, ${}_nc$, &c. respectively; and that of all those lives jointly surviving that term by ${}_n(abc,\&c.)$

Then will the probability that none of those lives will survive $n$ years, be $(1 - {}_na) \cdot (1 - {}_nb) \cdot (1 - {}_nc)$. &c.

139. But the probability that some one or more of these lives will survive $n$ years, will be just what the probability last mentioned is deficient of certainty; its measure therefore, being just what the measure of that probability is deficient of unity, will be

$$1 - (1 - {}_na) \cdot (1 - {}_nb) \cdot (1 - {}_nc) \cdot \&c.$$

140. *Corol.* 1. When there is only one life $A$, this will be ${}_na$.

141. *Corol.* 2. When there are two lives $A$ and $B$, it becomes ${}_na + {}_nb - {}_n(ab)$.

142. *Corol.* 3. When there are three lives $A$, $B$, and $C$, it becomes ${}_na + {}_nb + {}_nc - {}_n(ab) - {}_n(ac) - {}_n(bc) + {}_n(abc)$.

143. When three lives $A$, $B$, and $C$ are proposed, that at the expiration of $n$ years there will be

Algebraical View.

| living | dead | the probability is |
|---|---|---|
| $ABC$ | none | ................................ $+\ {}_n(abc)$ |
| $AB$ | $C$ | ${}_n(ab)\cdot(1-{}_nc) = {}_n(ab) - {}_n(abc)$ |
| $AC$ | $B$ | ${}_n(ac)\cdot(1-{}_nb) = {}_n(ac) - {}_n(abc)$ |
| $BC$ | $A$ | ${}_n(bc)\cdot(1-{}_na) = {}_n(bc) - {}_n(abc)$ |

And the sum of these four ${}_n(ab) + {}_n(ac) + {}_n(bc) - 2\,{}_n(abc)$, is the measure of the probability that some two at the least, out of these three lives, will survive the term.

## III. OF ANNUITIES ON LIVES.

144. Let the number of years purchase that an annuity on the life of $A$ is worth, that is, the present value of L. 1, to be received at the end of every year during the continuance of that life, be denoted by A; while the present value of an annuity on any number of joint lives $A, B, C$, &c. that is, of an annuity which is to continue during the joint existence of all the lives, but to cease with the first that fails, is denoted by ABC, &c.

Then will the value of an annuity on the joint continuance of the three lives $A, B$, and $C$, be denoted by ABC.

And on the joint continuance of the two $A$ and $B$, by AB.

145. Also let ${}^t\mathrm{A}$ and $\mathrm{A}_t$ denote the value of annuities on lives respectively older and younger than $A$, by $t$ years: While ${}^t(\mathrm{ABC}\ \&c.)$ designates the value of an annuity on the joint continuance of lives $t$ years older than $A, B, C$, &c. respectively; and $(\mathrm{ABC}\ \&c.)_t$ that of an annuity on the same number of joint lives, as many years younger than these respectively.

146. Let $\frac{1}{1+r}$, the present value of L. 1 to be received certainly at the expiration of a year, be denoted by $v$.

Then will $v^n$ be the present value of that sum certain to be received at the expiration of $n$ years.

But if its receipt at the end of that time, be dependent upon an assigned life $A$, surviving the term, its present value will, by that condition, be reduced in the ratio of certainty to the probability of $A$ surviving the term, that is, in the ratio of unity to ${}_na$, and will therefore be ${}_nav^n$.

In the same manner it appears, that if the receipt of the money at the expiration of the term be dependent upon any assigned lives, as $A, B, C$, &c. jointly surviving that period, its present value will be ${}_n(abc\ \&c.)v^n$.

147. Let us denote the sum of any series, as ${}_1(abc)v + {}_2(abc)v^2 + {}_3(abc)v^3 +$ &c. thus, $S_n(abc)v^n$, by prefixing the italic capital $S$ to the general term thereof. Then, from what has just been advanced, it will be evident, that $\mathrm{ABC}\ \&c. = S_n(abc\ \&c.)v^n$.

Algebraical View.

When there are but three lives $A, B$, and $C$; this becomes $\mathrm{ABC} = S_n(abc)v^n$.

When there are but two, $A$ and $B$, it becomes $\mathrm{AB} = S_n(ab)v^n$.

And in the same manner it appears, that for a single life $A$, $\mathrm{A} = S_nav^n$.

148. ${}_n(abc\ \&c.)v^n = \frac{{}^n(abc\ \&c.)v^n}{abc\ \&c.}$ (138), where the denominator ($abc$ &c.) is constant, while the numerator varies with the variable exponent $n$. And the most obvious method of finding the value of an annuity on any assigned single or joint lives, is to calculate the numerical value of the term ${}^n(abc\ \&c.)v^n$ for each value of $n$, and then to divide the sum of all these values by $abc$ &c.; for $\frac{S^n(abc\ \&c.)v^n}{abc\ \&c.} = S_n(abc\ \&c.)v^n = \mathrm{ABC}\ \&c.$

In calculating a table of the values of annuities on lives in that manner, for every combination of joint lives, it would be necessary to calculate the term ${}^n(abc\ \&c.)v^n$ for as many years as there might be between the age of the oldest life involved and the oldest in the table; and the same number of the terms ${}^nav^n$ for any single life of the same age.

But this labour may be greatly abridged as follows:

PROB. I.

149. Given ${}'(\mathrm{ABC}, \&c.)$, the value of an annuity on any number of joint lives, to determine ABC, &c. that of an annuity on the same number of joint lives respectively one year younger than them.

*Solution.*

If it were certain that the lives ABC, &c. would all survive one year, the proprietor of an annuity of L. 1, dependent upon their joint continuance, would, at the expiration of a year, be in possession of L. 1, (the first year's rent,) and an annuity on the same number of lives, one year older respectively than ABC, &c. therefore, in that case, the required present value of the annuity would be $v\left[1 + {}'(\mathrm{ABC}, \&c.)\right]$, (146.)

But the probability of the lives $A, B, C$, &c. jointly surviving one year, is less than certainty, in the ratio of ${}_{\prime}(abc\ \&c.)$ to unity; therefore $\mathrm{ABC}\ \&c. = {}_{\prime}(abc\ \&c.)v\left[1 + {}'(\mathrm{ABC}\ \&c.)\right]$.

150. *Corol.* 1. When there are but three lives, $A$, $B$, and $C$, this becomes $\mathrm{ABC} = {}_{\prime}(abc)v\left[1 + {}'(\mathrm{ABC})\right]$.

151. *Corol.* 2. When there are only two, $A$ and $B$, $\mathrm{AB} = {}_{\prime}(ab)v\left[1 + {}'(\mathrm{AB})\right]$.

152. *Corol.* 3. And for a single life $A$, it appears, in the same manner, that $\mathrm{A} = {}_{\prime}av\,(1 + {}'\mathrm{A})$.

153. Hence, in logarithms, we have these equations,

Algebraical View.

$\lambda\,\mathrm{A} = \lambda\,v + \lambda\,{}_{,}a + \lambda\,(1 + {}'\mathrm{A})$,

$\lambda\,\mathrm{AB} = \lambda\,v + \lambda\,{}_{,}a + \lambda\,{}_{,}b + \lambda\,[1 + {}'(\mathrm{AB})]$,

$\lambda\,\mathrm{ABC} = \lambda\,v + \lambda\,{}_{,}a + \lambda\,{}_{,}b + \lambda\,{}_{,}c + \lambda\,[1 + {}'(\mathrm{ABC})]$,

&c. &c. &c.

Upon which it may be observed, that $\lambda\,v + \lambda\,{}_{,}a$, the sum of the first two logarithms that are employed in determining A from $'$A, also enters the operation whereby AB is determined from $'$(AB). And that $\lambda\,v + \lambda\,{}_{,}a + \lambda\,{}_{,}b$, the sum of the first three logarithms that serve to determine AB from $'$(AB), is also required to determine ABC from $'$(ABC); which observation may be extended in a similar manner to any greater number of joint lives.

154. By these means it is easy to complete a table of the values of annuities on single lives of all ages; beginning with the oldest in the table, and proceeding regularly age by age to the youngest.

Also a table of the values of any number of joint lives, the lives in each succeeding combination, in any one series of operations, (according to the retrograde order of the ages in which they are computed), being one year younger respectively than those in the preceding combination.

And, if a table of single lives be computed first, then of two joint lives, next of three joint lives, and so on; the calculations made for the preceding tables will be of great use for the succeeding.

155. Having shown how to compute tables of the values of annuities on single and joint lives, we shall, in what follows, always suppose those values to be given.

156. Let the value of an annuity on the joint continuance of any number of lives, *A*, *B*, *C*, &c. that is not to be entered upon until the expiration of $t$ years be denoted by $\rceil_t$(ABC &c.)

Then, if it were certain that all the lives would survive the term, since the value of the annuity at the expiration of the term would be ${}^{t}$(ABC &c.), (145), its present value would be $v^t \cdot {}^{t}$(ABC &c.), (146).

But the measure of the probability that all the lives will survive the term is ${}_{t}(abc$ &c.), therefore

$\rceil_t$(ABC &c.) $= {}_{t}(abc$ &c.) $v^t.\ {}^{t}$ABC &c.).

In the same manner, it appears, that for a single life *A*, $\rceil_t \mathrm{A} = {}_{t}av^t.\ {}^{t}\mathrm{A}$.

157. Let an annuity for the term of $t$ years only, dependent upon the joint continuance of any number of lives, *A*, *B*, *C*, &c. be denoted by $\overline{\lceil}_{t|}$(ABC &c.); and, since this *temporary* annuity, together with an annuity on the joint continuance of the same lives *deferred* for the same term, will evidently be of the same value as an annuity to be entered upon immediately, and enjoyed during their whole joint continuance, we have $\overline{\lceil}_{t|}$(ABC &c.) + $\rceil_t$(ABC &c.) = ABC &c.; whence, $\overline{\lceil}_{t|}$(ABC &c.) = ABC &c. — $\rceil^{t}$(ABC &c.).

And for a single life *A*, $\overline{\lceil}_{t|}\mathrm{A} = \mathrm{A} - \rceil_t \mathrm{A}$.

Prob. II.

158. To determine the present value of an annuity on the survivor of the two lives *A* and *B*, (155), which we designate thus, $\overline{\mathrm{AB}}$.

*Solution.*

The probability that the survivor of these two lives will outlive the term of $n$ years, was shown in No. 141, to be ${}_{n}a + {}_{n}b - {}_{n}(ab)$; therefore, reasoning as in No. 146, it will be found, that the present value of the $n$th year's rent of this annuity is $\left[{}_{n}a + b - {}_{n}(ab)\right]v^n$, and the value of all the rents thereof will be $S\left[{}_{n}a + {}_{n}b - {}_{n}(ab)\right]v^n$, or $S_n av^n + S_n bv^n - S_n(ab)v^n$; so that $\overline{\mathrm{AB}} = \mathrm{A} + \mathrm{B} - \mathrm{AB}$ (147), agreeably to No. 48.

Prob. III.

159. To determine the present value of an annuity on the last survivor of three lives, *A*, *B*, and *C*, (155); which we denote thus, $\overline{\mathrm{ABC}}$.

*Solution.*

The present value of the *nth* year's rent is $\left[{}_{n}a + {}_{n}b + {}_{n}c - {}_{n}(ab) - {}_{n}(ac) - {}_{n}(bc) + {}_{n}(abc)\right]v^n$ (142 and 146); whence, it appears, as in the preceding number, that $\overline{\mathrm{ABC}} = \mathrm{A} + \mathrm{B} + \mathrm{C} - \mathrm{AB} - \mathrm{AC} - \mathrm{BC} + \mathrm{ABC}$, agreeably to No. 52.

Prob. IV.

160. To determine the present value of an annuity on the joint existence of the last two survivors out of three lives, *A*, *B*, *C*, (155); which we denote thus, $\overset{2}{\overline{\mathrm{ABC}}}$.

*Solution.*

The present value of the $n$th year's rent is $\left[{}_{n}(ab) + {}_{n}(ac) + {}_{n}(bc) - 2{}_{n}(abc)\right]v^n$ (143 and 146); whence, reasoning as in the two preceding numbers, we infer, that $\overset{2}{\overline{\mathrm{ABC}}} = \mathrm{AB} + \mathrm{AC} + \mathrm{BC} - 2\mathrm{ABC}$, as was demonstrated otherwise in No. 51.

161. Since the solutions of the last three problems were all obtained by showing each year's rent (as for instance the $n$th) of the annuity in question, to be of the same value with the aggregate of the rents for the same year, of all the annuities (taken with their proper signs) on the single and joint lives exhibited in the resulting formula: if any term of years be assigned, it is manifest that the value of such annuity for the term, must be the same as that of the aggregate of the annuities above mentioned, each for the same term.

Prob. V.

162. *A* and *B* being any two proposed lives now both existing, to determine the present value of an annuity receivable only while *A* survives *B*.

Algebraical View.

*Solution.*

A rent of this annuity will only be payable at the end of the $n$th year, provided that $B$ be then dead, and $A$ living; but the probability of $B$ being then dead is $1 - {}_nb$, and that of $A$ being then living ${}_na$, and these two events are independent; therefore, the probability of their both happening, or that of the rent being received, is $(1 - {}_nb)\,{}_na = {}_na - {}_n(ab)$; the present value of that rent is, therefore, $\left[{}_na - {}_n(ab)\right]v^n$; whence, it follows, that the required value of the annuity on the life of $A$ after that of $B$, is $\text{A} - \text{AB}$, agreeably to No. 60.

163. If the payment for the annuity which was the subject of the last problem, is not to be made in present money, but by a constant annual premium $p$ at the end of each year, while both the lives survive; since AB is the number of years purchase (6) that an annuity on the joint continuance of those lives is worth, the value of p will be determined by this equation, $\text{p} \cdot \text{AB} = \text{A} - \text{AB}$, whence we have $\text{p} = \frac{\text{A}}{\text{AB}} - 1$.

164. But if one premium $p$ is to be paid down now, and an equal premium at the end of each year while both the lives survive, we shall have $p \cdot (1 + \text{AB}) = \text{A} - \text{AB}$, and $p = \frac{\text{A} - \text{AB}}{1 + \text{AB}}$.

165. For numerical examples illustrative of the formulæ given from No. 158 to the present; see Nos. 66—74.

PROB. VI.

166. $A$ and $B$ are in possession of an annuity on the life of the survivor of them, which, if either of them die before a third person $C$, is then to be divided equally between $C$ and the survivor during their joint lives; to determine the value of $C$'s interest.

*Solution.*

| That at the end of the $n$th year there will be dead | living | the probability, multiplied by $C$'s proportion of the annuity in that circumstance, is |
|---|---|---|
| $A$ | $BC$ | $\frac{1}{2}(1 - {}_na) \cdot {}_n(bc) = \frac{1}{2}\left[{}_n(bc) - {}_n(abc)\right]$ |
| $B$ | $AC$ | $\frac{1}{2}(1 - {}_nb) \cdot {}_n(ac) = \frac{1}{2}\left[{}_n(ac) - {}_n(abc)\right]$ |

and the sum of these being $\frac{1}{2}\,{}_n(ac) + \frac{1}{2}\,{}_n(bc) - {}_n(abc)$, the value of $C$'s interest is $\frac{1}{2}\text{AC} + \frac{1}{2}\text{BC} - \text{ABC}$.

PROB. VII.

167. An annuity after the decease of $A$, is to be equally divided between $B$ and $C$ during their joint lives, and is then to go entirely to the last survivor for his life; it is proposed to find the value of $B$'s interest therein.

*Solution.*

Algebraical View.

| That at the end of the $n$th year there will be dead | living | The probability, multiplied by $B$'s proportion of the annuity in that circumstance, is |
|---|---|---|
| $A$ | $BC$ | ......... $+ \frac{1}{2}\,{}_n(bc) - \frac{1}{2}\,{}_n(abc)$ |
| $AC$ | $B$ | ${}_nb - {}_n(ab) - {}_n(bc) + {}_n(abc)$; and the |

sum of these being ${}_nb - {}_n(ab) - \frac{1}{2}\,{}_n(bc) + \frac{1}{2}\,{}_n(abc)$, the value of $B$'s interest is $\text{B} - \text{AB} - \frac{1}{2}\text{BC} + \frac{1}{2}\text{ABC}$.

PROB. VIII.

168. $A$, $B$, and $C$ purchase an annuity on the life of the last survivor of them, which is to be divided equally at the end of every year among such of them as may then be living; what should $A$ contribute towards the purchase of this annuity?

*Solution.*

| That at the end of $n$ years there will be dead | living | The probability, multiplied by $A$'s proportion of the annuity in that circumstance, is |
|---|---|---|
| none | $ABC$ | ............................ $+ \frac{1}{3}\,{}_n(abc)$ |
| $C$ | $AB$ | ... $+ \frac{1}{2}\,{}_n(ab)$ ......... $- \frac{1}{2}\,{}_n(abc)$ |
| $B$ | $AC$ | ............ $+ \frac{1}{2}\,{}_n(ac) - \frac{1}{2}\,{}_n(abc)$ |
| $BC$ | $A$ | ${}_na - {}_n(ab) - {}_n(ac) + {}_n(abc)$; and |

the sum of these being ${}_na - \frac{1}{2}\,{}_n(ab) - \frac{1}{2}\,{}_n(ac) + \frac{1}{3}\,{}_n(abc)$, the required value of $A$'s interest is $\text{A} - \frac{1}{2}\text{AB} - \frac{1}{2}\text{AC} + \frac{1}{3}\text{ABC}$.

PROB. IX.

169. As soon as any two of the three lives, $A$, $B$, and $C$, are extinct, $D$ or his heirs are to enter upon an annuity; which they are to enjoy during the remainder of the survivor's life; to determine the value of $D$'s interest therein.

*Solution.*

| That at the end of $n$ years there will be dead | living | The probability is |
|---|---|---|
| $AB$ | $C$ | ${}_nc - {}_n(ac) - {}_n(bc) + {}_n(abc)$ |
| $AC$ | $B$ | ${}_nb - {}_n(ab) - {}_n(bc) + {}_n(abc)$ |
| $BC$ | $A$ | ${}_na - {}_n(ab) - {}_n(ac) + {}_n(abc)$; and the |

sum of all these being ${}_na + {}_nb + {}_nc - 2\,{}_n(ab) - 2\,{}_n(ac) - 2\,{}_n(bc) + 3\,{}_n(abc)$, the value of $D$'s interest is

$$\text{A} + \text{B} + \text{C} - 2\,\text{AB} - 2\,\text{AC} - 2\,\text{BC} + 3\,\text{ABC}.$$

170. The last four may be sufficient to show the method of proceeding with any similar problems.

171. Let ${}_t\overset{m}{(abc, \&c.)}$ denote the probability that the

Algebraical View.

last $m$ survivors out of $m+\mu$ lives $A$, $B$, $C$, &c. will jointly survive the term of $t$ years. And when $\mu=0$, the expression will become $_t(abc, \text{\&c.})$ the probability that the lives will all survive the term (138).

When $m=1$ it will become $\frac{1}{_t(abc,\&c.)}$, the measure of the probability that the last survivor of them will outlive the term; which it will be better to write thus, $_t(\overline{abc, \&c.})$, retaining the vinculum, but omitting the unit over it, as in the notation of powers.

Also let $\overset{m}{\overline{\text{ABC, \&c.}}}$ denote the value of an annuity on the joint continuance of the same number of last survivors out of the same lives. Then, if $\mu$ be equal to 0, it will be ABC, &c. the value of an annuity on the joint continuance of all the lives; when $m=1$, it will be $\overline{\text{ABC, \&c.}}$ the value of an annuity on the last survivor of them. The values of annuities on the last survivor of two and of three lives, will be denoted as in Nos. 158 and 159 respectively; and that of an annuity on the joint continuance of the last two survivors out of three lives, as in No. 160.

The value of an annuity on the last $m$ survivors out of these $m+\mu$ lives, according as it is limited to the term of $t$ years, or deferred during that term, will also be denoted by $\urcorner_{t|}\overset{m}{\overline{\text{ABC, \&c.}}}$ or $\urcorner_{t}\overset{m}{\overline{\text{ABC, \&c.}}}$ (156 and 157.)

PROB. X.

172. An annuity certain for the term of $t+\nu$ years, is to be enjoyed by $P$ and his heirs during the joint existence of the last $m$ survivors out of $m+\mu$ lives, $A$, $B$, $C$, &c.; and if that joint existence fail before the expiration of $t$ years, the annuity is to go to $Q$ and his heirs, for the remainder of the term; to determine the value of $Q$'s interest in that annuity.

SOLUTION.

$Q$'s expectation may be distinguished into two parts:

1st, That of enjoying the annuity during the term of $t$ years.

2d, That of enjoying it after the expiration of that term.

The sum of the present values of the interests of $P$ and $Q$, together in the annuity for the term of $t$ years, is manifestly equal to the whole present value of the annuity certain for that term; that is, equal to $\frac{1-v^t}{r}$ (113 and 146); and the value of $P$'s interest for the term of $t$ years, is $\urcorner_{t|}\overset{m}{\overline{\text{ABC, \&c.}}}$ (171); therefore the value of $Q$'s interest for the same term is $\frac{1-v^t}{r} - \urcorner_{t|}\overset{m}{\overline{\text{ABC, \&c.}}}$

The present value of the annuity certain for $\nu$ years after $t$ years is $\frac{v^t(1-v^\nu)}{r}$ (114 and 146); and $Q$ and his heirs will receive this annuity, if the joint continuance of the last $m$ survivors above mentioned fail before the expiration of $t$ years; but the probability of their joint continuance failing in the term, is $1-\overset{m}{\overline{_t(abc, \&c.)}}$; therefore, the value of $Q$'s interest in the annuity to be received after $t$ years, is $\left[1-{}_t\left(\overset{m}{\overline{abc, \&c.}}\right)\right]\frac{v^t(1-v^\nu)}{r}$; and the whole value of $Q$'s interest, is $\frac{1}{r}\left[1-v^{\nu+t}-v^t(1-v^\nu)\cdot{}_t\left(\overset{m}{\overline{abc,\&c.}}\right)\right] - \urcorner_{t|}\overset{m}{\overline{\text{ABC, \&c.}}}$

173. *Corol.* 1. When the whole annuity certain is a perpetuity, $v^{t+\nu}=0$, and the value of $Q$'s interest is $\frac{1}{r}\left[1-{}_t\left(\overset{m}{\overline{abc, \&c.}}\right)v^t\right]-\urcorner_{t|}\overset{m}{\overline{\text{ABC, \&c.}}}$

174. *Corol.* 2. When the term $t$ is not less than the greatest joint continuance of any $m$ of the proposed lives, according to the tables of mortality adapted to them, $_t(\overset{m}{\overline{abc, \&c.}}) = 0$, and $\urcorner_{t|}\overset{m}{\overline{\text{ABC, \&c.}}} = \overset{m}{\overline{\text{ABC, \&c.}}}$; therefore, in that case, the general formula of No. 172 becomes $\frac{1-v^{\nu+t}}{r}-\overset{m}{\overline{\text{ABC, \&c.}}}$; that is, the excess of the value of an annuity certain for the whole term $\nu+t$, above that of an annuity on the whole duration of joint continuance of the last $m$ surviving lives.

175. And if, in the case proposed in the last No. the annuity certain be a perpetuity, as in No. 173, the formula will become $\frac{1}{r}-\overset{m}{\overline{\text{ABC, \&c.}}}$ the excess of the value of the perpetuity above the value of an annuity on the joint lives of the last $m$ survivors; agreeably to No. 63.

176. *Example* 1. Required the present value of the absolute reversion of an estate in fee simple, after the extinction of the last survivor of three lives, $A$, $B$, $C$, now aged 50, 55, and 60 years respectively; reckoning interest at 5 *per cent.*

The general Algebraical expression of this value has just been shown to be $\frac{1}{r}-\overline{\text{ABC}}.$

$$\text{But } \frac{1}{r}=\frac{1}{0{\cdot}5}=20{\cdot}000$$

$$\text{And } \overline{\text{ABC}}, \quad =14{\cdot}001 \ (68.)$$

Therefore 5·999 years' purchase is the value required. And if the annual produce of the estate, clear of all deductions, were L. 100, the title to the reversion would now be worth L. 599, 18s.—, agreeably to No. 76.

177. *Ex.* 2. An annuity for the term of 70 years certain (from this time), is to revert to $Q$ and his heirs at the failure of a life $A$, now 45 years of age; what is the present value of $Q$'s interest therein; reckoning the interest of money at 5 *per cent.*?

Algebraical View.

In No. 174, the Algebraical expression of the required value is shown to be $\frac{1-v^{70}}{r}$ — A.

$$\text{But } \lambda\, v = \lambda\, 1{\cdot}05 = \bar{1}{\cdot}9788107$$
$$\times\ 70$$

$$v^{70} = {\cdot}032866\ \lambda\ \bar{2}{\cdot}5167490$$
$$1-v^{70} = {\cdot}967134$$

$$\frac{1-v^{70}}{r} = \frac{{\cdot}967134}{{\cdot}05} = 19{\cdot}34268$$
$$\text{Subtract A} = 12{\cdot}64800 \text{ (Tab. VI.)}$$

remains $6{\cdot}69468$ years' purchase; so that if the annuity were L. 1000, the value of the reversion would be L. 6694, 13s. 7d.

178. *Ex.* 3. An annuity for the term of 70 years certain from this time, is to revert to *Q* and his heirs at the extinction of the survivor of two lives, *A* and *B*, now aged 40 and 50 years respectively; the interest of money being 5 *per cent.*, it is required to determine the value of *Q*'s interest in this annuity.

The algebraical expression of the value is,

$$\frac{1-v^{70}}{r} - \overline{\text{AB}} \quad (174 \text{ and } 171).$$

But by the last example $\frac{1-v^{70}}{r} = 19{\cdot}34268$

and by No. 66. $\overline{\text{AB}} = 15{\cdot}06600$

So that the required value is $4{\cdot}27668$ years' purchase; and if the annuity be L. 1,000, the present value of the reversion will be L. 4276, 13s. 7d.

## IV. OF ASSURANCES ON LIVES.

179. Let the present value of the assurance (77 and 78) of L. 1 on the life of *A* be denoted by the Old English capital $\mathfrak{A}$, and that of an assurance on the joint continuance of any number of lives *A*, *B*, *C*, &c. by $\mathfrak{ABC}$, &c. Also, let the value of an assurance on the joint continuance of any *m* of them, out of the whole number $m+\mu$ be denoted by $\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$

180. And, in every case, let us designate the annual premium (83) for an assurance, by prefixing the character ⊙ to the symbol for the single premium; so that $\odot\mathfrak{A}$ may denote the annual premium for an assurance on the life of *A*; $\odot\mathfrak{ABC}$, &c. the same for an assurance on the joint continuance of all the lives, *A*, *B*, *C*, &c.; and $\odot\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$ the annual premium for an assurance on the joint continuance of the last *m* survivors out of the whole number $m+\mu$ of those lives.

181. Then will ${}_{\overline{t|}}\mathfrak{A}$ and $\odot{}_{\overline{t|}}\mathfrak{A}$, ${}_{\overline{t|}}\mathfrak{ABC}$, &c. and $\odot{}_{\overline{t|}}\mathfrak{ABC}$, &c., ${}_{\overline{t|}}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$ and $\odot{}_{\overline{t|}}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$ designate the single and annual premiums for assurances on the same life or lives for the term of *t* years only.

Prob. XI.

182. To determine $\left({}_{\overline{t|}}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}\right)$ the present value of an assurance on the last *m* survivors out of $m+\mu$ lives *A*, *B*, *C*, &c. for the term of *t* years only; that is, the present value of L. 1, to be received upon the joint continuance of these last *m* survivors failing in the term.

*Solution.*

By reasoning as in No. 79, it will be found, that a perpetuity, the first payment of which is to be made at the end of the year in which the last *m* survivors out of these $m+\mu$ lives may fail in the term, will be of the same present value as $\left(1+\frac{1}{r}=\right)\frac{1}{1-v}$ pounds to be received in the same event (112 and 146); but, in No. 173, the value of the reversion of such a perpetuity in that event, was shown to be

$$\frac{v}{1-v}\left[1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t}\right] - {}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}};$$ whence it is manifest, that ${}_{\overline{t|}}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$

$$= v\left[1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t}\right] - (1-v)\,{}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}}$$

183. Since the annual premium for this assurance must be paid at the commencement of every year in the term, while the last *m* surviving lives all subsist (83); besides the premium paid down now, one must be paid at the expiration of every year in the term except the last, provided that these last *m* survivors all outlive it; but the present value of L. 1 to be received upon their surviving that last year is ${}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t}$, therefore all the future premiums are now worth ${}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}} - {}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t}$ years' purchase, and the present value of all the premiums, or the total present value of the assurance, is

$$\odot{}_{\overline{t|}}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}\left[1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t} + {}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}}\right] =$$
$$v\left[1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t}\right] - (1-v)\,{}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}} = 1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t}$$
$$-(1-v)\,.\left[1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t} + {}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}}\right],$$ whence we have

$$\odot{}_{\overline{t|}}\overset{m}{\overline{\mathfrak{ABC}, \&c.}} = \frac{1-{}_{t}\overset{m}{\overline{(abc, \&c.}}\,v^{t}}{1-{}_{t}\overset{m}{\overline{(abc, \&c.)}}\,v^{t} + {}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}}} +$$
$$v-1.$$

184. *Corol.* 1. When (*t*) the term of the assurance is not less than the greatest possible joint duration of any *m* of the proposed lives, ${}_{t}\overset{m}{\overline{(abc, \&c.)}} = 0$, ${}_{\overline{t|}}\overset{m}{\overline{\text{ABC}, \&c.}} = \overset{m}{\overline{\text{ABC}, \&c.}}$ and the general formulæ of the

Algebraical View.

two preceding numbers become respectively

$$\overset{m}{\overline{\mathfrak{ABC},\ \&c.}} = v-(1-v)\,\overset{m}{\overline{\text{ABC},\&c.}}$$

$$\text{and } \odot\,\overset{m}{\overline{\mathfrak{ABC},\ \&c.}} = \frac{1}{1+\overset{m}{\overline{\text{ABC},\&c.}}}+v-1$$

185. *Corol.* 2. In the same manner it appears, that, for a single life, $\mathfrak{A} = v-(1-v)\,\text{A}$,

$$\text{and } \odot\,\mathfrak{A} = \frac{1}{1+\text{A}}+v-1$$

186. *Corol.* 3. Also that ${}_{t\rceil}\mathfrak{A} = v\left(1-{}_{t}a v^{t}\right)-(1-v)\,{}_{t\rceil}\text{A}$

$$\text{or } {}_{t\rceil}\mathfrak{A} = v\left(1-\frac{{}^{t}a}{a}v^{t}\right)-(1-v).\left(\text{A}-\frac{{}^{t}a}{a}v^{t}.{}^{t}\text{A}\right).$$

$$\text{And } \odot\,{}_{t\rceil}\mathfrak{A} = \frac{1-{}_{t}a v^{t}}{1-{}_{t}a v^{t}+{}_{t\rceil}\text{A}}+v-1$$

$$\text{that is, } \odot\,{}_{t\rceil}\mathfrak{A} = \frac{1-\frac{{}^{t}a}{a}v^{t}}{1+\text{A}-\frac{{}^{t}a}{a}v^{t}.(1+{}^{t}\text{A})}+v-1.$$

187. *Corol.* 4. When the assurance is on the joint continuance of all the lives, the formulæ of No. 184 become respectively

$$\mathfrak{ABC},\ \&c. = v-(1-v)\ \text{ABC},\ \&c.$$

$$\text{and } \odot\ \mathfrak{ABC},\ \&c. = \frac{1}{1+\text{ABC},\ \&c.}+v-1.$$

And those of numbers 182 and 183,

$${}_{t\rceil}\mathfrak{ABC},\ \&c. = v\left(1-\frac{{}^{t}(abc,\ \&c.)}{abc,\ \&c.}v^{t}\right)-(1-v)\times\left[\text{ABC},\ \&c.-\frac{t(abc,\ \&c.)}{abc,\ \&c.}v^{t}.{}^{t}(\text{ABC},\ \&c.)\right],$$

and $\odot\,{}_{t\rceil}\mathfrak{ABC},\ \&c. =$

$$\frac{1-\frac{{}^{t}(abc,\ \&c.)}{abc,\ \&c.}v^{t}}{1+\text{ABC},\ \&c.-\frac{{}^{t}(abc,\ \&c.)}{abc,\ \&c.}v^{t}\left[1+{}^{t}(\text{ABC},\ \&c.)\right]}+v-1.$$

188. *Corol.* 5. According as the assurance is in the last survivor of two, or of three lives, the formulæ of No. 184 become respectively

$$\overline{\mathfrak{AB}} = v-(1-v)\ \overline{\text{AB}},$$

$$\text{and } \odot\ \overline{\mathfrak{AB}} = \frac{1}{1+\overline{\text{AB}}}+v-1\ ;$$

$$\text{or } \overline{\mathfrak{ABC}} = v-(1-v)\ \overline{\text{ABC}},$$

$$\text{and } \odot\ \overline{\mathfrak{ABC}} = \frac{1}{1+\overline{\text{ABC}}}+v-1.$$

And those of numbers 182 and 183 become

$${}_{t\rceil}\overline{\mathfrak{AB}} = v\left[1-{}_{t}(\overline{ab})v^{t}\right]-(1-v)\ {}_{t\rceil}\overline{\text{AB}},$$

$$\text{and } \odot\,{}_{t\rceil}\overline{\mathfrak{AB}} = \frac{1-{}_{t}(\overline{ab})v^{t}}{1-{}_{t}(\overline{ab})v^{t}+{}_{t\rceil}\overline{\text{AB}}}+v-1\ ;$$

$$\text{or } {}_{t\rceil}\overline{\mathfrak{ABC}} = v\left[1-{}_{t}(\overline{abc})v^{t}\right]-(1-v)\,{}_{t\rceil}\overline{\text{ABC}},$$

$$\text{and } \odot\,{}_{t\rceil}\overline{\mathfrak{ABC}} = \frac{1-{}_{t}(\overline{abc})v^{t}}{1-{}_{t}(abc)v^{t}+{}_{t\rceil}\overline{\text{ABC}}}+v-1$$

respectively.

Where ${}_{t}(\overline{ab}) = {}_{t}a+{}_{t}b-{}_{t}(ab)$, (141).

and ${}_{t}(\overline{abc}) = {}_{t}a+{}_{t}b+{}_{t}c-\left[{}_{t}(ab)+{}_{t}(ac)+(bc)\right]+{}_{t}(abc)$, (142).

For the values of $\overline{\text{AB}}$, $\overline{\text{ABC}}$, ${}_{t\rceil}\overline{\text{AB}}$, and ${}_{t\rceil}\overline{\text{ABC}}$, see numbers 157—159, and 161.

189. *Corol.* 6. When the assurance is on the joint continuance of the two last survivors out of the three lives *A*, *B*, *C* ; the formulæ of No. 184 become respectively

$$\overset{2}{\overline{\mathfrak{ABC}}} = v-(1-v)\,\overset{2}{\overline{\text{ABC}}},$$

$$\text{and } \odot\,\overset{2}{\overline{\mathfrak{ABC}}} = \frac{1}{1+\overset{2}{\overline{\text{ABC}}}}+v-1.$$

Those of numbers 182 and 183,

$${}_{t\rceil}\overset{2}{\overline{\mathfrak{ABC}}} = v\left[1-{}_{t}\overset{2}{\overline{(abc)}}\,v^{t}\right]-(1-v)\,{}_{t\rceil}\overset{2}{\overline{\text{ABC}}},$$

$$\text{and } \odot\,{}_{t\rceil}\overset{2}{\overline{\mathfrak{ABC}}} = \frac{1-{}_{t}\overset{2}{\overline{(abc)}}\,v^{t}}{1-{}_{t}\overset{2}{\overline{(abc)}}\,v^{t}+{}_{t\rceil}\overset{2}{\overline{\text{ABC}}}}+v-1.$$

Where ${}_{t}\left(\overset{2}{\overline{abc}}\right) = {}_{t}(ab)+{}_{t}(ac)+{}_{t}(bc)-2\,{}_{t}(abc)$, (143).

For the values of $\overset{2}{\overline{\text{ABC}}}$ and ${}_{t\rceil}\overset{2}{\overline{\text{ABC}}}$ see numbers 157, 160, and 161.

190. $v\left[1-{}_{t}\overset{m}{\overline{(abc,\ \&c.)}}\,v^{t}\right]-(1-v)\,{}_{t\rceil}\overset{m}{\overline{\text{ABC},\ \&c.}}$ the value of an assurance on any life or lives for the term of *t* years, which was given in No. 182, may also be expressed thus :

$$\left[1+{}_{t\rceil}\overset{m}{\overline{(\text{ABC},\ \&c.)}}-{}_{t}\overset{m}{\overline{(abc,\ \&c.)}}\,v^{t}\right]v-{}_{t\rceil}\overset{m}{\overline{\text{ABC},\ \&c.}}$$

And this, in words at length, is the rule given in No. 93.

191. When *t* is not less than the greatest possible joint duration of any *m* of the proposed lives, the last expression becomes $\left(1+\overset{m}{\overline{\text{ABC},\ \&c.}}\right)v-\overset{m}{\overline{\text{ABC},\ \&c.}}$ which is also equivalent to the first in No. 184 ; and, in words at length, is the rule given in No. 97, for determining the value of an assurance on any life or lives for their whole duration.

192. By substituting $\frac{1}{1+r}$ for $v$ (146) in the last expression, it becomes $\frac{1+\overset{m}{\overline{\text{ABC},\ \&c.}}}{1+r}-\overset{m}{\overline{\text{ABC},\ \&c.}}$

$$= \frac{1-r.\overset{m}{\overline{\text{ABC},\&c.}}}{1+r},\ \text{or } \frac{\frac{1}{r}-\overset{m}{\overline{\text{ABC},\&c}}}{1+\frac{1}{r}}.$$ And

Algebraical View.

$\dfrac{\frac{1}{r}\overline{\overset{m}{-\text{ABC, \&c.}}}}{1+\frac{1}{r}} = \overline{\overset{m}{\mathfrak{ABC}}}$, &c. is the proposition enunciated in No. 81; $\frac{1}{r}$ being the value of the perpetuity (112).

193. Examples of the determination of the single premiums for assurances, and of the derivation of the annual premiums from them, have been given in numbers 82—88, also in 95 and 96; but by the algebraical formulæ given here, the annual premiums may be determined directly, without first finding the total present values of the assurances.

194. *Example* 1. Required the annual premium for an assurance on the life $A$ now 50 years of age, interest 5 *per cent.*

According to No. 185, the operation is thus,

$$\left.\begin{aligned} 1+A &= 12{\cdot}660\ \lambda \\ \frac{1}{1+A} &= {\cdot}0789890\ \kappa \end{aligned}\right\} \bar{2}{\cdot}8975663$$

adding $v = {\cdot}9523809$, and subtracting unity,

we have $\odot\, \mathfrak{A} = {\cdot}0313699$, agreeably to No. 85.

195. *Ex.* 2. What should the annual premium be for an assurance on the last survivor of three lives $A, B, C$, now aged 50, 55, and 60 years respectively, rate of interest 5 *per cent.*?

Operation by No. 188.

$$\left.\begin{aligned} (68)\ 1+\overline{\text{ABC}} &= 15{\cdot}001\ \lambda \\ \frac{1}{1+\overline{\text{ABC}}} &= {\cdot}0666622\ \kappa \end{aligned}\right\} \bar{2}{\cdot}8238798$$

$$v = {\cdot}9523809$$

$\odot\,\overline{\mathfrak{ABC}} = {\cdot}0190431$, agreeably to No. 88.

196. *Ex.* 3. Required the annual premium for an assurance for 10 years only, on a life now 45 years of age, interest 5 *per cent.*

Operation according to No. 186.

$$\begin{aligned} v^{10} &= {\cdot}613913\ \lambda\ \bar{1}{\cdot}7881068 \\ {}^{10}a &= 4073\ \lambda\ 3{\cdot}6099144 \\ a &= 4727\ \kappa\ \bar{4}{\cdot}3254144 \\ \hline {}_{10}av^{10} &= {\cdot}528976\ \lambda\ \bar{1}{\cdot}7234356 \\ 1+{}^{10}A &= 11{\cdot}347\ \lambda\ 1{\cdot}0548811 \\ \hline \text{Subtract}\quad & 6{\cdot}002\ \lambda\ 0{\cdot}7783167 \\ \text{from } 1+A &= 13{\cdot}648 \\ \hline \text{remains}\quad & 7{\cdot}646\ \kappa\ \bar{1}{\cdot}1165657 \\ 1-{}_{10}av^{10} &= {\cdot}471024\ \lambda\ \bar{1}{\cdot}6730430 \\ \hline & {\cdot}061604\ \lambda\ \bar{2}{\cdot}7896087 \\ v &= {\cdot}952381 \end{aligned}$$

$\odot\ {}_{\overline{10|}}\mathfrak{A} = .013985$, agreeably to No. 96.

What has been advanced from numbers 99 to 109, needs no algebraical illustration. (υ.)

# TABLE I.

Showing the present Value of One Pound to be received at the End of any Number of Years not exceeding 50.

(See No. 9——12 of the preceding Article.)

| Years. | 2 per Cent. | 2½ per Cent. | 3 per Cent. | 4 per Cent. | 5 per Cent. | 6 per Cent. | 7 per Cent. | 8 per Cent. | 9 per Cent. | Years |

# ANNULOSA.*

General Arrangement.

The Linnean arrangement of the Animal Kingdom has, with some slight emendations, been adopted as the ground-work of the zoological articles contained in the later editions of the *Encyclopædia*. In these Supplemental volumes, we propose to introduce all the recent discoveries in Zoology, and also to avail ourselves of the opportunity thus afforded, of describing the various classes of animals under an arrangement more accordant to the improved views of Science, and to the Order of Nature. We shall have occasion fully to explain the principles upon which our system is founded, in the article Zoology. At present, it is only necessary to mention, that all the different branches of this grand department of Natural History will be treated of under these heads; *viz.* Annulosa, Cirrhipedes, Insecta, Mollusca, Radiata, and Vertebrosa. From these heads, references will be made to the zoological articles in the body of the work, and also from the older names to the corresponding appellations in the arrangement adopted in these volumes.

The term Annulosa (from *Annulus*, a ring or segment), is applied to animals whose bodies are more or less divided transversely into segments.

General Arrangement.

This type of animals was proposed in one of the last volumes of the *Annales de Muséum*, by M. G. Cuvier. It comprehends *five* classes, the classification of which will form the subject of the present article.†

As the leading characters of the classes are very obvious, we shall, in the first place, lay them before our readers through the medium of a table, and shall then detail them more fully.

Class 1. Crustacea. Branchiæ or gills for respiration. Legs ‡ for motion.

Class 2. Myriapoda. || Tracheæ or air-tubes for respiration. Legs more than eight. Head distinct from the thorax. Antennæ two.

Class 3. Arachnides. Tracheæ for respiration. Legs eight or six. Head not distinct from the thorax. Antennæ none.

Class 4. Insecta. Tracheæ for respiration. Legs six. Head distinct from the thorax. Antennæ two.

Class 5. Vermes. Tracheæ for respiration. Legs none. Antennæ none.

## Class I.—CRUSTACEA.

### *History.*

All the Crustacea, as their name imports, are enveloped in a crust or shell (*crusta*). Many of the larger species were known to ancient Naturalists. They were named Crustacea by the Latins, Malacostracoi (Μαλακόστρακοι) by the Greeks. Aristotle has dedicated a chapter to the species known to him; Athenæus enumerates those used as food; and Hippocrates has made mention of such species as were considered useful in medicine.

To the observations of Aristotle, very little was added by Pliny; and from his time until that of Rondeletius, Belon, Gesner, Aldrovandus, and Johnson, who placed the Crustacea between the Fishes and Mollusca, little or nothing was done that tends in any way to elucidate the natural history or structure of these animals.

By the great reformer Linné, they were arranged under the genera Monoculus, Cancer, and Oniscus, along with apterous insects; but the most prejudiced of his followers now admit that they have characters sufficient to establish them as a distinct class.

J. C. Fabricius, a pupil of Linné, divided the Crustacea from insects, and formed several distinct classes for their reception; but as he has altered his system in his different works, it seems necessary only to state the last, which is given in the Supplement to his *Entomologia Systematica*. In this work is the following arrangement:

Class Polygonata. Many maxillæ within the lip.

Gen. 1. Oniscus, 2. Ligia, 3. Idotea, 4. Cymothoa, 5. Monoculus.

Class Kleistagnatha. Many maxillæ, closing the mouth. Lip none.

Gen. 1. Cancer, 2. Calappa, 3. Ocypode, 4. Leucosia, 5. Parthenope, 6. Inachus, 7. Dromia, 8. Dorippe, 9. Orithyia, 10. Portunus, 11. Matuta, 12. Hippa, 13. Symethis, 14. Limulus.

Class Exochnata. Many maxillæ outside the lip, covered by the palpi.

Gen. 1. Albunea, 2. Scyllarus, 3. Pallinurus, 4. Palæmon, 5. Alpheus, 6. Astacus, 7. Penæus, 8. Crangon, 9. Pagurus, 10. Galathea, 11. Squilla, 12. Posydon, 14. Gammarus.

Before the publication of this work, Müller (in

* The animals which compose this type are partly treated of in the Articles Entomology and Helminthology of the *Encyclopædia*.

† For the comparative characters of this type, see Zoology. In the present article, we propose to give the characters and economy of the Genera, and an example of one Species of each, with the exception of Insecta, which will be treated of under that head in a separate article.

‡ By this term, we mean those organs which actually perform the functions of legs. On this subject more will be said under the article Zoology.

|| This class was instituted by Dr Leach. Latreille comprehended the animals composing it under the general denomination Arachnides.

Crustacea. 1792) produced his celebrated work on the *Entomostraca*, which contains several crustaceous genera, which he disposed into the following groups.

Division I. MONOCULI. With but one eye.

* *Shell univalve.*

Gen. 1. Amymone, 2. Nauplius. (These two genera, Jurine of Geneva has discovered to be but larvæ of the genus Cyclops of Müller.)

** *Shell bivalve.*

Gen. 3. Cypris, 4. Cythere, 5. Daphnia.

*** *Shell composed of a solid crust.*

Gen. 6. Cyclops, 7. Polyphemus.

Div. II. BINOCULI. With two eyes.

* *Shell univalve.*

Gen. 8. Argulus, 9. Caligus, 10. Limulus.

** *Shell bivalve.*

Gen. 11. Lynceus.

A great portion of the species, composing the Entomostraca of Müller, were described by the microscopic observers, Joblot, Frish, Réaumur, De Geer, Baker, Ledermüller, and Geoffroy, and were by the latter author arranged into two genera, which he named Binoculus and Monoculus.

By that learned anatomist G. Cuvier, the Crustacea were considered as forming a class, which he placed between the Vermes and Insecta. This indefatigable observer discovered, that the Crustacea breathed by branchiæ or gills, and he disposed them into three great sections, viz.

I. MONOCULUS, including the genera, 1. Limulus, 2. Caligus, 3. Cyclops, 4. Apus, 5. Polyphemus of Müller:

II. CANCER, comprehending the genera, 6. Cancer, 7. Inachus, 8. Astacus, 9. Palinurus, 10. Squilla, 11. Scyllarus of Fabricius:

III. ONISCUS, including, 12. Physodes, 13. Oniscus, 14. Cymothoa of Fabricius.

Lamarck, in his *Systême des Animaux sans Vertebres,* has disposed the Crustacea into the two following orders, viz.

Ord. I. CRUSTACE'S PE'DIOCLES, including the genera, * 1. Cancer, 2. Calappa, 3. Ocypode, 4. Grapsus, 5. Dorippe, 6. Portunus, 7. Podophthalmus, 8. Matuta, 9. Maja, 10. Porcellana, 11. Leucosia, 12. Arctopsis, ** 13. Albunea, 14. Hippa, 15. Ranina, 16. Scyllarus, 17. Astacus, 18. Pagurus, 19. Galathea, 20. Palinurus, 21. Crangon, 22. Palæmon, 23. Squilla, 24. Branchiopoda.

Ord. II. CRUSTACE'S SESSILIOCLES, * 25. Gammarus, 26. Asellus, 27. Caprella, 28. Oniscus, 29. Cyamus, 30. Ligia, 31. Cyclops, ** 32. Polyphemus, 33. Limulus, 34. Daphnia, 35. Amymone, 36. Cephaloculus. With the second section, Lamarck has placed the genus Forbicina (Lepisma saccharina of Linné), which, in our opinion, belongs to the genuine class Insecta.

By Dumeril (*Zoologie Analatique*), these animals are placed in two orders, which are divided into families.

Ord. I. ENTOMOSTRACE'S.

*Fam.* 1. ASPIDIOTES. Gen. 1. Limulus, 2. Calius, 3. Binoculus, 4. Ozolus, 5. Apus.

*Fam.* 2. OSTRACINS. Gen. 6. Lynceus, 7. Daphnia, 8. Cypris, 9. Cythere.

*Fam.* 3. GYMNONECTES. Gen. 10. Argulus, 11. Cyclops, 12. Polyphemus, 13. Zöe, 14. Branchiopoda. Crustacea.

Ord. II. ASTACOIDES.

*Fam.* 4. CARCINÖIDES. Gen. 15. Calappa, 16. Hepatus, 17. Dromia, 18. Cancer, 19. Matuta, 20. Portunus, 21. Podophthalmus, 22. Porcellana, 23. Ocypode, 24. Grapsus, 25. Pinnotheres.

*Fam.* 5. OXYRINQUES. Gen. 26. Maja, 27. Leucosia, 28. Dorippe, 29. Orithyia, 30. Ranina.

*Fam.* 6. MACROURES. Gen. 31. Pagurus, 32. Albunea, 33. Hippa, 34. Scyllarus, 35. Palinurus, 36. Galathea, 37. Astacus, 38. Penæus, 39. Palæmon, 40. Crangon.

*Fam.* 7. ARTHROCE'PHALES. Gen. 41. Squilla, 42. Mysis, 43. Phronima, 44. Talitrus, 45. Gammarus.

The genera, 46. Oniscus, 47. Physodes, and 48. Armadillo, he has placed with apterous insects.

Bosc, in his *Histoire Naturelle des Crustacés,* has adopted, with some slight modifications, the system of Lamarck: he divides the Crustacea into two sections, viz.

Sec. I. CRUSTACE'S PE'DIOCLES. Eyes pedunculated.

*Div.* 1. Body short; tail flat, simple, applied against the lower part of the abdomen.

Gen. 1. Cancer, 2. Calappa, 3. Ocypode, 4. Grapsus, 5. Dorippe, 6. Portunus, 7. Podophthalmus, 8. Orithyia, 9. Matuta, 10. Dromia, 11. Porcellana, 12. Leucosia, 13. Pinnotheres, 14. Maja.

*Div.* 2. Body oblong; tail elongated, terminated with appendices.

Gen. 15. Albunea, 16. Posydon, 17. Hippa, 18. Ranina, 19. Scyllarus, 20. Astacus, 21. Pagurus, 22. Galathea, 23. Palinurus, 24. Crangon, 25. Palæmon, 26. Alpheus, 27. Penæus, 28. Squilla, 29. Branchiopoda.

Sec. II. CRUSTACE'S SESSILIOCLES. Eyes sessile.

*Div.* 1. Body covered with several crustaceous segments.

Gen. 1. Zöe, 2. Gammarus, 3. Talitrus, 4. Caprella, 5. Asellus, 6. Idotea, 7. Sphæroma, 8. Ligia, 9. Cyamus, 10. Cymothoa, 11. Cyclops, 12. Bopyrus.

*Div.* 2. Body covered with a crustaceous shield, composed of one or two parts.

Gen. 30. Caligus, 31. Binoculus, 32. Limulus, 33. Apus, 34. Daphnia, 35. Cythere, 36. Cypris, 37. Polyphemus.

We shall now give the system of Latreille, published in his *Considérations Générales.*

Order I. ENTOMOSTRACA.

*Fam.* 1. ASPIDIOTA. Gen. 1. Limulus, 2. Apus, 3. Caligus, 4. Binoculus.

*Fam.* 2. OSTRACODA. Gen. 5. Lynceus, 6. Daphnia, 7. Cypris, 8. Cythere.

*Fam.* 3. GYMNOTA. Gen. 9. Cyclops, 10. Polyphemus, 11. Zöe, 12. Branchiopoda.

Ord. II. MALACOSTRACA.

*Fam.* 1. CANCERIDES. Gen. 13. Podophthalmus, 14. Portunus, 15. Dromia, 16. Cancer, 17. Hepatus, 18. Calappa, 19. Ocypode, 20. Grapsus, 21. Plagusia, 22. Pinnotheres.

*Fam.* 2. Oxyrinchi. Gen. 23. Dorippe, 24. Mictyris, 25. Leucosia, 26. Corystes, 27. Lithodes, 28. Maja, 29. Macropus, 30. Orithyia, 31. Matuta, 32. Ranina.

*Fam.* 3. Pagurii. Gen. 33. Albunea, 34. Remipes, 35. Hippa, 36. Pagurus.

*Fam.* 4. Palinurini. Gen. 37. Scyllarus, 38. Palinurus, 39. Porcellana, 40. Galathea.

*Fam.* 5. Astacini. Gen. 41. Astacus, 42. Thalassina, 43. Alpheus, 44. Penæus, 45. Palæmon, 6. Crangon.

*Fam.* 6. Squillares. Gen. 46. Squilla, 47. Mysis.

*Fam.* 7. Gammarinæ. Gen. 48. Phronima, 49. Gammarus, 50. Talitrus, 51. Corophium, 52. Caprella, 53. Cyamus.

Some other animals which we consider as genuine Crustacea, he has arranged with the class Arachnides; and has formed an order for their reception, named Tetracea, which he has divided into two families, viz.

*Fam.* 1. Asellota. Gen. 54. Asellus, 55. Idotea, 56. Cymothoa, 57. Sphæroma.

*Fam.* 2. Oniscides. Gen. 58. Ligia, 59. Philoscia, 60. Oniscus, 61. Porcellio, 62. Armadillo.

In the article *Crustaceology* of the *Edinburgh Encyclopædia*, Dr Leach gave the system of Latreille, with some modifications; and arranged with the Crustacea those animals which he afterwards separated as a distinct class under the title *Myriapoda*. We shall now lay before our readers a sketch of the system there proposed, as altered by the remarks in the Appendix to that article.

Class. CRUSTACEA.

Subclass I. Entomostraca.

Tribe I. Thecata. Shell shield-shaped.

*Fam.* 1. Xiphosura. Gen. 1. Limulus.

*Fam.* 2. Pneumonura. Gen. 2. Caligus, 3. Binoculus.

*Fam.* 3. Phyllopoda. Gen. 4. Apus.

Tribe II. Ostracoda. Shell bivalve.

*Fam.* 1. Monophthalma. Gen. 5. Lynceus, 6. Daphnia, 7. Cypris, 8. Cythere.

Tribe III. Gymnota. Shell naked.

*Fam.* 1. Pseudopoda. Gen. 9. Cyclops.

*Fam.* 2. Cephalota. Gen. 10. Polyphemus, 11. Zöe, 12. Branchiopoda.

Subclass II. Malacostraca.

Order I. Brachyura.

*Tribe* 1. Cancerides. Gen. 13. Podophthalmus, 14. Lupa, 15. Portunus, 16. Carcinus, 17. Portumnus, 18. Cancer, 19. Xantho, 20. Atelecyclus, 21. Dromia, 22. Hepatus, 23. Ocypode, 24. Uca, 25. Gonoplax, 26. Gecarcinus, 27. Grapsus, 28. Plagusia, 29. Pinnotheres.

*Tribe* 2. Oxyrynchi. Gen. 30. Leucosia, 31. Maja, 32. Parthenope, 33. Hyas, 34. Eurynome, 35. Blastus, 36. Pisa, 37. Inachus, 38. Macropodia (falsely written Septopodia), 39. Megalopa, 40. Corystes, 41. Mictyris, 42. Dorippe, 43. Orithyia, 44. Matuta, 45. Ranina.

Order II. Macroura.

*Tribe* 1. Pagurii. Gen. 46. Albunea, 47. Remipes, 48. Hippa, 49. Pagurus.

*Tribe* 2. Palinurii. Gen. 50. Scyllarus, 51. Palinurus, 52. Porcellana, 53. Galathea.

*Tribe* 3. Astacini. Gen. 54. Astacus, 55. Nephrops, 56. Thalassina, 57. Gebia (misprinted Upogebia), 58. Callianassa, 59. Alpheus, 60. Hippolyte, 61. Pandalus, 62. Penæus, 63. Palæmon, 64. Athanas, 65. Crangon, 66. Mysis (repeated under the generic title Praunus).

Order III. Gasteruri.

*Tribe* 1. Gnathides. Gen. 67. Gnathia.

*Tribe* 2. Gammerides. Gen. 68. Talitrus, 69. Orchestia, 70. Dexamine, 71. Leucothöe, 73. Melita, 74. Mæra, 75. Gammarus, 76. Ampithöe, 77. Pherusa, 78. Corophrium, 79. Podocerus, 80. Jassa.

*Tribe* 3. Phronimarides. Gen. 81. Phronima.

*Tribe* 4. Caprellides. Gen. 82. Cyamus, 83. Caprella, 84. Proto.

*Tribe* 5. Apseudides. Gen. 85. Apseudes.

*Tribe* 6. Asellides. Gen. 86. Anthura, 87. Campecopea, 88. Nesæa, 89. Cymodoce, 90. Dynamene, 91. Sphæroma, 92. Cymothoa, 93. Limnoria, 94. Idotea, 95. Stenosoma, 96. Jæra, 97. Janira.

*Tribe* 7. Oniscides. Gen. 98. Ligia, 99. Philoscia, 100. Oniscus, 101. Porcellio, 102. Armadillo.

Lamarck, in his *Extrait du Cours de Zoologie du Muséum d'Histoire Naturelle*, &c. has given the following classification of these animals:

Order I. Cryptobrancha.

Section I. Brachyuri.

* *Body broader than long, rounded or truncated anteriorly.*

Cancerides.

*a Shore Crabs.*

Genus 1. Cancer, 2. Dromia, 3. Hepatus, 4. Calappa, 5. Ocypode, 6. Grapsus, 7. Plagusia, 8. Pinnotheres.

*b Swimming Crabs.*

Genus 9. Podophthalmus, 10. Portunus, 11. Matuta, 12. Orithyia.

** *Body subtriangular, terminated anteriorly in a point.*

Oxyrhynci.

Genus 13. Dorippe, 14. Leucosia, 15. Macropus, 16. Arctopsis, 17. Maja.

Section II. Macrouri.

* *Tail furnished with ciliæ or hooks.*

Pagurii.

Genus 18. Porcellana, 19. Corystes, 20. Ranina, 21. Albunea, 22. Hippa, 23. Pagurus.

** *Tail furnished with swimming scales.*

Astacini.

Genus 24. Scyllarus, 25. Palinurus, 26. Astacus, 27. Galathea, 28. Crangon, 29. Alpheus, 30. Palæmon.

Order II. Gymnobrancha.

Section I. Pediocculi.

Squillarii.

Genus 31. Squilla, 32. Mysis, 33. Branchiopoda.

Section II. Sessioculi.

Genus 34. Caprella, 35. Phronima, 36. Gammarus, 37. Asellus, 38. Idotea, 39. Cymothoa, 40. Sphæroma, 41. Ligia, 42. Oniscus, 43. Cyamus.

Section III. Entomostraca.

1. *With two eyes.*

Genus 44. Polyphemus, 45. Limulus, 46. Caligus, 47. Ozolus, 48. Zöe, 49. Lynceus.

2. *With one eye.*

Genus 50. Daphnia, 51. Cytherea, 52. Cypris, 53. Cyclops, 54. Cephaloculus.

Having given a sketch of the systems adopted by these authors, we shall proceed to detail that proposed by Dr Leach in the Second Part of the eleventh Volume of the *Transactions of the Linnean Society of London*.

*Classification.*

Subclass I. Entomostraca. *Legs* branchial, or furnished with appendages. *Mandibles* wanting or simple. *Eyes* sessile or pedunculated.

Subclass II. Malacostraca. *Legs* simple, without appendages. Mandibles palpigerous. *Eyes* pedunculated or sessile.

### Subclass I. ENTOMOSTRACA.

The animals of this subclass are but little known, and consequently their arrangement is extremely imperfect. Some of the genera are parasitic, being found on the bodies of other animals, and some even undergo transformation during their growth.

The following arrangement is artificial; but is well calculated to enable the student to discover the genera.

*Synopsis of the Genera.*

Division I. Body covered by a horizontal shield. Eyes sessile.

*Subdivision* 1. Shield composed of two distinct parts.

Gen. 1. Limulus.

*Subdivision* 2. Shield composed of but one part.

* *With jaws.*

Gen. 2. Apus.

** *With a rostrum, but no jaws.*

*a* Antennæ, four.

Gen. 3. Argulus.

*b* Antennæ, two.

4. Cecrops, 5. Caligus, 6. Pandarus, 7. Anthosoma.

Division II. Body covered by a bivalve shell. Eyes sessile.

*Subdivision* 1. Head porrected.

Gen. 8. Lynceus, 9. Chydorus, 10. Daphnia.

*Subdivision* 2. Head concealed.

Gen. 11. Cypris, 12. Cythere.

Division III. Body covered neither by a bivalve shell or shield. Eye one, sessile.

Gen. 13. Cyclops, 14. Calanus, 15. Polyphemus.

Division IV. Body covered by neither a bivalve shell or shield. Eyes pedunculated.

Gen. 16. Branchiopoda.

#### Division I. *Subdivision* 1.

Gen. 1. Limulus, *Müller, Fabr.* &c.

Xiphosura, *Gronovius.*

Polyphemus, *Lamarck.*

*Shell* coriaceous, rounded in front, narrower behind; *anterior shell* largest, somewhat lunate, convex, with three carinæ or keels; *eyes* two, ovate, very small, and scarcely prominent, one on each side of the lateral carina; *hinder shell* somewhat triangular, truncate-marginate, the sides toothed, having a moveable spine between each tooth; *tail* horny, three-sided, articulated to the notched extremity of the second shell by a hinge-like joint.

*Antennæ* none.

*Mandibles* two, two-jointed, inserted under the anterior margin of the shell, their bases meeting; the second joint furnished with a moveable thumb-like process.

*Legs* ten, didactyle; fifth pair longest, the last joint but one with its extremity bearing elongate lamellæ; anterior legs internally spinose near their base.

All the Limuli inhabit the sea. *Monoculus Polyphemus* of Linné belongs to the genus.

*Limulus heterodactylus* and *L. virescens* of Latreille, probably form two distinct genera, belonging to the same subdivision.

Sp. 1. *Sowerbii.* Anterior shell with seven spines, arranged 1, 3, 3; hinder shell with five, 3, 1, 1, the lateral spines elongate and simple; tail above somewhat spinulose.

Limulus Sowerbii. *Leach, Zool. Miscel.* ii. 72. tab. 84.

The locality of this species, which is extremely common, is unknown.

*Subdivision* 2. *

Gen. 2. Apus. *Cuvier, Latreille, Leach.*

Apos, *Scopoli.*

*Shell* crustaceous-membranaceous, orbiculate-ovate, behind deeply emarginate; the back, with the exception of the anterior part, carinated; *eyes* two, inserted at the anterior and middle part of the back, somewhat prominent, slightly lunate, approaching each other, especially anteriorly where they touch each other.

*Antennæ* two, short, somewhat filiform, biarticulated, scarcely esserted, inserted behind the mandibles.

*Mandibulæ* two, corneous, somewhat cylindric, short, hollow within, points arcuated and compressed, the extreme apex strait and very much denticulated.

*Legs* branchial and very numerous.

The Api inhabit stagnant waters and ponds their anterior legs are spiny at the base, like those of the Limuli.

Sp. 1. *Montagui.* Carina of the shell produced into a point behind; anterior legs with articulated setæ; no lamella between the caudal setæ.

Plate XX. fig. 1. *Apus Montagui*, natural size; 2. anterior leg magnified; 3. part of one of the setæ of the anterior leg highly magnified; 4. setæ of the tail magnified.

Inhabits England, near Christ-church in Hampshire, where it was discovered by Montagu, who sent it to Dr Leach as the Linnean *Monoculus apus.*

*Apus productus* of Latreille, is synonymous with the Linnean *Monoculus apus.*

*Subdivision* 2. ** *a.*

Gen. 3. Argulus, *Müller, Jurine, Leach.*

Binoculus, *Geoffroy, Latreille.*

*Shell* oval, somewhat membranaceous, semi-transparent, anteriorly rounded, behind deeply notched; *eyes* two, hemispheric, inserted at the anterior and lateral parts of the clypeus.

*Antennæ*, very small, inserted above the eyes.

*Rostellum* sterniform.

*Legs* twelve, unequal in size and form; *first pair* shorter, very membranaceous, capable of changing their form, broader at their tips, and formed for adhering to objects; *second pair* prehensile, curved, much thicker towards their base, the thighs furnished with three spinules beneath; tarsi three-jointed, the last joint with two claws and a pulvillus; *four hinder pair* inserted at the sides of the abdomen, somewhat cylindric, formed for swimming, with their points bifid.

*Abdomen* cylindric; *tail* bilobate.

Sp. 1. *Foliaceus*, Jurine.

Argulus delphinus. *Müll. Entom.* 123.
Monoculus argulus. *Fabr. Ent. Syst.* ii. 489.
Monoculus gyrini. *Cuv. Tab. Elém.* 454.
Binoculus gasterostei. *Latr. Gen. Crust. et Ins.*
Argulus foliaceus. *Jurine, An. de Museum*, vii. 451.
Argulus argulus. *Leach, Edin. Encycl.* vii. 388.

This species, which is the only one of the genus that has hitherto been noticed, inhabits ponds and rivulets, adhering to the larvæ of frogs and to fishes.

The larva has been described by Müller as a destinct species, under the name *Argulus charon:* in this state it differs from the full grown animal in size, and in having four cylindric, equal, biarticulated, penicillated oars, two of which are attached to the animal above the eyes, and are furnished at their tips with four setæ, the other two below the eyes being terminated with three setæ: The two anterior legs are incrassated, elongated, and terminated by a strong bent claw.

The full grown animal lays from one to four hundred eggs, which are ovate and smooth, being generally deposited on stones in two contiguous longitudinal series. These eggs are hatched in about thirty days.

*Subdivision* 2. ** b.

Gen. 4. Cecrops. New Genus.

*Shell* coriaceous-membranaceous, composed of two parts; the *anterior segment* inverse heart-shaped, deeply and obtusely notched behind; anteriorly notched; the laciniæ rounded and externally bearing the antennæ. *Antennæ* two-jointed, the first joint largest, thickest, the second bearing at its point a simple seta; *hinder segment* smaller, inversely heart-shaped, occupying the notch of the anterior segment.

*Abdomen* of the breadth of the shell, notched behind.

*Rostrum* elongate-conic, perpendicular, inserted between the middle and anterior legs; having on each side of its base a moveable ovate appendage.

*Legs* six; *anterior pair* biarticulated with a strong curved claw; *second pair* triarticulate, more slender, the last joint double, the exterior joint shortest; *third* pair strong, uniarticulate, with a very strong claw. *Four legs* spurious, placed behind the others, double, the double parts biarticulate, situated on a common coxa.

Female with two large ovate connected bags of a coriaceous substance, situated beneath the abdomen and projecting behind, in which she carries her eggs.

Sp. 1. *Latreillii.*

Plate XX. fig. 1. male; 2. female; 3. under side of male; 4. under side of female; 5. antennæ magnified, 6. Anterior leg magnified; 7. hinder leg magnified; 8. middle leg.

Of this curious animal the history is unknown. That it is parasitic its structure evidently shows, and from analogy we may infer, that it is an inhabitant of the ocean, and that it attaches itself to the larger marine animals. There are several specimens preserved in the British Museum.

Gen. 5. Caligus, *Müll. Latr. Bosc*, &c.

*Shell* coriaceous-membranaceous, bipartite; the anterior segment inversely cordiform, very deeply notched behind (the notch receiving the hinder segment, which is round), the anterior part subproduced, notched; the laciniæ at their base externally bearing antennæ; *antennæ* biarticulate, the first joint thickest, the second with a simple seta at its extremity.

*Abdomen* narrower than the thorax; with its base contracted and bearing the hinder legs, its extremity on each side with a rounded process of the length of the body. *Rostrum* rounded, rather more slender towards its apex, which is obtuse. *Legs* fourteen; anterior, second, and fourth pairs with a strong claw; the second pair short; the third slender elongate, the last joint double, with unequal laciniæ; the fifth with the last joint on one side setose, the setæ ciliated on each side; the sixth with a double triarticulated tarsus, the last joints on each side setose, the setæ ciliated on each side; the seventh part with its last joint trifid.

The hinder segment of the thorax beneath, terminated by a large broad lamella, ciliated behind.

*Caligus curtus* of Müller, forms the type of this genus.

Sp. 1. *Mülleri.*

Plate XX. fig. 1. Natural size; 2. magnified; 3. seventh leg; 4. fifth leg; 5. one of the ciliated setæ of the fifth leg much magnified; 6. third leg; 7. fourth leg; 8. sixth leg.

Inhabits the common cod-fish. It was first sent to us by Dr Spalding, of Edinburgh, to whose kindness we are indebted for several very curious animals.

Gen. 6. Pandarus. New genus.

Caligus, *Müller, Latr. Bosc, Leach*, &c.

*Shell* coriaceous-membranaceous, composed of but one part, deeply notched behind; the angles acute; the middle of the notch toothed; anteriorly narrower, rounded, with a process on each side externally bearing the antennæ. *Antennæ* composed of two joints, the second joint terminated by several setæ. *Abdomen* somewhat narrower than the shell, the base above with two transverse lamellæ, the first of which is four-lobed, the second bilobate; the apex notched, with two filaments, longer than the body, with a lamella at their base above. *Rostrum* elongate, attenuated, inserted behind the anterior legs. *Legs* fourteen; anterior pair short, terminated by a short claw, and arising from beneath an ovate process; second pair with a double unequal tarsus; third pair without any determinate form, without any claw; fourth pair bifid; fifth and sixth pairs bifid, their coxæ connected by a lamella; seventh pair bifid, the exterior lacinia longest, with a notch externally towards its apex.

Sp. 1. *Bicolor.* Shell and the middle of the abdominal lamellæ black; tail with filaments double the length of the body.

Inhabits the *Squalus galeus* of Linné.

Sp. 2. *Boscii.* Body entirely pale, testaceous; tail with filaments once and an half the length of the body.

Inhabits the *Squalus mustelus* of Linné.

Plate XX. fig. 1. *Pandarus Boscii* natural size; 2. magnified; 3. anterior leg magnified; 4. antenna magnified; 5. sixth leg magnified; 6. seventh leg magnified; 7. fifth leg magnified; 8. fourth leg magnified; 9. second leg magnified; 10. third leg magnified.

Gen. 7. Anthosoma. New genus.

*Shell* coriaceous-membranaceous unipartite, rounded before and behind; the anterior part as if unilobate, the lobe higher than the shell, behind on each side, bearing the antennæ; *antennæ* six-jointed. *Abdomen* much narrower than the shell, on every side imbricated with membranaceous foliaceous lamellæ which surround or embrace it. Two of the lamellæ are dorsal, the one being placed over the other; the other lamellæ are placed on the sides of the belly, three on each side; apex of the abdomen terminated by two very long filaments, and with two shorter filaments below them. *Rostrum* elongate cylindric, inserted behind the anterior legs, furnished at its extremity with two strait corneous mandibles. *Legs* six; anterior pair three-jointed, the second joint near the apex above unidentate, the last terminated by a claw; second pair triarticulated, the last joint ovate, compressed; third pair biarticulate, the second joint very thick, internally dentated, armed at its extremity by a strong claw.

Sp. 1. *Smithii.* Plate XX. fig. 1. natural size; 2. two specimens adhering to part of the gill-cover of a shark; 3. antenna magnified; 4. middle leg magnified; 5. hinder leg magnified; 6. anterior leg magnified.

This species was discovered sticking to a shark which was thrown ashore on the coast of Exmouth in Devon, by T. Smith, Esq. of Paper Buildings, Temple. He informed the writer of this article, that it adhered solely by means of its anterior legs to the axillæ and gill-covers, which were much thickened by the inflammation caused by their irritation.

Division II. *Subdivision* 1.

Gen. 8. Lynceus, *Müll. Latr. Bosc, Leach.*

*Eyes* two. *Antennæ* four, capillary.

Sp. 1. *Brachyurus.* Shell globose; tail deflexed.

Lynceus brachyurus.
*Müll. Entomost.* 69. tab. 8. f. 1. 12.
*Bosc, Hist. Nat. des Crust.* ii. 264.
*Leach, Edin. Encycl.* vii. 388.
*Latr. Gen. Crust. et Ins.* i. 17.

Monoculus brachyurus.
*Fabr. Ent. Syst.* ii. 407.

Inhabits marshes; is very common in the spring, moving about with great agility amongst aquatic plants. The female carries her eggs on the posterior and superior part of her belly.

Gen. 9. Chydorus.

Lynceus, *Müll. Latr. Bosc, Leach.*

*Eyes* two. *Antennæ* two, capillary.

Sp. 1. *Sphæricus.* Shell globose; tail inflexed.

Lyncæus sphericus.
*Müll. Entomost.* 71. t. ix. f. 7, 9.
*Latr. Gen. Crust. et Ins.* i. 17.
*Bosc, Hist. Nat. des Crust.* ii. 264.
*Leach, Edin. Encycl.* vii. 388.

Monoculus sphericus.
*Fabr. Ent. Syst.* ii. 497.

Gen. 10. Daphnia.
*Müll. Latr. Bosc, Leach.*

*Eye* one only. *Antennæ* two, branching.

The extraordinary appearance presented by the animals of this genus caused them to be mentioned by Leuwenhoeck, Needham, Swammerdam, and other microscopical investigators. Their shell, although apparently bivalve, is formed but of one piece, open in front. Their head is terminated by a kind of pointed but immoveable beak. Their mouth is placed within the shell. The eye is absolutely single, and not formed by the union of two eyes, and is covered by granules. The number of legs is not known. One of the species is called Pulex caudatus by Schœffer, 1755, t. 1. f. 1. 8. and in the *Encyclopædia Britannica*, Pl. 37. fig. 1, a species is rudely figured as an animalcule.

Sp. 1. *Pulex.* Tail inflexed; shell mucronated behind.

Monoculus pulex.
*Linn. Faun. Suec.* 2047.
*Fabr. Ent. Syst.* ii. 491.

Daphnia pennata.
*Müll. Entom.* 82. t. 12. f. 4. 7.

Daphnia pulex.
*Latr. Gen. Crust. et Ins.* i. 18.
*Leach, Edin. Encycl.* vii. 338.

Inhabits ponds and marshes. Geoffroy (*Hist. des Insect.* ii. 655.) has given a description of this species under the very expressive name of *Monocle le Perroquet d'eau.*

*Subdivision* 2.

Gen. 11. Cypris. *Müll. Latr. Bosc, Leach.*

*Antennæ* terminated by a brush.

Many of the *Cyprides* were noticed by Joblot, Ledermuller, Baker, and De Geer, but they were first reduced to one genus by the illustrious Müller.

The animals of this genus inhabit pools and ditches, containing pure water; they swim with very great rapidity, and, whilst in motion, conceal their whole body within their shell, which is truly bivalve. The members of the body of the cyprides are not known; they move with such quickness whilst living, and are so soft when dead, that it is scarcely possible to investigate their characters more fully. Their antennæ are long, and very flexible; these organs are furnished at their tips with a brush or pencil, composed of hairs. The hinder part of their bodies is formed of a tail, which is almost entirely concealed within their shell. Their head is terminated by an elongate point, and they have but one eye. Of their economy nothing is known, but they have been observed to change their covering like other Entomostraca.

Plate XX. fig. 1. Cypris nephröides natural size; 2. magnified.

Sp. 1. *Conchacea.* Shell ovate, tomentose.

Monoculus conchaceus.
*Linn. Fn. Suec.* 2050.
*Fabr. Ent. Syst.* ii. 496.

Cypris pubera.
*Müll. Entomost.* 56. t. 5. f. 1. 5.

Cypris conchacea.
*Latr. Gen. Crust. et Insect.* i. 18.
*Leach, Edin. Encycl.* vii. 388.
Inhabits France, Germany, and England.

Gen. 12. CYTHERE. *Müll. Latr. Bosc, Leach.*
*Antennæ* simply pilose.

This genus was first discovered and established by Müller, who first observed all the species described in his Entomostraca. It is distinguished from *Cypris* by the antennæ, which are not terminated by a pencil of hairs. The legs are eight in number, and are rarely drawn within the shell, which is really bivalve.

The Cytheres have no tail, and their antennæ, like those of the Cyprides, have their articulations pilose. They have but one eye. All the species inhabit the sea, and may be found among the confervæ and corallines, which fill the pools left by the tide in most of the rocky coasts of Europe.

Sp. 1. *Viridis.* Shell reniform, velvety, and green.
Cythere viridis. *Müll. Entomost.* 64, tab. 7. f. 1. 2.
*Latr. Gen. Crust. et Ins.* i. 19.
*Bosc, Hist. Nat. des Crust.* ii. 261.
*Leach, Edin. Encycl.* vii. 388.
Inhabits the European Ocean. Is occasionally found on the shores of Scotland amongst fuci and confervæ.

Division III.

Gen. 13. CYCLOPS, *Müll. Lam. Latr. Bosc, Leach.*
*Body* ovate-conic, elongate. *Eye* one, situated on the thorax. *Antennæ* four, simple. *Legs* eight.

All the animals of this genus inhabit fresh waters. The females carry their eggs in a pouch resembling a bunch of grapes on each side of the tail. The organs of generation of the male are placed in the antennæ; those of the female beneath the belly, at the base of the tail, which is abruptly narrower than the abdomen. The antennæ are hairy at the base of their joints.

Sp. 1. *Geoffroyii.* Tail strait and bifid; colour brownish.
Monoculus quadricornis.
*Linn. Fn. Su.* 2049.
*Fabr. Entom. Syst.* ii. 500.
Cyclops quadricornis.
*Müll. Entomost.* 109. t. 18. f. 1. 14.
*Latr. Gen. Crust. et Insect.* i. 19.
*Bosc, Hist. Nat. des Crust.* ii. 228. pl. 18. f. 4. female.
*Leach, Edin. Encycl.* vii. 388.
Inhabits Europe. Is very common in fresh waters. Geoffroy, in his *Histoire Naturelle des Insectes* (tom. ii. 656. pl. 21. f. 5.), has described and figured this species under the title *Le Monocle à queue fourchue.* It was first noticed by Leuwenhoeck, and his observations were afterwards increased by those of Baker, Roesel, and De Geer.

Gen. 14. CALANUS.
CYCLOPS, *Müll. Latr. Bosc, Leach.*
*Body* ovate conic, elongate. *Eye* one, situated on the thorax. *Antennæ* two, simple. *Legs* eight.
Cyclops longicornis.
*Müll. Entomost.* 115. t. 19. f. 7, 9.
*Latr. Gen. Crust. et Insect.* i. 20.
*Bosc, Hist. Nat. des Crust.* ii. 229.
*Leach, Edin. Encycl.* vii. 389.
Monoculus longicornis.
*Fabr. Ent. Syst.* ii. 501.
Inhabits the Norwegian and German Ocean. It was first discovered by the celebrated Gunnerus in the Finmarchian Sea, and was described by Müller in his *Zoologiæ Danicæ Prodromus*, under the title Cyclops Finmarchicus, which name he afterwards changed in his *Entomostraca.*

Gen. 15. POLYPHEMUS, *Müll. Latr. Bosc, Leach.*
CEPHALOCULUS. *Lamarck.*
*Eye* one, forming the head; *legs* ten; two bifid, elongate, and extended horizontally.

This genus, containing one species, was established by Müller. Naturalists have generally considered it as the larva of some other genus, but the multiplied observations of Müller, Lamarck, and Bosc, have cleared up all doubts on the subject, and it is now generally admitted as a distinct and perfect animal. The head is round, distinct from the thorax, and apparently composed of one large eye. The body is divided into two parts by a kind of contraction; the anterior part contains the legs and tail; the posterior part contains only the eggs and the young. The tail is long, and is attached to the under part of the body, being terminated by two setæ.

The *polyphemus* inhabits marshes and moves quickly by the combined efforts of its short legs and bifid oars, generally swimming on its back.

Sp. 1. OCULUS. Body luteous, with a few blue spots.
Polyphemus oculus.
*Müll. Entom.* 119. pl. 20, f. 1. 5.
*Latr. Gen. Crust. et Insect.* i. 20.
*Bosc, Hist. Nat. des Crust.* ii. 290. pl. 18. f. 5. 6.
*Leach, Edin. Encycl.* vii. 389.
Cephaloculus stagnorum.
*Lam. Syst. des Anim. sans Vert.* 170.
Inhabits lakes and marshes. In the *Edinburgh Encyclopædia*, Dr Leach stated it as probable that there were several species that had been confounded with *P. oculus;* but repeated observations have since convinced him of the error of this conjecture, and led to the conclusion that there is but one, which is subject to very considerable variation in size and colour.

Division IV.

Gen. 16. BRANCHIOPODA,
*Lam. Latr. Bosc, Leach.*
*Body* filiform and very soft. *Head* divided from the thorax by a very narrow but distinct neck. *Eyes* two, lateral. *Antennæ* two, short, two-jointed, capillary inserted behind and above the eyes. *Front* with two moveable processes (which are broader towards the apex in the male sex), that are notched, those of the female furnished with a papilla at their point.

*Subsidiary Observations.* In the front of the male, at the base of the moveable processes on the front, are two long hair-like filaments, and the clypeus is, as it were, double. In both sexes, the mouth is armed with a hooked rostriform papilla, supported by four little processes. The trunk of the body is keel-shaped, and is formed of eleven joints, each of which is furnished with two branchial feet, the anterior pair with two, the posterior pairs with three lamellæ. The tail is about the length of the body, composed of

six or nine obscure joints, the oval segment bearing two fins.

The organs of generation are situate at the base of the tail.

Sp. 1. *Stagnalis.* Body transparent, of a light brown colour, slightly tinged with green or blue, particularly on the head and legs.

Cancer stagnalis. *Linn. Fn. Su.* 2043.

Branchiopoda stagnalis.

*Lam. Syst. des Anim. sans Vert.* 161.

*Latr. Gen. Crust. et Ins.* i. 22.

*Leach, Edin. Encycl.* vii. 389.

We shall transcribe the ingenious observations made on this species by the late Dr Shaw of the British Museum, published in the first volume of the *Transactions of the Linnean Society of London.*

"It is generally found in such waters as are of a soft nature, and particularly in those shallows of rain-water which are so frequently seen in the spring and autumn, and in which the *Monoculus pulex* of Linnæus, and other small animals, abound. At first sight, it bears some resemblance to the larva of a dytiscus; but, when viewed closely, it is found to be of a much more curious and elegant appearance than that animal. The legs, of which there are several pair (eleven?) on each side, are flat and filmy, and have the appearance of so many waving fins, of the most delicate structure imaginable. The whole animal is extremely transparent, and the general colour is brown, slightly tinged with blueish-green.

"*Monoculus conchaceus* of Linnæus very frequently assaults them, and adheres with such force to their tails and legs, as sometimes to tear off a part in the struggle. It delights much in sunshine, during which it appears near the surface of the water, swimming on its back, and moving in various directions, by the successive undulations of its numerous fin-like legs, and moving its tail in the manner of a rudder. On the least disturbance, it starts in the manner of a small fish, and endeavours to secret itself, by diving in the soft mud. It changes its skin at certain periods, as is evident from the exuviæ or shoughs being frequently found in the water in which these animals are kept.

"In March and April, the females deposit their eggs without any settled order, and perfectly loose in the water. They appear to the naked eye, like very minute globules of a light brown colour. Each ovum, when magnified, closely resembles the farina of a mallow. It is thickly beset with spines on every side, and coated over with a transparent gelatinous substance, reaching just to the extremities of the spines, and is most probably intended to assist in causing them to adhere to the substances on which they may chance to fall, or as a security from the attacks of smaller animals. In about a fortnight or three weeks, the eggs are hatched, and the young animals may be seen to swim with great liveliness, by means of three very long pair of arms or rowers, which appear disproportionate to the size of the animal, and indeed it bears, in this very small state, not much resemblance to the form it afterwards assumes; but, in the short space of a very few hours, the body assumes a lengthened form, and begins to acquire the tail-fin. The eyes in this state do not appear pedunculated. On the seventh day after hatching, they approach pretty nearly the form of the perfect animal; they, however, still retain the two first pairs of rowers or arms. The legs are at this period very visible. About the ninth day it loses the long oars, and appears still more like the animal in its advanced state."

The Doctor farther observes, that it is highly probable, that a considerable time elapses before the animal assumes its full size, but the time he was unable to determine, as those he kept died before they had acquired any considerable size. When first hatched, they are scarcely larger than the common mite.

## Subclass II. MALACOSTRACA.

This subclass has occupied a very considerable portion of attention, the result of which shall be given in the following pages.

Legion I. PODOPHTHALMA. *Eyes* pedunculated or elevated on footstalks.

Order I. Brachyura. *Tail* short and simple at its extremity.

Order II. Macroura. *Tail* lengthened with appendices at its extremity.

Legion II. EDRIOPHTHALMA. *Eyes* sessile.

### Legion I. PODOPHTHALMA.

The *Malacostraca podophthalma* include those animals, which, in common language, are denominated Crabs, Lobsters, Cray-fish, Prawns, Pandals, and Shrimps, all of which have the power of reproducing their claws when they are lost.

Crabs and Lobsters are said "to change their crust annually," but this, like many other statements in zoology, is incorrect. We have seen *Maja squinado* and the common Lobster (*Astacus gammarus*) so overgrown with Ostreæ, Anomiæ, Flustræ, Spongiæ, and Sertulariæ, as scarcely to be enabled to move the joints of their legs, and as the oysters were of a year's growth, and as the anomiæ were above them, and the coralline matters upon the anomiæ, there can be no doubt but the crust was at least two years old.

### Order I. Brachyura.

Latreille arranges the *Brachyura* (from the proportional breadth and length of the thorax or shell) into two families; but the discovery of genera, unknown to that illustrious Entomologist, has convinced us that such a distribution is extremely unnatural; and although, from the infant state of our knowledge, we cannot venture to propose named divisions; yet we shall endeavour to dispose the genera into what appear to be natural groupes.

*Synopsis and distribution of the Genera.*

A. *Abdomen of the male five-jointed, the middle joint longest; of the female seven-jointed. Anterior pair of legs didactyle.*

Division I. Shell nearly rhomboidal. Two anterior legs very long, with deflexed fingers.

Genus 1. Lambrus.

Division II. Shell truncate behind. Two anterior legs of the male elongate, of the female moderate.

*Subdivision* 1. Antennæ long, ciliated on each side.
Genus 2. CORYSTES.
3. THIA.
4. ATELECYCLUS.
*Subdivision* 2. Antennæ moderate, simple. Hinder pair of legs with compressed claws.
Genus 5. PORTUMNUS.
6. CARCINUS.
7. PORTUNUS.
8. LUPA.
*Subdivision* 3. Antennæ moderate, simple. Four hinder pair of legs compressed.
Genus 9. MATUTA.
*Subdivision* 4. Antennæ simple, short. Four hinder pair of legs simple.
Genus 10. CANCER.
11. XANTHO.
12. CALAPPA.
B. *Abdomen in both sexes seven-jointed. Two anterior legs didactyle.*
Division III. Eight hinder legs simple, and alike in form.
*Subdivision* 1. Shell anteriorly arcuated, the sides converging to an angle.
(Two anterior legs unequal).
Genus 13. PILUMNUS.
14. GECARCINUS.
*Subdivision* 2. Shell quadrate or subquadrate. Eyes inserted in the front.
* Shell quadrate. Eyes with a short peduncle.
Genus 15. PINNOTERES.
** Shell quadrate. Eyes with a long peduncle.
Genus 16. OCYPODE.
17. UCA.
18. GONOPLAX.
*Subdivision* 3. Shell quadrate. Eyes inserted at the anterior angles of shell.
Genus 19. GRAPSUS.
Division IV. Two hinder legs at least dorsal.
*Subdivision* 1. Two posterior legs dorsal. Eyes with the first joint of the peduncle elongated.
Genus 20. HOMOLA.
*Subdivision* 2. Four hinder legs dorsal. Eyes with the first joint of the peduncle short.
Genus 21. DORIPPE.
22. DROMIA.
Division V. Shell rostrated in front. Eight hinder legs alike and simple.
*Subdivision* 1. Fingers deflexed.
Genus 23. EURYNOME.
24. PARTHENOPE.
*Subdivision* 2. Fingers not deflexed. External antennæ with the first joint simple. Anterior pair of legs distinctly thicker than the rest.
Genus 25. PISA.
26. LISSA.
*Subdivision* 3. Fingers not deflexed. External antennæ with their first joint simple. Anterior pair of legs scarcely thicker than the others, which are moderately long.
Genus 47. MAJA.
*Subdivision* 4. Fingers not deflexed. External antennæ with the first joint simple. Anterior pair of legs about the thickness of the rest, which are very long and slender.

Genus 28. EGERIA.
29. DOCLEA.
*Subdivision* 5. Fingers not deflexed. External antennæ with the first joint externally dilated.
Genus 30. HYAS.
C. *Abdomen in both sexes six-jointed. Two anterior legs didactyle.*
Division VI. Fifth pair of legs minute, spurious.
Genus 31. LITHODES.
Division VII. Second, third, fourth, and fifth pair of legs alike and slender.
*Subdivision* 1. Eyes retractile.
Genus 32. INACHUS.
*Subdivision* 2. Eyes not retractile.
Genus 33. MACROPODIA.
D. *Abdomen of the male six-jointed: of the female five-jointed; the last joint very large. Eyes not retractile.*
Division VIII.
Genus 34. LEPTOPODIA.
35. PACTOLUS.
E. *Abdomen of both sexes four-jointed. Two anterior legs didactyle.*
Division IX.
Genus 36. LEUCOSIA.
37. IXA.
The following genera belong to this order, but their situation has not yet been fixed, namely,
Genus 38. HEPATUS.
39. PLAGUSIA.
40. MICTYRIS.
41. ORITHYIA.
42. RANINA.
43. MEGALOPA.

A. Division I.

Gen. 1. LAMBRUS. *Leach.*
*External antennæ* simple. *External double palpi*, with the second joint of their internal footstalk, internally notched for the insertion of the palpi.
Sp. 1. *Longimanus.* Thorax spiny, the spines simple: arms smooth beneath.
Parthenope longimana. *Fabr. Ent. Syst. Supl.* 353.
Maja longimana.
*Bosc, Hist. Nat. des Crust.* i. 250. pl. 7. f. 1.
Lambrus longimanus.
*Leach, Trans. Linn. Soc.* xi. 310.
This species inhabits the Indian Ocean.

Division II. *Subdivision* 1.

Gen. 2. CORYSTES, *Latr. Leach.*
*External antennæ* longer than the body, the third segment composed of elongate, cylindric joints. *External double palpi* with the internal footstalk narrow, the second joint largest, having its internal side broadly emarginate. *Anterior pair of legs*; of the male twice the length of the body, subcylindric, the hand gradually somewhat thicker and somewhat compressed; of the female of the length of the body, with a compressed hand: *other legs* with tibiæ and tarsi of equal length; *claws* elongate, strait, acute and longitudinally sulcated. *Abdomen* of the male with the first joint linear transverse, the second longer and produced on each side, third nearly equally quadrate, the fourth transverse and narrower than the third, the fifth narrower, nearly triangular, with the tip rounded; of the female with six first joints transverse ar-

cuated in front, seventh triangular, with the apex rounded. *Shell* oblong-ovate, anteriorly slightly rostrated, behind margined. *Eyes* not thicker than their bending-backward peduncles; *orbits* above with one fissure.

Sp. 1. *Cassivelaunus.* Shell granulated, crenulated behind; front bifid; the sides tridentate.

Cancer cassivelaunus.
*Penn. Brit. Zool.* iv. 6. t. 7. male and female.
*Herbst*, i. 195. t. 12. f. 72. male.
Cancer personatus. *Herbst*, i. 193. t. 12. f. 71. female.
Albunea dentata. *Fabr. Supl. Ent. Syst.* 398.
*Bosc, Hist. Nat. des Crust.* ii. 4.
Corystes dentatus. *Latr. Gen. Crust. et Ins.* i. 40.
Corystes cassivelaunus.
*Leach, Edinb. Encycl.* vii. 395.
——. *Trans. Linn. Soc.* xi. 312.

C. cassivelaunus inhabits most of the sandy shores of the European Ocean, and are often thrown up after heavy gales of wind. Latreille formerly considered the male as a distinct species, under the title Corystes longimanus.

Gen. 3. Thia. *Leach.*

*External antennæ* longer than the body, the third segment composed of elongate cylindric joints. *External double palpi* with the second joint of their internal footstalk much shorter than the first, with its internal apex truncate-emarginate. *Anterior pair of legs* of the male a little longer than the body, with the hand compressed: *other legs* with the tarsi half the length of the tibiæ, with acute flexuous claws, which are longitudinally sulcated. Abdomen of the male with the first joint transverse, arcuate, linear; the second a little longer, anteriorly slightly arcuately produced; the third very long, narrower towards the apex, which is slightly emarginate; the fourth subquadrate, apex slightly notched; the fifth triangular. *Shell* somewhat circular with the sides gradually converging into an angle behind; hinder part somewhat granulate-margined; the front somewhat produced. *Eyes* very small, scarcely prominent; *orbit* without any fissure behind.

Sp. 1. *Polita.* Shell convex, polished and sprinkled with punctures; orbit behind emarginate; sides on each side obscurely four-folded; front entire and arcuate.

Cancer residuus. *Herbst*, iii. 53. t. 48. f. 1?
Thia polita. *Leach, Trans. Linn. Soc.* xi. 312.

Locality unknown.

Gen. 4. Atelecyclus. *Leach.*

*External antennæ* half the length of the body, the third segment composed of elongate and cylindric joints. *External double palpi* with the second joint of the internal footstalk shortest, with the internal apex produced, and the internal side notched towards the joint. *Anterior legs* of the male longer than the body, with a compressed hand; of the female as long as the body, with a compressed hand: *other legs* with tibiæ and tarsi of equal lengths, furnished with elongate, quadrate nails, that are longitudinally sulcated, having their tips naked, rounded and sharp, the hinder ones obscurely subcompressed. Abdomen of the male with the first joint transverse, linear, twice the length of the second; the third much elongated, narrower towards its extremity, the apex nearly strait; the fourth subquadrate, with the anterior angles produced; fifth flask-shaped, with a very sharp extremity; of the female with the first five joints transverse, and of nearly an equal length; the sixth joint transverse quadrate, anteriorly notched, the last elongate, subtriangular behind, subproduced. *Shell* subcircular, the sides gradually converging into an angle behind; hinder part truncate and granulate-margined. *Eyes* narrower than their footstalks; *orbits* behind with two fissures, below with one.

Sp. 1. *Heterodon.* Shell granulated, the sides with seven serrulated teeth, and other smaller teeth between some of the other teeth: Front with three serrulated teeth, the middle of which is the largest.

Cancer *(hippa)* septem-dentatus.
*Montagu, Trans. Linn. Soc.* xi. tab. 1.
Atelecyclus septem-dentatus.
*Leach, Edinb. Encycl.* vii. 430.
——. *Trans. Linn. Societ.* xi. 313.

This elegant crab was discovered by Montagu on the southern coast of Devon, where it is not an uncommon species in deep water. To the fishermen it is well known by the name of *old-man's face crab.*

Division II. *Subdivision* 2.

Gen. 5. Portumnus. *Leach.*

*Eyes* not thicker than their peduncles; *orbits* entire. *Anterior pair of legs* equal; *other legs* with compressed claws, internally towards their base dilated; *fifth pair* with a compressed, foliaceous, lanceolate claw. *Abdomen* of the male with the fourth joint elongate. *Shell* with the transverse and longitudinal diameters the same.

Sp. 1. *Variegatus.* Shell obscurely granulated on each side with five teeth, the second and third somewhat obsolete; front with three teeth; wrists internally with one tooth.

Cancer *(latipes)* variegatus.
*Planc, de Conch. Min. notis*, p. 34. t. iii. f. 7. B. C. male.
Cancer latipes.
*Penn. Brit. Zool.* iv. 3. t. 1. f. 4. female.
Portumnus variegatus.
*Leach, Edinb. Encycl.* vii. 391.
——. *Malac. Podoph. Britann.* t. iv. male and female.
——. *Trans. Linn. Soc.* xi. 314.

Planc first discovered this species on the shores of the Adriatic sea. It burrows beneath the sand, where it may be found by digging at low water, on most of our sandy shores.

When living it is most beautifully mottled, and the legs are sometimes of a luteous-orange colour.

Gen. 6. Carcinus. *Leach.*

*Eyes* narrower than their peduncles; *orbits* behind and beneath with one fissure. *Anterior pair of legs* unequal, the hands externally smooth; *hinder pair* compressed, and slightly formed for swimming. *Abdomen* of the male with the fourth joint transverse, and scarcely narrower than the third. *Shell* with the transverse diameter greatest.

Sp. 1. *Mænas.* Shell with five teeth on each side; front with three rounded teeth or lobes: hands with one tooth, wrist with a spine.

Cancer Mænas of authors.

Carcinus Mænas.
*Leach, Edinb. Encycl.* vii. 390.
—— *Trans. Linn. Societ.* xi. 314.

This most common species inhabits all the shores and estuaries of Britain. It burrows under the sand, or conceals itself beneath fuci and stones. It is sent to London in immense quantities, and is eaten by the poor.

Gen. 7. PORTUNUS. *Fabr. Latr. Bosc, Lam. Leach.*

*Eyes* much thicker than their peduncles; *orbits* behind with two fissures, below with one fissure. *Abdomen* of the male with the fourth joint transverse. *Anterior pair of legs* somewhat unequal, the hands externally with elevated lines, arms generally unarmed; *hinder pair* compressed, foliaceous and formed for swimming. *Shell* with the transverse diameter greatest; the side with five, rarely with six teeth.

* *Hinder claws with an elevated longitudinal line; external double palpi, with the second joint of their internal footstalk, truncate at the internal apex.*

*a* Orbits at the insertion of the antennæ imperfect. Wrists bidentate.

Sp. 1. *Puber.* Antennæ half the length of the body, shell pubescent, front with many teeth.
Cancer puber. *Linn. Syst. Nat.*
Cancer velutinus. *Penn. Brit. Zool.* iv. 8. pl. iv. fig. 8.
Portunus puber.
*Latr. Gen. Crust. et Ins.* i. 27.
*Leach, Edin. Encycl.* vii. 390.
—— *Trans. Linn. Soc.* xi. 315.

Inhabits the rocky shores of the Mediterranean Sea and European Ocean. It is very common all along the southern coasts of Devon. In France it is used as an article of food.

*b.* Orbit internally slightly imperfect. Wrists unidentate.

Sp. 2. *Corrugatus.* Shell convex, with transverse serrate-granulate ciliated lines, the sides with five teeth on each side, the three hinder of which are more acute; front trilobate, the lobes subgranulate-serrate, the middle one largest; hands above unidentate, hinder claws with sharp points.
Cancer corrugatus.
*Penn. Brit. Zool.* iv. 5. pl. v. fig. 9.
Portunus corrugatus.
*Leach, Edin. Encycl.* vii. 390.
—— *Trans. Linn. Soc.* xi. 315.

Inhabits the British Seas. Pennant observed it opposite to Loch Jura in Sky, and the young state has been taken by C. Prideaux, Esq. in the Plymouth Sound.

** *Hinder claws without the elevated line. External double palpi with the internal apex of the second joint of the internal footstalk emarginate. Orbits internally beneath the insertion of the antennæ imperfect.*

Sp. 3. *Marmoreus.* Shell convex, obsoletely and slightly granulated, with five nearly equal teeth on each side; front with three equal teeth, with rounded points; hands smooth, with one tooth above; hinder tarsi with acute points.
Cancer (*pinnatus*) marmoreus.
*Montagu's MS.*
Portunus marmoreus.
*Leach, Edin. Encycl.* vii. 390.
—— *Malacost. Podophth. Britan.* tab. 8.
—— *Trans. Linn. Soc.* xi. 317.

This elegant species, which derives its name from its colour, was discovered by G. Montagu, Esq. It is very common on the sandy shores of southern Devon, from Torcross to the mouth of the river Ex, and is frequently found entangled in the shore-nets of the fishermen, or thrown on the shore after storms.

It is distinguished from every other discovered species, by the rounded dentations of the front, the very slight elevation of the lines on the hands, and by the convexity, remarkable smoothness, and marbled appearance of the shell.

Young specimens are plain brown, and much resemble the young of *P. depurator*, from which they may very easily be separated by their more considerable convexity.

Gen. 8. LUPA. *Leach.*

*Eyes* much thicker than their peduncles; orbit above with two fissures, beneath with one fissure. *Anterior pair of legs* equal, the arms anteriorly spinose; *hinder pair* very much compressed. *Abdomen* of the male with the fourth joint much lengthened, much narrower than the third. *Shell* very transverse, furnished on each side with nine teeth, the last of which is the longest.

This genus was instituted by Dr Leach in the *Edinburgh Encyclopædia*, and has since been given, with amended characters, in the *Zoological Miscellany*, and in the eleventh volume of the *Transactions of the Linnean Society.* As far as we have been enabled to learn, all the species inhabit the Great Ocean, harbouring amongst floating marine plants, swimming with great swiftness and ease near the surface of the water.

* *Shell on each side terminated by a very long spine.*

*a.* Fingers very long and filiform, hands externally smooth.

Sp. 1. *Forceps.* Shell granulated, wrists with a spine on each side, hands above at the base, and externally at the base, with one spine; fingers slightly bending upwards, and denticulated within; hinder claw very much compressed, round ovate.
Portanus forceps.
*Fabr. Suppl. Ent. Syst.* 368.
*Bosc, Hist. Nat. des Crust.* i. 220.
Cancer forceps. *Herbst,* iii. t. 55. fig. 4.
Lupa forceps.
*Leach, Zool. Miscel.* i. 123. t. 54.
—— *Trans. Linn. Societ.* xi. 319.

Plate XXI. This curious Lupa inhabits the Carribean Sea. It was first figured by Dr P. Browne, in his *History of Jamaica.*

*b.* Fingers moderately long; hands externally with elevated lines.

Sp. 2. *Trispinosa.* Shell granulated, arms anteriorly with three spines.
Lupa trispinosa. *Leach, Trans. Linn. Soc.* xi. 319.

** *Shell with the hinder lateral spine not very long.*

Sp. 3. *Banksii.* Shell pubescent, front with four teeth, arms anteriorly with five teeth.
Lupa Banksii. *Trans. Linn. Soc.* xi. 319.

A. Division II. *Subdivision* 3.

Gen. 9. MATUTA.

*Dald. Fabr. Lam. Bosc, Latr. Leach.*

*External double palpi*, with the internal footstalk, elongate-subtriangular, the second joint with the internal side excavated and palpigerous. *Fourth pair of legs*, with the claw acute and narrower than the others. *Shell* very transverse on each side, terminated by a long spine.

Sp. 1. *Victor*. Shell on every side punctate, not striated behind.

Matuta victor. *Latr. Gen. Crust. et Insect.* i. 42.

Inhabits the Indian Ocean.

A. Division II. *Subdivision* 4.

Gen. 10. CANCER *of authors.*

*External antennæ* short, inserted between the internal canthus of the eye and the front; *internal antennæ* placed in foveolæ in the middle of the clypeus, with their peduncle nearly lunate. *External double palpi* with the second joint of the internal footstalk notched at the internal apex. *Shell* margined behind; *orbits* behind with one fissure, and externally with one fold; beneath with one fissure and externally with one fold. Anterior pair of legs unequal.

Sp. 1. *Pagurus*. Shell granulated with nine folds on each side; front with three lobes.

Cancer pagurus *of authors*.

This species is the common crab of Britain. It is considered to be in season between Christmas and Easter, and about harvest, being much esteemed as an article of food. Its natural history is but little known. During the summer months, it is very abundant on all our rocky coasts, especially where the water is deep. At low tide, they are often found in holes of rocks, in pairs, male and female; and if the male be taken away, another will be found in the hole at the next recess of the tide. By knowing this fact, an experienced fisherman may twice a-day take, with little trouble, a vast number of specimens, after having once discovered their haunts.

In the winter, they are supposed to burrow in the sand, or to retire to the deeper parts of the ocean. They are taken in wicker-baskets, resembling mouse-traps, or in large nets with open meshes, which are placed at the bottom of the ocean, and baited with garbage.

Gen. 11. XANTHO. *Leach*.

*External antennæ* very short, inserted in the internal corner of the eye; *internal antennæ* received in foveolæ under the prominent margin of the clypeus, the peduncle sublinear. *External double palpi*, with the second joint of the internal footstalk notched at the internal apex. *Shell* submargined behind; *orbits* entire above, below externally with one fissure; *anterior pair of legs* unequal.

Sp. 1. *Florida*. Wrists above with two tubercles; shell on each side with four obtuse teeth; the interstices cut out; fingers black.

Cancer floridus.

*Montagu, Trans. Linn. Societ.* xi. 85. t. 2. f. 1.

Cancer incisus. *Leach, Edin. Encycl.* vii. 391.

Xantho incisa. *Leach, Edin. Encycl.* vii. 430.

Xantho florida. *Leach, Trans. Linn. Societ.* xi. 320.

This species was first described by Montagu, who considered it to be the *Cancer floridus* of Linné; but an examination of the characters in the Amœnitates Academicæ, will readily convince the naturalist of the incorrectness of this opinion; nor is it the *Cancer floridus* of Herbst; which induces me to believe that some one must have misled Mr Montagu with regard to the synonym, as he could never have considered them the same, had he examined the reference.

Cancer donone of Herbst, probably is referable to the genus Xantho.

Gen. 12. CALAPPA. *Dald. Fabr. Lam. Latr. Bosc, Leach.*

*Shell* with the hinder angles arched, receiving the legs when contracted. *Hands* crested, and equal.

One of the species is very common in the Mediterranean Sea, and is mentioned by Aristotle and Athenæus. Of the economy of the genus nothing is known, but, from the general structure of the parts, it is probably similar to that of Cancer.

Sp. 1. *Granulatus*. Shell tuberculated, the hinder angles dentated; hinder teeth strong, acute; hinder margin subemarginated at the base of the tail.

Calappa granulata.

*Fabr. Supl. Ent. Syst.* 346.
*Latr. Gen. Crust. et Insect.* i. 28.
*Bosc, Hist. Nat. des Crust.* i. 184.
*Leach, Edinb. Encycl.* vii. 391.

Inhabits the Mediterranean Sea.

B. Division III. *Subdivision* 1.

Gen. 13. PILUMNUS. *Leach*.

*External double palpi*, with the second joint of the internal footstalk with the internal apex truncate-emarginate. *Claws* simple, with naked tips.

Sp. 1. *Hirtellus*. Body and legs bristly; shell with five teeth on each side; claws somewhat muricated on the outside.

Cancer hirtellus.

*Linn. Syst. Nat.* 1045.
*Penn. Brit. Zool.* iv. 6. p. 6. f. n.
*Leach, Edinb. Encycl.* vii. 391.

Inhabits the south coast of Devonshire.

Gen. 14. GECARCINUS. *Leach*.

*External double palpi*, with the internal footstalk composed of two nearly equal joints; *palpi* inserted beneath or within; *anterior pair of legs*, unequal; *claws* and *tibiæ* spinose; shell truncate-subcordate.

There are probably many species of this genus, but their characters have not been made out by naturalists. Travellers speak of three sorts. Their economy is very curious, and is detailed by Sloane, Catesby, and others.

They inhabit the mountains of the Antilles. In the beginning of the year they descend from the mountains in vast numbers, and deposit their eggs in the sea. During this march, which is said to be conducted with great regularity, and to be under the guidance of a commander, the strongest proceed first. They are often obliged to halt for want of rain, and to go into the most convenient encampment until the weather change. The main body is said to consist of females, which never leaves the mountains till the rain be set in. They chiefly proceed during the

Crustacea. night, sheltering in hollow trees and in shady places during the hot part of the day.

Sp. 1. *Ruricola.* Tarsi with six elevated, serrated lines; hands smooth.

Cancer ruricola.

*Linn. Syst. Nat.* 2040.
*Fabr. Supl. Ent. Syst.* 339.
*Herbst*, tab. 3. f. 36.

Ocypode ruricola.

*Bosc, Hist. Nat. des Crust.* i. 196.
*Leach, Edinb. Encycl.* vii. 393.

Gecarcinus ruricola.

*Leach, Edinb. Encycl.* vii. 330.
—— *Trans. Linn. Societ.* xi. 322.

Inhabits Southern America.

B, Division III. *Subdivision* 2. *

Gen. 15. Pinnoteres. *Latr. Bosc, Leach.*

Alphæus. *Daldorff.*

*Antennæ* very short (the three first joints largest), inserted in the interior corner of the eyes. *External double palpi*, with the internal footstalk, one-jointed. *Anterior pair of legs* unequal. *Eyes* thick. *Shell* ovate-orbicular, orbiculate-quadrate, or transverse-subquadrate.

All the species of this most interesting genus, inhabit the bivalve shells of the acephalous Mollusca, and were supposed by the ancients to be consentareous inmates with the animal, bound by mutual interest. The fable is beautifully told by Oppian, and is alluded to by Cicero. "*Pinna verò (sic enim Græcè dicitur), duabus grandis patulis conchis, cum parva squilla quasi societatem coit comparandi cibi. Itaque cùm pisciculi parvi in concham hiantem innativerint, tum admonita à squilla pinna morsu, comprimit conchas.*" Nat. Deor. Lib. ii. sec. 48.

Aristotle supposed them to act as centinels, and believed that they guarded the pinna (the animal in whose shell they were first observed), from the attacks of its enemies. Rondeletius and some other naturalists held the same opinion.

Sp. 1. *Cranchii.* Shell orbiculate-subquadrate, soft, very smooth, with the sides dilated behind; front strait, obscurely subemarginate; hands oblong, below and the thighs above with a ciliated line; thumb subarcuate; abdomen very broad, the sides of the segments arcuate, the second, and following ones distinctly notched; the fifth segment somewhat broader; the last narrower than the preceding segment. *Female.*

Pinnoteres Cranchii.

*Leach, Malacost. Podophth. Britann.* tab. 14. fig. 4—5.

The male of this species, which was discovered by Mr J. Cranch, whose name it bears, is unknown. It is distinguished from *P. pisum* (the common species), by the form of the front of the shell, which is strait and slightly notched; by the dilated hinder part of the shell, and by the abdomen, all the joints of which, excepting the first, are distinctly notched behind.

Plate XXI.

Division III. *Subdivision* 2. **.

Gen. 16. Ocypode.

*Dald. Fabr. Latr. Lam. Bosc, Leach.*

*Eyes* very large, with their peduncle generally extending beyond their tips, in the form of a spine. *Anterior pair of legs* unequal. Crustacea.

The economy of the *Ocypodes* is unknown, but it is probably not very different from that of the *Ucæ*. They inhabit the shores of the sea; and, as their name indicates, run with great swiftness.

Sp. 1. *Ceratophthalma.* Arms granulated; hands cordate; spine of the peduncle of the eye smooth and very long.

Ocypode Ceratophthalma.

*Fabr. Supl. Entom. Syst.* 465.
*Latr. Gen. Crust. et Ins.* i. 32.
*Leach, Trans. Linn. Soc.* xi. 322.

Inhabits the shores of the Indian Ocean.

Gen. 17. Uca. *Leach.*

Ocypode. *Latr. Bosc, Fabr.* &c.

*Eyes* small, terminating their peduncle. *Anterior pair of legs* very unequal.

The *Ucæ* inhabit the shores of the sea, swamps, and the banks of rivers, living in holes beneath the ground. They multiply very much, and serve as food to otters, bears, birds, crocodiles, &c. The females carry about their eggs under the abdomen. They live on animal substances, which they devour with avidity. Their motion is rapid; Sir J. Banks assures us that he could never come up with them when running, and that the only means by which he could take them was by running to and stopping their holes before they could reach it, and which he effected by lying in ambush until the animals had gone to a very considerable distance from their haunts.

Sp. 1. *Una.* Shell with one tooth on each side.

Cancer vocans major. *Herbst*, t. i. f. 10.

Cancer vocans. *Bosc, Hist. Nat. des Crust.* i. 198.

Uca una. *Leach, Trans. Linn. Soc.* xi. 323.

Inhabits South America.

Gen. 18. Gonoplax. *Leach.*

Ocypoda. *Bosc.*

*Eyes* terminating their peduncle. *Anterior pair of legs* equal; of the male very long; of the female twice the length of the body. *Antennæ* half of the length of the body, inserted at the internal canthus of the eyes.

The animals of this genus inhabit the ocean, preferring such parts as have a slimy bottom. They burrow laterally in the clay or slime, making two entrances to their hole; entering by one, and going out by the other. We have seen several fossil species inclosed in marle, that appear to belong to this genus.

Sp. 1. *Bispinosa.* Shell on each side with two spines, arms above, and wrists internally with one spine.

Cancer angulatus. *Penn. Brit. Zool.* iv. t. 5. f. 10.

*Fabr. Supl. Entom. Syst.* 341.

Ocypoda angulata. *Bosc, Hist. Nat. des Crust.* i. 198.

Gonoplax bispinosa.

*Leach, Edinb. Encycl.* vii. 430.
——, *Trans. Linn. Soc.* xi. 323.

Inhabits the British Sea. It is not uncommon at Salcombe and in the Plymouth Sound; and likewise occurs at Weymouth, and at Redwharf in Anglesea.

Division III. *Subdivision* 3.

Gen. 19. Grapsus. *Lam. Latr. Bosc, Leach.*

Crustacea.

Sp. 1. *Pictus.* Shell with the sides plicated behind, anteriorly with the angles bidentate; front with four dentated folds; fingers with their joints concave: wrists internally strongly unidentate.

Cancer grapsus.
*Linn. Syst. Nat.* 1048.
*Fabr. Supl. Ent. Syst.* 342.

Grapsus pictus.
*Latr. Gen. Crust. et Insect.* i. 33.
*Leach, Edinb. Encycl.* vii. 393.
——, *Trans. Linn. Soc.* xi. 323.

Inhabits the South American Ocean.

B. Division IV. *Subdivision* 1.

Gen. 20. Homola. *Leach.*

*Shell* elongate-quadrate, a little produced in front: *eyes* large, somewhat globose, their footstalks lengthened, the second joint very short and very abruptly thicker than the first. *External antennæ* very long, inserted beneath the eyes, the two first joints long, the first thickest: *internal antennæ* inserted within the orbit of the eye, and capable of being lodged in the internal corner. *External double palpi* with their internal footstalk composed of two lengthened and narrow joints; *palpi* three-jointed; the first joint shortest. *Legs* ten; first pair largest and didactyle; the three following pair simple, alike in form, and having their *claws* spiny within; fifth pair monodactyle, the *claws* and *tarsi* being spiny within. *Abdomen* composed of seven joints.

Sp. 1. *Spinifrons.* Shell anteriorly spinous; sides anteriorly beset with small spines; hinder thighs internally with three spines.

Homola spinifrons.
*Leach, Trans. Linn. Soc.* xi. 324.
——, *Zoolog. Miscel.* ii. 82. t. 88.

Inhabits the Mediterranean Sea.

B. Division IV. *Subdivision* 2.

Gen. 21. Dorippe. *Dald. Fabr. Lam. Latr. Bosc, Leach.*

*External double palpi* with the internal footstalk having its first joint dilated interiorly, the second narrow, bearing palpi at its extremity. *Shell* subtriangular, anteriorly truncated. *Second* and third *pair of legs* alike, with acute, elongate, simple subquadrate *claws; fourth* and *fifth pair* shorter, dorsal and monodactyle. *External antennæ* inserted above and between the eyes: *internal antennæ* inserted below and between the eyes.

Sp. 1. *Quadridens.* Middle of the clypeus with four teeth, the lateral ones shortest; sides of the shell unidentate at their middle part; four anterior thighs subdentate.

Dorippe quadridens.
*Fabr. Supl. Ent. Syst.* 361.
*Bosc, Hist. Nat. des Crust.* i. 207.
*Latr. Gen. Crust. et Ins.* i. 41.
*Leach, Edin. Encycl.* vii. 395.
—— *Trans. Linn. Societ.* xi. 324.

Inhabits the Mediterranean Sea.

Gen. 22. Dromia. *Dald. Fabr. Latr. Bosc, Leach.*

*External double palpi* two-jointed, with the second joint somewhat broader, shorter, and at its interior apex palpigerous. *Second* and *third pair of legs* simple; *fourth* and *fifth* shorter and didactyle. *External antennæ* inserted below the eyes; the two first joints largest, and abruptly thicker than the others; *internal antennæ* inserted below, and somewhat between the eyes.

Crustacea.

Sp. 1. *Rumphii.* Shell hairy, on each side with five strong teeth, without any remarkable interval between them; arms and legs without knots.

Cancer Dromia. *Linn. Syst. Nat.* 1043.

Dromia Rumphii.
*Fabr. Supl. Ent. Syst.* 359.
*Leach, Edin. Encycl.* vii. 391.

Inhabits the East Indian Ocean. It is named after Rumphius, by whom it was first described and figured. *Rarit. Amb.* t. 11. No. 1.

B. Division V. *Subdivision* 1.

Gen 23. Eurynome. *Leach.*

*External antennæ* rather long, with the first joint shorter than the second. *Shell* verrucated, anteriorly terminated by a bifid rostrum, with divaricating laciciæ. *Eyes* distant, thicker than their peduncle, which is of moderate length. *External double palpi* with the interior point of the second joint of their internal footstalks truncate-emarginate. *Anterior legs* equal; of the male three times the length of the body; of the female longer than the body.

Sp. 1. *Aspera.* Anterior legs and thighs tuberculated; shell with eight tubercles on the back that are more elevated than the others, which are irregular and margined with hairs; the sides with four lamellæ; rostrum with simple acuminate laciniæ.

Cancer asper. *Penn. Brit. Zool.* iv. 8.

Eurynome aspera.
*Leach, Edin. Encycl.* vii. 431.
——— *Malac. Podophth. Britan.*
——— *Trans. Linn. Societ.* xi. 326.

Inhabits the British Sea.

Gen. 24. Parthenope. *Fabricius, Leach.*

Maja I. *Latreille.*

*External antennæ* very short; the two first joints largest, the first more so than the second. *Shell* tuberose, anteriorly acuminated; the rostrum entire; *eyes* distant, not thicker than their peduncles, which are very short. *External double palpi* with the internal apex of the second joint of their internal footstalk truncate-emarginate. *Anterior legs* unequal; of the male very thick.

Sp. 1. *Horrida.* Tubercles of the shell impressed; the punctures as if eaten; legs spiny; hands and wrists verrucated; abdomen and breast carious.

Cancer longimanus spinosus.
*Seb. Mus.* iii. 48. tab. 19. fig. 16, 71.

Cancer horridus. *Linn. Syst. Nat.* i. 104.

Parthenope horrida.
*Fabr. Suppl. Ent. Syst.* 353.
*Leach, Edin. Encycl.* vii. 431.
——— *Zoologic. Miscel.* ii. tab. 98.

Maja horrida.
*Latr. Gen. Crust. et Insect.* i. 37.
*Leach, Edin. Encycl.* vii. 394.

Inhabits the Asiatic Ocean.

B. Division V. *Subdivision* 2.

Gen. 25. Pisa. *Leach.*

Blastus. *Leach.*

*External antennæ* with clubbed hairs, the first joint longer than the second. *External double palpi* with the second joint of the internal footstalk with its internal apex truncate or emarginate. *Claws* internally denticulated. *Shell* villose, the laciniæ of the rostrum divaricating. *Orbits* behind with two, below with one fissure.

* *Shell densely villose, the sides on each side behind terminated with a spine.*

Sp. 1. *Gibbsii.* Rostrum descending; shell with a spine behind the eyes on each side; arms and thighs simple.

Cancer biaculeatus.
*Montagu, Trans. Linn. Soc.* xi. 2. t. 1. f. 1.
Pisa biaculeata. *Leach, Edin. Encycl.* vii. 431.
Pisa Gibbsii.
*Leach, Trans. Linn. Soc.* xi. 327.
——— *Malac. Podophth. Britan.* tab. 19.

Inhabits deep water on the coasts of Devon and Cornwall.

Sp. 2. Nodipes. Rostrum horizontal; arms and tips of the thighs knotted.

Pisa nodipes.
*Leach, Zool. Miscell.* ii. t. 78.
——— *Trans. Linn. Soc.* xi. 328.

** *Shell villose, with spiny sides.*

Sp. 3. *Tetraodon.* Shell on each side with six spines; two small, the rest larger.

Cancer tetraodon. *Penn. Brit. Zool.* iv. 7. t. 8. f. 15.
Maja tetraodon. *Bosc, Hist. Nat. des Crust.* i. 254.
Blastus tetraodon. *Leach, Edin. Encycl.* vii. 431.
Pisa tetraodon. *Leach, Trans. Linn. Soc.* xi. 328.

Inhabits the south-west coast of England.

Gen. 26. Lissa. *Leach.*

Maja. *Latr. Bosc.*

*External antennæ* with clubbed hairs, the first joint longer than the second. *External double palpi* with the second joint of the internal footstalk truncate-emarginate at the internal apex. *Claws* internally simple, with naked points. *Shell* tuberose, the laciniæ of the rostrum meeting together. *Orbits* with one fissure behind, and one below.

Sp. 1. *Chiragra.* Rostrum obtuse, with the anterior angles subreflexed; legs knotted.

Cancer chiragra. *Herbst,* tab. 17. f. 96.
Inachus chiragra. *Fabr. Supl. Ent. Syst.* 357.
Maja chiragra.
*Bosc, Hist. Nat. des Crust.* i. 255.
*Latr. Hist. Nat. des Crust. et des Insect.* vi. 97.
Lissa charagra. *Leach, Zool. Miscel.* ii. 70. t. 73.

Inhabits the Mediterranean Sea.

Division V. *Subdivision 3.*

Gen. 27 Maja. *Lam. Latr. Bosc, Leach.*

*External antennæ* with two first joints thickest, and of nearly equal length. *Shell* convex ovate-subtriangular, very spiny. *Eyes* not thicker than their elongate peduncle. *External double palpi* with the second joint of their internal footstalk, deeply notched at its internal apex. *Claws* with naked sharp points.

Sp. 1. *Squinado.* Shell fasciculate-pilose, orbit above with one spine, the sides with five strong spines, clypeus beneath the front with a short spine excavated above.

Cancer squinado.
*Herbst,* iii. t. 56. full grown.
——— i. t. 14. f. 85—84. junior.
Cancer maja.
*Scopoli, Entom. Carn.* 1126.
*Sowerby, Brit. Miscell.* t. 39.
Maja squinado.
*Latr. Gen. Crust. et Insect.* i. 37.
*Bosc, Hist. Nat. des Crust.* i. 257.
*Leach, Edinb. Encycl.* vii. 394—431.
——— *Trans. Linn. Societ.* xi. 326.

Inhabits the southern coasts of Devon and Cornwall. By the fishermen it is named Thornback, or king-crab.

B. Division V. *Subdivision 4.*

Gen. 28. Egeria. *Leach.*

*Shell* spinous anteriorly, terminated by an elongate rostrum; *eyes* large, much thicker than their peduncles; *orbits* behind with two fissures, below with one fissure. *External antennæ* inserted at the sides of the rostrum with the two first joints thickest, the second joint much thicker than the first. *Two anterior legs* of the male about twice the length of the body, filiform, and scarcely thicker than the others; *eight hinder legs* very long very slender, alike in form, in order of size 2, 3, 4, and 5. *Claws* elongate, somewhat arcuate, and very slender. *External double palpi* with the second joint of the internal footstalk with its internal side strait, the interior apex being abruptly produced.

Sp. 1. *Indica.* Beak acutely notched; shell behind the beak with six tubercles, arranged in transverse lines, 3, 2, 1, 1.

Doclea Indica. *Leach, Zool. Miscel.* ii. 40. tab. 73.

Inhabits the Indian Ocean, where it is by no means uncommon.

Gen. 29. Doclea. *Leach.*

*Shell* villose, with the sides somewhat spinous; front terminated by a short beak; *eyes* moderate in size, but much thicker than their peduncles; *orbits* behind and below with one fissure. *External antennæ* inserted at the base of the beak, the second joint shorter than the first. *Anterior pair of legs* of the female as long as the body, and more slender than the *others,* which are very long and slender; *claws* elongate, arcuate, slender. *External double palpi* with their internal footstalk having the internal side of the second joint towards the apex deeply notched.

Sp. 1. *Rissonii.* Shell and legs with brown pubescence; hinder part of the shell with one spine; each side with three spines.

Doclea Rissonii. *Leach, Zool. Miscel.* ii. 42. tab. 74.

Locality unknown.

B. Division V. *Subdivision 5.*

Gen. 30. Hyas. *Leach.*

*Shell* elongate-subtriangular, subtuberculated, the sides behind the eyes produced into a lanceolate projection; *rostrum* fissured, the laciniæ approximating. *External antennæ* with the first joint dilated, larger than the second. *External double palpi* with the second joint emarginate at the internal apex.

Crustacea.

Sp. 1. *Araneus.* The lastiform process behind the eyes, tuberculated behind.
Cancer araneus.
*Lin. Syst. Nat.* 1044.
Cancer bufo.
*Herbst*, i. 142. t. 17. f. 59.
Inachus araneus.
*Fabr. Supl. Ent. Syst.* 359.
Hyas araneus.
*Leach, Edin. Encycl.* vii. 437.
—— *Trans. Linn. Soc.* xi. 329.

Inhabits the Scotish Sea in great plenty; on the English coasts it is more rare.

Division VI.

Gen. 31. Lithodes. *Latreille, Leach.*

*External* double palpi with narrow subcylindric footstalks. *Eyes* approximating at their base. *Shell* very spiny, anteriorly rostrated.

Sp. 1. *Maja.* Legs and shell with sharp spines; beak spiny, with the tip bifurcate; fingers with tufts of hair.
Cancer maja.
*Lin. Syst. Nat.* 1046.
Cancer horridus.
*Pen. Brit. Zool.* iv. 7. pl. 7. fig. 14.
Inachus maja. *Fabr. Ent. Syst. Suppl.* 358.
Maja vulgaris.
*Bosc, Hist. Nat. des Crust.* i. 251.
Lithodes arctica.
*Latr. Gen. Crust. et Insect.* i. 40.
Lithodes maja.
*Leach, Edin. Encycl.* vii. 395.
—— *Trans. Linn. Soc.* xi. 332.

Inhabits the Northern Sea, and in our seas is very rare, or at least very local; occurring only on the rocky shores of Yorkshire, and of Scotland.

C. Division VII. *Subdivision* 1.

Gen. 31. Inachus. *Fabricius, Leach.*

Shell slightly spined, with a spine on each side protecting the eye when retracted. *Eyes* distant, scarcely thicker than their peduncles. *External double palpi*, with the second joint of the internal footstalk, truncate at its internal point. *External antennæ* with the three first joints thickest. *Second pair of legs* thicker than the following ones. *Claws* curved.

Sp. 1. *Dorsettensis.* Beak short, emarginate, the clypeus beneath produced into a spine; shell anteriorly with four little tubercles placed transversely; then with three spines (the anterior one strongest); behind with three strong sharp spines (the middle one generally longest and strongest), forming a slightly recurved line; hinder margin with two distinct obsolete tubercles.
Cancer Dorsettensis.
*Pen. Brit. Zool.* iv. 8. pl. 9. fig. 18.
Cancer scorpio.
*Fabr. Sp. Ins.* i. 504.
*Gmel. Syst. Natur.* i. 2078.
*Herbst*, i. 237, 130.
Inachus scorpio.
*Fabr. Ent. Syst. Supl.* 358.
Macropus scorpio.
*Latr. Hist. Nat. des Crust. et des Insect.* vi. 109.
Maja scorpio.
*Bosc, Hist. Nat. des Crust.* i. 252.
Inachus Dorsettensis.
*Leach, Edin. Encycl.* vii. 431.
—— *Malac. Podolph. Britan.* tab. 22. fig. 1—6.
—— *Trans. Linn. Soc.* xi. 330.

Inhabits the British Seas.

Division VI. *Subdivision* 2.

Gen. 32. Macropodia. *Leach.*
Macropus. *Latreille.*

*Shell* slightly spined, beak long and fissured. *Eyes* distant, subreniform, much thicker than their peduncles. *External antennæ* half the length of the body, the second joint three times the length of the first. *External double* palpi slender, the internal footstalk with two equal joints; *palpi* very hairy, the middle joint shortest, the third a little longer than the first. *Four* anterior claws with their tips bent; four hinder ones abruptly curved at their base.

Sp. 1. *Phalangium.* Beak accuminate, much shorter than the antennæ; shell behind the rostrum with three tubercles placed in a triangle, the hinder tubercle largest; arms internally subscabrous and hirsute.
Cancer phalangium.
*Penn. Brit. Zool.* iv. 8. pl. 9. fig. 17.
Macropus longirostris.
*Latr. Gen. Crust. et Insect.*
Macropodia longirostris.
*Leach, Edin. Encycl.* vii. 395.
*Leach, Zool. Miscel.* ii. 18.
—— *Trans. Linn. Soc.* xi. 331.
—— *Malac. Podolph. Britan.* tab. 23.

Inhabits the mouths of rivers, and is very common in Great Britain.

D. Division VIII.

Gen. 33. Leptopodia. *Leach.*

*Shell* not spinous, the beak very long and entire. *Eyes* distant, globose. *External antennæ* half the length of the body, the second joint three times the length of the third. *External double palpi* slender, the internal footstalk, with the second joint half the length of the first. *Palpi* very hairy, the last joint largest, the two first joints nearly equal. *Claws* long, alike in form, and slightly bent.

Sp. 1. *Sagittaria.* Hands granulose; beak on each side, and the arms and thighs anteriorly spinous.
Inachus sagittarius.
*Fabr. Supl. Ent. Syst.* 359.
Cancer sagittarius. *Herbst*, 3.
Macropus sagittarius.
*Latr. Hist. Nat. des Crust. et des Insect.* vi. 112.
Maja sagittaria.
*Latr. Gen. Crust. et Insect.* i. 38, 4.
*Leach, Edin. Encycl.* vii. 395.
Maja sagittis.
*Bosc, Hist. Nat. des Crust.* i. 253.
Leptopodia sagittaria.
*Leach, Zool. Miscel.* ii. 16. tab. 67.
—— *Trans. Linn. Soc.* xi. 332.

Inhabits the Carribean Sea.

Gen. 35. Pactolus. *Leach.*

*Shell* not spiny. *Beak* very long and entire. *Legs* of moderate length; the first, second (and third), pairs furnished with a simple claw; the fourth and fifth pairs didactyle.

The abdomen of the female has the first joint narrow, the second, third, and fourth joints tranverse-linear, the fifth very large and somewhat rounded, as in the case with the genus Leptopodia.

Sp. 1. *Boscii.* Beak on each side spinulose; legs ciliate-punctate.

Pactolus Boscii.

*Leach, Zool. Miscel.* ii. 20. tab. 68.

—— *Trans. Linn. Soc.* xi. 333.

A single specimen of this curious animal is preserved in the British Museum; but its locality is not known. Fabricius seems to have described it as the other sex of his *Inachus sagittarius.*

E. Division IX.

Gen. 36. Leucosia. *Fabr. Latr. Bosc, Leach.*

*Shell* rounded or rhomboidal, slightly produced in front. *External double palpi* with the second joint of their internal footstalk simple. *Anterior pair of legs* distinctly thicker than the others, which are simple.

This genus requires to be investigated. It contains two indigenous species; namely Cancer tumefactus of Montagu, and Cancer tuberosus of Pennant.

* *Second joint of the internal footstalk of the external double palpi dilated.*

Sp. 1. *Anatum.*

Cancer anatum.

*Herbst,* i. 95. tab. 3. fig. 19.

** *Second joint of the internal footstalk of the external double palpi nearly linear.*

Sp. 2. *Craniolaris.*

Cancer craniolaris. *Herbst,* i. 90. tab. 2. fig. 17.

Gen. 37. Ixa. *Leach.*

*Shell* very transverse, subcylindric, much broader than long. *External double palpi* with the second joint of the internal footstalk excavated. *Anterior pair of legs* scarcely thicker than the rest.

Sp. 1. *Cylindrus.* Shell with two channels, the sides rough and terminated by a spine.

Leucosia cylindrus.

*Latr. Hist. Nat. des Crust. et des Insect.* vi. 119.

Cancer cylindrus.

*Herbst,* i. 108. tab. 2. f. 29, 30, 31. male.

Ixa cylindrus.

*Leach, Trans. Linn. Soc.* xi. 334.

Inhabits the Indian Ocean.

*Brachyurous Genera of uncertain situation.*

Gen. 38. Hepatus. *Latreille.*

*External double palpi* with the second joint of their internal footstalk elongate-triangular, gradually becoming sharp from the base to the point. *Shell* arcuate before, the sides converging behind. *Legs* all formed for walking; anterior pair didactyle, the hands crested.

Sp. 1. *Fasciatus. Latreille.*

This species is figured by Herbst, tab. 38. fig. 2. The shell and legs are banded with red, sometimes with brown.

Gen. 39. Plagusia. *Latreille.*

*Eyes* with a short peduncle, inserted at the anterior angles of the shell. *Shell* quadrate. *Interior antennæ* inserted in two fissures on the clypeus.

Sp. 1. *Depressa.* Middle of the clypeus with two teeth; sides of the shell with five teeth; dorsal tubercles naked.

Cancer depressus. *Fabr. Ent. Syst. Suppl.* 343.

Plagusia depressa. *Latr. Gen. Crust. et Insect.* i. 34.

Inhabits the shores of the Mediterranean Sea.

Gen. 40. Mictyris. *Latreille.*

*External double palpi* with the first joint very large. *Antennæ* very short. *Shell* subovate, truncate behind, elevated. *Arms* at the base of the wrist bent like a knee.

Sp. 1. *Longicarpus.*

*Latr. Gen Crust. et Insect.* i. 41.

*Leach, Edin. Encycl.* vii. 395.

Gen. 41. Orithyia. *Daldorff, Fabricius, Latreille, Bosc, Leach.*

*Shell* rounded. *Legs* all placed in the same horizontal line, the hinder pair with the last joint compressed, or formed for swimming; the first pair didactyle.

Sp. 1. *Mamillaris.*

Orithyia mamillaris.

*Fabr. Suppl. Ent. Syst.* 363.

*Latr. Gen. Crust. et Insect.*

Inhabits the Indian Ocean. It is figured by *Herbst,* tab. 18. f. 101.

Gen. 42. Ranina. *Lamarck, Latreille, Leach.*

*Legs,* with the exception of the first pair, which is monodactyle, formed for swimming; the two hinder pairs placed above the others.

Sp. 1. *Serrata.* Arms much dentated; front of the shell with dentated lobes.

Ranina serrata.

*Latr. Gen. Crust. et Insect.* i. 48.

*Leach, Edinb. Encycl.* vii. 396.

Inhabits the Indian Ocean.

Gen. 43. Megalopa. *Leach.*

This genus contains but one species, which is described in the seventh volume of the *Transactions of the Linnean Society,* under the title *Cancer rhomboidalis. Cancer granarius* of Herbst probably belongs to the same genus. See *Trans. Linn. Soc.* vii. tab. vi. fig. 1.

Order II. Macroura.

This order contains the families, *Pagurii, Palinurini, Astacini,* and *Squillares* of Latreille.

*Synopsis and distribution of the Genera.*

A. *Tail on each side with simple appendices.*

Division I. Legs ten; anterior pair largest and dactyle.

Genus 44. Pagurus.

45. Birgus.

B. *Tail on each side with foliaceous appendages, forming with the middle tail-process a fan-like fin.*

a. *Interior antennæ with very long footstalks.*

Division II. External antennæ squamiform. Legs ten, alike and simple.

Genus 46. Scyllarus.

47. Thenus.

Division III. External antennæ setaceous, and very long. Legs ten, alike and simple.

Crustacea.

Genus 48. Palinurus.

Division IV. External antennæ very long and setaceous. Legs ten, anterior pair didactyle, fifth pair spurious.

Genus 49. Porcellana.

50. Galatea.

b. *Interior antennæ with moderate peduncles.*

Division V. Exterior lamella of the tail simple. Antennæ inserted in the same horizontal line, the interior ones with two setæ, the exterior ones simple. Legs ten.

Genus 51. Gebia.

52. Callianassa.

53. Axius.

Division VI. Exterior lamella of the tail bipartite. Antennæ inserted in the same horizontal line, the internal ones with two setæ, the external ones with a spine-shaped squama at the first joint of the peduncle. Legs ten (anterior pair largest and didactyle).

Genus 54. Astacus.

55. Nephrops.

Division VII. External antennæ with a large broad squama or scale at their base. Abdomen with the second joint anteriorly and posteriorly produced below. Legs ten.

*Subdivision* 1. External antennæ inserted in the same horizontal line with the interior ones, which have two setæ. Tail with the external lamella composed of but one part.

Genus 56. Crangon.

*Subdivision* 2. External antennæ inserted below the internal ones; interior ones with two setæ inserted in the same horizontal line. Exterior lamella of the tail bipartite.

Genus 57. Atya.

58. Processa.

*Subdivision* 3. External antennæ inserted below the internal ones; interior ones with two setæ, one placed above the other. (External lamella of the tail composed of but one part).

* *Internal antennæ with the superior seta excavated below. Claws spinulose.*

Genus 59. Pandalus.

60. Hippolyte.

61. Alpheus.

** *Internal antennæ with the superior seta not excavated. Claws simple.*

Genus 62. Penæus.

*Subdivision* 4. External antennæ inserted below the internal; interior ones with three setæ. (External lamella of the tail composed of but one part).

Genus 63. Palæmon.

64. Athanas.

Division VIII. External antennæ inserted below the internal ones, with a large scale at their base. Legs sixteen.

Genus 65. Mysis.

C. Tail with two setæ, one on each side.

Division IX.

Genus 66. Nebalia.

The genera whose situation has not been ascertained are the following, namely,

Genus 67. Albunea.

68. Remipes.

69. Hippa.

Genus 70. Thalassina.

71. Squilla.

Division I.

Gen. 44. Pagurus. *Fabr. Latr. Bosc, Leach*, &c.

*External antennæ*, with the second joint of their peduncle, with a moveable spine affixed to the apex above. *Abdomen* membranaceous. *Tail* three-jointed, crustaceous, the second joint on each side appendiculated. *Four hinder legs* spurious, short, didactyle.

The curious economy of the genus Pagurus attracted the attention of the ancients. One species is well described by Aristotle under the name καρκινιον.

All the species are parasitical, and inhabit the cavities of turbinated univalves. They all change their habitation during their growth, first occupying the smallest shells, and latterly those of very considerable dimensions. The abdomen is naked and slender, being covered merely with a skin of a delicate texture; but its extremity is furnished with appendages, by means of which it secures itself within the shell of which it makes choice. It is really astonishing with what facility these animals move, bearing at the same time the shell, which is destined to preserve the body from injury, and to guard these animals from the attacks of fishes, who would otherwise devour them. All the species are termed indiscriminately *Soldier-crabs* and *Hermit-crabs*, from the idea of their living in a tent, or retiring to a cell.

Sp. 1. *Bernhardus* (common soldier-crab). Arms hairy, muricated, the left the largest; hands subcordate, fingers broad.

Pagurus, Bernhardus.

*Fabr. Suppl. Ent. Syst.* 411.

*Latr. Gen. Crust. et Insect.* i. 46.

*Leach, Edinb. Encycl.* vii. 396.

Cancer Bernhardus. *Linn. Syst. Nat.*

Inhabits the European Ocean, and is very abundant in the British Seas, inhabiting various kinds of univalve shells, changing its habitation as it grows. Pagurus araneiformis, *Edinb. Encycl.* vii. 396, is merely the young of this species.

Gen. 45. Birgus. *Leach.*

*External antennæ* with the second joint of its peduncle crested. *Abdomen* crustaceous. *Tail* two-jointed, crustaceous, the first joint on each side appendiculated. *Fourth pair of legs* didactyle; *fifth pair* (didactyle?).

Sp. 1. *Latro.* Shell anteriorly with a simple acuminate rostrum.

Cancer latro. *Linn. Syst. Nat.* 1049.

Cancer (*astacus*) latro. *Herbst*, ii. 34. tab. 24.

Pagurus latro.

*Fabr. Ent. Syst.* ii. 468.

*Leach, Edinb. Encycl.* vii. 390.

Birgus latro. *Leach, Trans. Linn. Soc.* xi. 337.

This species is said to inhabit Amboyna, and to live in cavities and holes of rocks, from whence it wanders abroad in the night, in order to procure cocoa nuts, on which it is supposed to feed.

Division II.

Gen. 46. Scyllarus.

*Fabr. Dald. Lam. Latr. Bosc, Leach.*

*Hinder legs* with the tarsi beneath produced into

a thumb. *Thorax* convex, sublinear. *Eyes* inserted behind the exterior antennæ.

Sp. 1. *Arctus.* External antennæ very much dentated; shell above with a triple series of dentations. Cancer arctus. *Linn. Syst. Nat.* 1053.
Scyllarus arctus.
*Latr. Gen. Crust. et Insect.* i. 47.
*Leach, Edinb. Encycl.* vii. 397.

Inhabits the European Ocean, and is said by Pennant to have been taken in the British Sea.

Gen. 47. Thenus. *Leach.*

*Hinder legs* with simple tarsi. *Thorax* subdepressed, broader anteriorly. *Eyes* inserted at the anterior angles of the thorax.

Sp. 1. *Indicus.* External antennæ serrated; thorax granulated, carinated, trispinous; abdomen granulated, the granules arranged transversely.

Inhabits the Indian Ocean.

Division III.

Gen. 48. Palinurus.
*Dald. Fabr. Lam. Latr. Bosc, Leach.*

The animals of this genus have the power of producing a sound by rubbing their exterior antennæ against the sides of the projecting clypeus.

Sp. 1. *Vulgaris.*
Astacus homarus. *Penn. Brit. Zool.* iv. 16. pl. 11.

Inhabits the European Ocean. It is commonly eaten in London, and is sometimes denominated spiny-lobster or sea crey-fish.

Division IV.

Gen. 49. Porcellana. *Lam. Latr. Bosc, Leach.*

*External double palpi* with the first joint of the internal footstalk dilated internally. *Shell* orbiculate subquadrate.

Sp. 1. *Platycheles.* Anterior margin of the shell with three entire teeth; claws very large and much depressed; wrists internally denticulated; hands externally deeply ciliated.
Cancer platycheles.
*Penn. Brit. Zool.* iv. 6. pl. 6. and 12.
Porcellana platycheles.
*Latr. Gen. Crust. et Insect.* i. 49.
*Leach, Edinb. Encycl.* vii. 398.
——, *Trans. Linn. Soc.* xi. 339.

Inhabits the rocky shores of the southern and western coasts of Britain, concealing itself beneath stones, to the under side of which it adheres closely.

Gen. 50. Galatea.
Galathea. *Fabr. Latr. Lam. Bosc, Leach.*

*External double palpi* with the internal edge of the first joint not dilated. *Shell* ovate.

* *Rostrum acuminate, acute, with four spines on each side. Anterior legs compressed. Abdomen with the sides of the segments obtuse. Tail with the intermediate lamella triangular, the tip emarginate, the apex of the laciniæ rounded. Interior antennæ with the first joint of the peduncle trispinose.*

a *Second joint of the internal footstalk of the external double palpi longer than the first.*

Sp. 1. *Fabricii.* Anterior legs granulate-spinose; hands externally subserrated; wrists and arms internally spinose. Plate XXI.
Galathea Fabricii. *Leach, Trans. Linn. Soc.* xi. 340.

b. *Second joint of the internal footstalk of the external double palpi shorter than the first.*

Sp. 2. *Spinigera.* Anterior legs subgranulate squamose, above and on each side spinose; arms externally without spines.
Astacus strigosus. *Penn. Brit. Zool.* iv. 18. pl. 14.
Cancer (*astacus*) strigosus. *Herbst,* tab. 26. f. 2.
Galathea strigosa.
*Fabr. Ent. Syst.* ii. 471.—*Suppl.* 414.
*Latr. Gen. Crust. et Insect.* i. 49.
*Leach, Edinb. Encycl.* vii. 398.
Galathea spinigera.
*Leach, Malac. Podoph. Brit.* tab. 28. B.

** *Rostrum elongate, spiniform, the base on each side bispinose. Anterior pair of legs subcylindric. Abdomen with the sides of the segments acute. Tail with the intermediate lamella transverse-quadrate, the apex subemarginate. Interior antennæ with the first joint of the peduncle four-spined. (External double palpi with the first joint of the internal footstalk longer than the second.)*

Sp. 2. *Rugosa.* Anterior legs spinose, especially internally; abdomen with the second segment anteriorly with six, the third with four spines.
Astacus Bamffius. *Pennant, Brit. Zool.* iv. 17. pl. 27.
Galathea rugosa.
*Fabr. Suppl. Ent. Syst.* 415.
*Bosc, Hist. Nat. des Crust.* ii. 87.
*Latr. Hist. Nat. des Crust. et des Insect.* vi. 199. 2.
Cancer rugosus. *Gmelin, Syst. Nat.* i. 2985.
Galathea longipeda. *Lam. Syst. des Anim. sans Vert.* 158.
Galathea Bamffia. *Leach, Edinb. Encycl.* vii. 398.
Galathea rugosa. *Leach, Malac. Podoph. Brit.* tab. 29.
*Trans. Linn. Soc.* xi. 341.

Inhabits the European Ocean and Mediterranean Sea. It is very rare in Britain, but has been found on the Bamffshire coast and in the Plymouth Sound.

Division V.

Gen. 51. Gebia. *Leach.*

*Two anterior legs* equal, subdidactyle, with the thumb short. *Interior* antennæ with an elongate peduncle, the second joint shortest, the third largest and cylindric. *External double palpi* with the third joint of the internal footstalk shortest. *Tail* with broad lamellæ, the exterior ones costated, the middle one quadrate.

Sp. 1. *Deltäura.* Abdomen with the back membranaceous; tail with the apex of the exterior lamella dilated, and somewhat rounded; interior one truncate and formed like the Greek Delta.
Gebia deltäura. *Leach, Trans. Linn. Soc.* xi. 342.

Inhabits beneath the sand on the southern coast of Devonshire, and is found by digging to the depth of two or three feet.

Gen. 52. Callianassa. *Leach.*

*Four anterior legs* didactyle; anterior pair largest, very unequal; second pair less; third pair monodactyle; fourth and fifth pairs spurious. *Internal antennæ* with an elongate biarticulate peduncle, the

second joint longest. *External double palpi* with the second joint of the internal footstalk largest and compressed. *Tail* with broad lamellæ, the middle process elongate-triangular, with the apex rounded.

The thorax anteriorly abruptly subacuminate, the rostriform process divided from the shell by a suture. Anterior pair of legs very much compressed, the hand articulated. The larger leg, with the base of its wrist furnished with a curved process.

Sp. 1. *Subterranea.* Shell with the rostriform process with one longitudinal ridge, the point rounded.
Cancer astacus subterraneus.
*Montagu, Trans. Linn. Soc.* xi.
Callianassa subterranea.
*Leach, Edin. Encycl.* vii. 400.
—— *Trans. Linn. Soc.* xi. 343.

This animal lives beneath the sand on the sea-shore. It was first described by Montagu, who found it by digging in a sand-bank in the estuary of Kingsbridge, on the southern coast of Devon.

Gen. 53. Axius. *Leach.*

*Four anterior legs* didactyle; anterior pair largest, and somewhat unequal; third, fourth, and fifth pairs, furnished with a compressed claw. *Interior antennæ* with a three-jointed peduncle, the first joint longest. *External double palpi* with the two first joints somewhat large and equal. *Tail* broad, the intermediate lamella elongate-triangular.

Sp. 1. *Stirynchus.* Rostrum margined, the middle carinated; thorax behind the rostrum with two elevated abbreviated lines notched behind.
Axius Stirynchus. *Leach, Trans. Linn. Soc.* xi. 343.
Inhabits the British Sea.

### Division VI.

Gen. 54. Astacus.
*Fabr. Lam. Latr. Bosc, Penn. Leach.*

*Eyes* subglobose, not thicker than their peduncles. *Exterior antennæ*, with the first joint of the peduncle furnished with a spiniform squama that does not reach to the apex of the peduncle.

The coxæ of the third pair of legs of the female, of the fifth pair of the male, perforated. These perforations are for the passage of the semen and of the eggs, and although placed differently in other genera, yet they serve the same functions.

* *Abdomen with the sides of its segments obtuse.*

#### Astaci Marini.

Sp. 1. *Gammarus.* Rostrum on each side with four teeth, and with one on each side of its base.
Cancer gammarus. *Linn. Syst. Nat.* i. 1050.
Astacus gammarus. *Penn. Brit. Zool.* iv. 9. pl. 10.
Astacus marinus.
*Fabr. Suppl. Ent. Syst.* 406.
*Latr. Gen. Crust. et Insect.* i. 51.
Astacus gammarus.
*Leach, Edin. Encycl.* vii. 398.
—— *Trans. Linn. Soc.* xi. 344.

This species, which is the common lobster of our markets, inhabits deep clear water at the foot of rocks which hang over the sea. They breed during the early summer months, and are very prolific, Baxter having counted no less than 12,444 eggs under the abdomen. In warm weather they are very active; they have the power of springing backward in the water to a most astonishing distance into their holes in the rocks, as has been repeatedly observed by naturalists of credit. Their food consists of dead animal matter, and, it is said, also of sea-weeds. The female is stated to deposit her eggs in the sand, but the young state is not known.

The common lobster inhabits the European Ocean. It is found in very great abundance in the north of Scotland, but it is much more common on the coast of Norway, from whence the London markets are for the most part supplied.

Aristotle has very distinctly described this species under the name ἀσταχος.

** *Abdomen with the sides of its segments sharp.*

#### Astici Fluviatiles.

Sp. 1. *Fluviatilis.* Rostrum laterally dentated, the base with one tooth on each side.
Cancer astacus. *Linn. Syst. Nat.* i. 1051.
Astacus astacus.
*Penn. Brit. Zool.* iv. 18. pl. 15. fig. 27.
Astacus fluviatilis.
*Fabr. Suppl. Ent. Syst.* 406.
*Latr. Gen. Crust. et Insect.* i. 51.
*Leach, Edin. Encycl.* vii. 400.
—— *Trans. Linn. Soc.* xi. 344.

Gen. 55. Nephrops. *Leach.*

*Eyes* reniform, abruptly much thicker than their peduncles. *External antennæ* with the first joint of their peduncle furnished at its apex with a squama, which is produced beyond the apex of the peduncle.

The coxæ of the third pair of legs of the female, of the fifth pair of the male, perforated.

Sp. 1. *Norvegicus.* Abdomen with hairy areolæ; shell somewhat spiny in front.
Cancer Norwegicus. *Linn. Syst. Nat.* i. 1053.
Astacus Norwegicus.
*Penn. Brit. Zool.* iv. 17. pl. 12. fig. 24.

Inhabits the northern parts of Europe. It is found in the Frith of Forth during the summer months, often attaching itself to the lines of the fishermen. Colour, when living, flesh red. Fabricius, Bosc, and Latreille, cannot have seen this animal, as they all describe it as having four, instead of six didactyle legs.

### Division VII. *Subdivision* 1.

Gen. 56. Crangon. *Fabr. Latr. Bosc, Leach.*

*Anterior pair of legs* largest, with a compressed monodactyle hand, the rest simple; the second and third pair more slender, the fourth and fifth thicker.

Sp. 1. *Vulgaris.* Thorax behind, and on each side of the rostrum, unispinose.
Cancer crangon. *Linn. Syst. Nat.* i. 1052.
Astacus crangon. *Penn. Brit. Zool.* iv. 20.
Crangon vulgaris. *Fabr. Suppl. Ent. Syst.* 410.
*Latr. Gen. Crust. et Insect.* i. 55.
*Bosc, Hist. Nat. des Crust.* ii. 96.
*Leach, Edin. Encycl.* vii. 401. pl. 21. fig. 5.
—— *Trans. Linn. Soc.* xi. 346.

Inhabits the sandy coasts of the European Ocean, often entering estuaries, especially during the breeding season. It is the common shrimp of our markets.

Division VII. *Subdivision* 2.

Gen. 57. Atya. *Leach.*

*Four anterior legs* equal, the last joint cloven; third pair largest, unequal, with a simple claw; fourth and fifth pairs simple, terminated by a simple claw. *Tail* broad, the intermediate lamella with its extremity subacuminate, rounded.

Sp. 1. *Scabra.* Rostrum carinated trifid, the middle tooth longest; six hinder legs rough. Plate XXI.
Atya scabra. *Leach, Trans. Linn. Soc.* xi. 345.

Gen. 58. Processa. *Leach.*

*Anterior pair of legs*, with one side didactyle, the other armed with a simple claw; second pair unequal, didactyle, slender; one very long, with the wrist and fore-arm many jointed; the other shorter, with the wrist many-jointed; other legs terminated by simple claws.

Sp. 1. *Canaliculata.* Base of the rostrum with one tooth; intermediate lamella of the tail longitudinally canaliculated.
Processa canaliculata.
*Leach, Malac. Podoph. Brit.* tab. 41.

The thighs of the third and fourth pairs of legs are spinulose beneath; at the base of the rostrum there is an elevation dividing it from the thorax.

The above species, which forms the type of the genus, was discovered at Torcross, on the southern coast of Devon, by Montagu.

Division VII. *Subdivision* 3. *

Gen. 59. Pandalus. *Leach.*

*Anterior pair of legs* adactyle; second pair didactyle, unequal. *External double palpi* with the last joint of the internal footstalk longer than the preceding joint.

Sp. 1. *Annulicornis.* Rostrum ascending, many-toothed, apex notched; inferior antennæ annulated with red, and internally spinulose.
Pandalus annulicornis.
*Leach, Malac. Podoph. Britann.* tab. 40.
———, *Trans. Linn. Soc.* xi. 346.

Gen. 60. Hippolyte. *Leach.*

*Four anterior legs* didactyle. *Exteral double palpi* with the last joint of the internal footstalk shorter than the preceding joint.

Sp. 1. *Varians.* Rostrum strait, with two teeth above and below; shell above and beneath the eyes with one spine.
Hippolyte varians.
*Leach, Trans. Linn. Societ.* xi. 347.

Inhabits the rocky shores of southern Devonshire. It varies much in colour, being often found red, green, and blueish-green.

Gen. 61. Alpheus. *Fabr. Latr. Bosc, Leach.*

*Four anterior legs* didactyle. *External double palpi* with the last joint of the internal footstalk three times longer than the preceding joint.

Sp. 1. *Spinus.*
Cancer spinus. *Sowerby, Brit. Miscel.*
*Leach, Trans. Linn. Soc.* xi. 347.

Inhabits the Scottish Ocean.

Division VII. *Subdivision* 3. **

Gen. 62. Penæus. *Fabr. Latr. Bosc, Leach.*

*Six anterior legs* didactyle. *External double palpi* with five exserted joints, the last of which is obtuse.

Sp. 1. *Trisulcatus.* Thorax trisulcated behind; rostrum descending, multidentate above.
Penæus trisulcatus.
*Leach, Trans. Linn. Soc.* xi. 347.

Inhabits the Welsh Sea.

Division VII. *Subdivision* 4.

Gen. 63. Palæmon. *Fabr. Latr. Bosc, Leach.*

*Four anterior legs* didactyle; anterior pair smaller than the second pair. *External double palpi* with the last joint shorter than the preceding joint.

Sp. 1. *Serratus* (*common Prawn*). Rostrum ascending above, with from six to eight teeth, the apex emarginate; below with from four to six teeth.
Astacus serratus.
*Penn. Brit. Zool.* iv. 19. pl. 16. f. 28.
Cancer (*astacus*) squilla. *Herbst,* ii. 55. tab. 27. f. 1.
Palæmon squilla.
*Latr. Gen. Crust. et Insect.* i. 54.
*Leach, Edinb. Encycl.* vii. 401.
Palæmon serratus.
*Leach, Trans. Linn. Soc.* xi. 348.

Variety α Rostrum with six teeth above.
Subvariety 1. Rostrum beneath with four teeth.
———— 2. Rostrum beneath with five teeth.
Variety β Rostrum above with seven teeth.
Subvariety 1. Rostrum beneath with four teeth.
———— 2. ———————— five teeth.
———— 3. ———————— six teeth.
Variety γ Rostrum with eight teeth above.
Subvariety 1. Rostrum beneath with four teeth.
———— 2. ———————— five teeth.
———— 3. ———————— six teeth.

Although all the above varieties are common, yet β occurs most frequently. We have seen the upper edge of the rostrum with ten, the lower with five teeth; and both edges with but three teeth. The apex is generally notched above, but in two instances we observed the point to be entire. The situation of the teeth on the upper edge is variable, but in most instances the second tooth is at a greater distance from the first than the rest, which are generally equidistant, and rarely extend far beyond the middle, the rostrum from that part being edentate, with the exception of the emarginate apex.

Herbst, Latreille, and Dr Leach, formerly considered this species as *Cancer squilla* of Linné, but Dr L. has, since the publication of the error, met with the true *C. squilla* of that author, and has described it in the eleventh volume of the *Transactions of the Linnean Society*, p. 348.

*Palæmon serratus* of Fabricius is distinct, and, if his description be correct, it is not even referable to this Genus, he having expressly given, as its specific character ("Antennis posticis bifidis"), hinder antennæ bifid; whereas, in his generic character, he has stated these organs to be trifid ("Antennæ superiores trifidæ").

Gen. 64. Athanas. *Leach.*

*Four anterior legs* didactyle. Anterior pair larger than the second pair. *External double palpi* with the last joint longer than the preceding joint.

Sp. 1. *Nitescens.* Rostrum strait, and simple.

Crustacea.

Cancer (astacus) nitescens. *Montagu's* MSS.
Athanas nitescens.
*Leach, Trans. Linn. Soc.* xi. 349.
Inhabits the southern coast of Devonshire.

Division VIII.

Gen. 65. MYSIS.* *Latreille, Leach.*
PRAUNUS. *Leach.*

*Legs* bifid, the last joint of the four anterior pairs with the interior lacinia uniarticulate, ovate, compressed; of the other pairs of legs multiarticulate. *External double palpi* with the middle joint of the internal footstalk longest, the first very short.

At the base of the abdomen of the female is situated the external uterus, composed of two valve-like membranes, in which the young ones, just excluded from the egg, live and grow until they become strong enough to take care of themselves.

The animals of this genus swim with their head uppermost, and with their eyes spreading, which gives to them a singular and grotesque appearance.

* *Intermediate lamella of the tail emarginate.*

Sp. 1. *Spinulosa.* Tail with the intermediate lamella externally spinulose, the apex acutely emarginate; exterior lamellæ acuminate, and very broadly ciliated.
Praunus flexuosus. *Leach, Edinb. Encycl.* vii. 401.
Mysis spinulosa. *Leach, Trans. Linn. Soc.* xi. 350.
Inhabits the Frith of Forth near Leith.

Colour when alive, pellucid cinereous. Eyes black, red at their base. *Laminæ* of the external antennæ with a black longitudinal line and spots. A clouded spot on each side of the hinder part of the thorax, and another above the legs. Every segment of the body most beautifully marked with a reddish-rust-coloured spot, disposed in an arborescent form; tail fin spotted with the same colour, mixed with black. Pouch of the female with two rows of fuscous-black spots. Under side of the abdomen regularly mottled with rufous black.

It was observed with young from the middle of June to the middle of July. The females are one-third more abundant than the males. Length an inch and a quarter.

Sp. 2. *Fabricii.* Intermediate lamella of the tail obtusely notched; exterior lamellæ with rounded points.
Mysis Fabricii. *Leach, Trans. Linn. Soc.* xi. 350.
Inhabits the Greenland Sea, affording the principal sustenance of the great northern whale (Balæna mysticetus.)

** *Intermediate lamella of the tail entire.*

Sp. 3. *Integra.*
Praunus integer.
*Leach, Edinb. Encycl.* vii. 401.
Mysis integra. *Trans. Linn. Soc.* xi. 350.
Inhabits brackish pools of water left by the tide at Loch Ranza in the isle of Arran. Common in the month of August with young.

Length one-third of an inch. Females more abundant than the males. Colour whilst living pellucid, cinereous, spotted with black and reddish brown.

Crustacea.

Division IX.

Gen. 66. NEBALIA. *Leach.*

*Thorax* anteriorly with a moveable rostrum. *Anterior pair of legs* longest, simple; other pairs equal, approximate with the last joint bifid. *Antennæ* two, inserted above the eyes, the last joint bifid and multiarticulate.

Sp. 1. *Herbstii.* Gray or cinereous-yellowish; eyes black.
Cancer bipes.
*Oth. Fabr. Fn. Grön.* No. 223. fig. 2.
*Herbst*, ii. tab. 24. fig. 7.
Mysis bipes.
*Latr. Hist. Nat. des Crust. et des Insect.* vi. 285.
Monoculus rostratus.
*Montagu, Trans. Linn. Soc.* xi. 14. tab. 2. f. 5.
Nebalia Herbstii.
*Leach, Zool. Miscel.* i. 100. t. 44.
———, *Trans. Linn. Societ.* xi. 351.
Inhabits the European Ocean; it is common beneath stones lying on black mud, on the southern coast of Devon.

*Macrourous Genera of uncertain situation.*

Gen. 67. ALBUNEA.
*Dald. Fabr. Bosc, Lam. Latr. Leach.*

*Internal antennæ* with their peduncles shorter than the two setæ by which they are terminated. Legs ten, anterior pair with monodactyle hands, the thumb uncinated; hinder legs minute, spurious, filiform; the other legs terminated by a compressed sulcate joint. *Tail* not fan-shaped.

Sp. 1. *Symnista.* Shell anteriorly serrated.
Cancer symnista. *Linn. Syst. Nat.* i. 1053.
Albunea symnista.
*Fabr. Ent. Syst. Suppl.* 397.
*Latr. Gen. Crust. et Insect.* i. 44.
*Leach, Edinb. Encycl.* vii. 396.
Inhabits the Indian Ocean.

Gen. 68. REMIPES. *Latreille, Leach.*

*Internal antennæ* with their peduncles shorter than the two setæ by which they are terminated. *Legs* ten; the three hinder pairs, alike, and formed for swimming; second pair longer than the first, terminated by a conic compressed joint. *Tail* not fan-shaped.

Sp. 1. *Testudinarius.*
Remipes testudinarius.
*Latr. Gen. Crust. et Insect.* i. 45.
*Leach, Edinb. Encycl.* vii. 396.
Inhabits the New Holland Seas.

Gen. 69. HIPPA. *Fabr. Lam. Latr. Bosc, Leach.*
EMERITA. *Gronovius.*

*Internal antennæ*, with their peduncles shorter than the two setæ by which they are terminated. *Legs* ten; anterior pair adactyle, second and third pair with the last joint lunate; fourth pair with the last

* In the *Edinburgh Encyclopædia* Dr Leach gave the Genus MYSIS solely on the authority of the generally accurate Latreille, who formed the genus without any actual examination of its characters; and as he described but twelve legs, and misplaced it in the system, Dr Leach holds himself justified in having described the same Genus under the new name (PRAUNUS), which we have now rejected for that given by Latreille.

joint trigonal; hinder pair minute, filiform, spurious. *Tail* not fan-shaped.

Sp. 1. *Emeritus*. Tail inflexed, the last joint ovate.
Hippa emeritus.

*Fabr. Ent. Syst. Suppl.* 370.
*Latr. Gen. Crust. et Insect.* i. 45.
*Leach. Edinb. Encycl.* vii. 396.

Inhabits the Indian Ocean.

Gen. 70. THALASSINA. *Latreille, Leach.*

*Internal antennæ* terminated by two setæ, and inserted in the same horizontal line with the external ones. *Legs* ten, the two anterior pairs didactyle. *Tail* composed of five plates resembling a fan.

Sp. 1. *Scorpionoides*.
Thalassina scorpionoides.

*Latr. Gen. Crust. et Insect.* i. 52.
*Leach, Edinb. Encycl.* vii. 400.

Gen. 71. SQUILLA.

*Fabr. Bosc, Lam. Latr. Leach*, &c.

*Internal antennæ* with three setæ. *Legs* fourteen; anterior pair largest, monodactyle, the thumb much spined within; second, third, and fourth pairs with a monodactyle hand, the thumb being crooked and simple; the fifth, sixth, and seventh pairs spurious.

Sp. 1. *Mantis*. Body above with many elevated longitudinal lines; thumbs with six teeth.
Squilla mantis.

*Latr. Gen. Crust: et Insect.* i. 55.
*Leach, Edinb. Encycl.* vii. 402.

Inhabits the Mediterranean Sea.

Gen. 72. ZÖE. *Latr. Leach.*

ZÖEA. *Bosc.*

*Eyes* two, sessile, inserted one on each side of the head; *Rostrum* perpendicular, of the length of the thorax. *Thorax* somewhat ovate; shell diaphonous, with the back produced into a spine. *Legs* obscure and short, with the exception of the hinder ones, which are elongate, and formed for swimming. *Tail* as long as the thorax, and generally bent under it, composed of five joints, the first four very narrow, the last larger, lunate and spinulose.

Sp. 1. *Pelagica*. Spine of the back twice the length of the thorax, and bent backwards.

ZÖE Pelagica.

*Bosc, Hist. Nat. des Crust.* ii. 135. pl. 15. f. 3, 4.
*Latr. Gen. Crust. et Ins.* i. 21.
*Leach, Edin. Encycl.* vii. 389.

Inhabits the Atlantic Ocean. Was first described by Bosc in the above quoted work.

### Legion II. EDRIOPHTHALMA.

The *Malacostraca Edriophthalma*, or at least a greater part of them, were placed amongst the MACROURA by Latreille, who considered them as forming a particular family of that order. Had he examined the following new and curious genera, he would doubtless have formed a very different opinion. Many of the genera he even included amongst the Arachnides, as shall be shown hereafter.

*Synopsis and distribution of the Genera.*

#### SECTION I.

*Body laterally compressed. Legs fourteen. Antennæ two, inserted one on each side of the front of the head. (Tail furnished with styles.)*

Genus 1. PHRONYMA.

#### SECTION II.

*Body laterally compressed. Legs fourteen, with lamelliform coxæ. Antennæ four, inserted by pairs. (Tail furnished with styles.)*

Division I. Antennæ four-jointed, the last segment composed of many little joints; the upper ones very short.

Genus 2. TALITRUS.
3. ORCHESTIA.

Division II. Antennæ four-jointed, the last joint composed of several little joints; upper ones rather shortest.

Genus 4. ATYLUS.

Division III. Antennæ three-jointed, the last joint composed of several little joints; upper ones longest.

Genus 5. DEXAMINE.
6. LEUCOTHÖE.

Division IV. Antennæ four-jointed, the last segment composed of several little joints; upper ones longest.

*Subdivision* 1. Four anterior legs monodactyle, second pair with a much dilated compressed hand.

Genus 7. MELITA.
8. MÆRA.

*Subdivision* 2. Two anterior pair monodactyle and alike.

Genus 9. GAMMARUS.
10. AMPITHÖE.
11. PHERUSA.

Division V. Antennæ four-jointed, under ones longest, leg-shaped. (Four anterior legs monodactyle.)

*Subdivision* 1. Second pair of legs with a large hand.

Genus 12. PODOCERUS.
13. JASSA.

*Subdivision* 2. Second pair of legs with a moderate-sized hand.

Genus 14. COROPHIUM.

#### SECTION III.

*Body depressed. Antennæ four. Legs fourteen.*

A. *Tail without appendices.*

Division I. Body with all the segments bearing legs.

*Subdivision* 1. Body linear.

Genus 15. PROTO.
16. CAPRELLA.

*Subdivision* 2. Body broad.

Genus 17. LARUNDA.

Division II. Body with all the segments not bearing legs.

Genus 18. IDOTEA.
19. STENOSOMA.

B. *Tail on each side, with one or two appendices.*

Division III. Antennæ inserted in nearly the same horizontal line.

Genus 20. ANTHURA.

Division IV. Antennæ inserted in pairs, one above the other.

*Subdivision* 1. Tail with one lamella on each side.

Genus 21. CAMPECOPÆA.
22. NÆSA.

*Subdivision* 2. Tail with two lamellæ on each side.

* *Superior antennæ with a very large peduncle. Claws bifid.*

Genus 23. CYMODICE.
24. DYNAMENE.
25. SPHÆROMA.

** *Superior antennæ with a very large peduncle. Claws single.*

Genus 26. ÆGA.

*** *Superior antennæ with a moderate peduncle.*

Genus 27. EURYDICE.
28. LIMNORIA.
29. CYMOTHOA.

C. *Tail terminated with two setæ.*

Division V.

Genus 30. APSEUDES.

D. *Tail furnished with styles.*

Division VI. Interior antennæ distinct.

*Subdivision* 1. Styles of the tail exserted. Anterior legs monodactyle.

Genus 31. JANIRA.
32. ASELLUS.

*Subdivision* 2. Styles of the tail not exserted. Anterior legs simple.

Genus 33. JÆRA.

Division VII. Interior antennæ not distinct.

*Subdivision* 1. Styles of the tail double, with a double footstalk.

Genus 34. LIGIA.

*Subdivision* 2. Styles of the tail four, the lateral ones biarticulate.

* *Body not capable of contracting into a ball.*

*a*. External antennæ eight-jointed.

Genus 35. PHILOSCIA.
36. ONISCUS.

*b*. External antennæ with seven joints.

Genus 37. PORCELLIO.

** *Body contractile into a ball.*

Genus 38. ARMADILLO.

*Genus of uncertain situation.*

Genus 39. BOPYRUS.

SECTION I.

Gen. 1. PHRONYMA. *Latreille, Leach, Lamarck.*

*Head* large, nutant; *antennæ* biarticulate, the first joint small. Thorax seven-jointed, all its segments bearing legs. *Legs* compressed, *two anterior pairs* with the antepenultimate joint furnished at its point with a foliaceous process; the penultimate joint with the point bifid and terminated with a small claw; *third* and *fourth pairs* simple, longer, somewhat thicker, terminated by a bent claw; *fifth pair* large, very long, thicker, didactyle; the first joint gradually thickened towards its point; the second subtrigonate; the third ovate, and abruptly narrowed at its base; the last narrowed at its base; the fingers curved, and internally furnished each with one tooth; *sixth* and *seventh* pairs simple, terminated with a nearly strait claw. *Abdomen* triarticulate, each segment, on each side, with a double appendice, placed on a peduncle. *Tail* biarticulate, the first joint on each side furnished with a biarticulate process, terminated by two styles; second joint with four processes, each terminated by two styles; the inferior processes biarticulate, the superior triarticulate.

Sp. 1. *Sedentaria.* Fifth legs with the apex of the thumb and base of the finger internally denticulated.

Cancer sedentarius. *Forsk. Fn. Arab.* 95.

Phronima sedentaria.
*Latr. Gen. Crust. et Ins.* i. 57.
*Leach, Edin. Encycl.* vii. 403—433.
—— *Trans. Linn. Soc.* xi. 355.

Cancer *(gammarellus)* sedentarius.
*Herbst*, ii. 136. tab. 37. fig. 8.

Inhabits the Mediterranean Sea and Zetland Sea, residing in a cell composed of a gelatinous substance, open at each extremity, where it sits in an incurved posture.

The only specimen of this most interesting, rare, and curious animal, that has come under our inspection, was sent to us by the Reverend Dr J. Fleming, one of our most zealous Naturalists, who found it on the 3d November 1809, at Burray in Zetland, amongst rejectamenta of the sea.

All authors have erred in giving but ten legs to this animal. Of the parts of the mouth, we can, at present, say nothing.

SECTION II.

Division I.

Gen. 2. TALITRUS. *Latreille, Bosc, Leach.*

*Four anterior legs* in both sexes subequal, monodactyle. *Upper antennæ* shorter than the two first joints of the under ones.

Sp. 1. LOCUSTA. Antennæ subtestaceous-rufous, of the male longer than the body, of the female shorter; body cinereous, varied with darker cinereous.

Oniscus locusta. *Pallas?*

Talitrus locusta.
*Latr. Gen. Crust. et Insect.* i. 58.
*Bosc, Hist. Nat. des Crust.* ii. 152.
*Leach, Edin. Encycl.* vii. 402.

Astacus locusta. *Penn. Brit. Zool.* iv. 21.

Cancer *(gammarus)* saltator.
*Montagu, Trans. Linn. Soc.* xi. 94.

Inhabits the sandy shores of the European Ocean. The specific name Locusta is probably derived from the form of its protruded mouth, which has a general resemblance to the same part in the gryllides.

It has never been observed in the water; it burrows in the sand, and leaps about on the shore.

*Talitrus littoralis*, described in the seventh volume of the *Edinburgh Encyclopædia*, is merely the female of T. locusta.

The use of this animal (which is generally denominated *sand-hopper*) in the economy of nature, appears to be that of contributing to the dissolution of putrid animal and vegetable matter; serving in return as food to the shore-birds, who devour it with avidity.

Gen. 3. ORCHESTIA. *Leach.*

*Four anterior legs* of the male monodactyle, second pair with a compressed hand; of the female with the anterior pair monodactyle, the second didactyle. *Upper antennæ* not longer than the two first joints of the under ones.

Sp. 1. Littorea.

Cancer *gammarus* littoreus.
*Montagu, Trans. Soc.* xi. 96.
*Leach, Edinb. Encycl.* vii. 402. pl. 21. fig. 6.
—— *Trans. Linn. Soc.* xi. 356.

Inhabits many of our shores, and is found at the

Crustacea. mouths of rivers, but has never been observed in the water. It resides under stones and fuci, and in the evening it leaps about, and is devoured by birds.

Division II.

Gen. 4. Atylus. *Leach.*

*Upper antennæ* with the second joint longer than the third; *under ones* with the second joint somewhat shorter than the third. *Eyes* sub-prominent, rounded, inserted in a process on each side of the head, between the antennæ. *Tail* on each side with three double styles, and above with one moveable style on each side.

Sp. 1. *Carinatus.* Head with the rostrum descending; five last segments of the abdomen carinated, and acutely produced behind.

Gammarus carinatus. *Fabr. Ent. Syst.* ii. 515. 3.

Atylus carinatus.

*Leach, Zool. Miscel.* ii. 22. tab. 69.

—— *Trans. Linn. Soc.* xi. 357.

The locality is unknown.

Division III.

Gen. 5. Dexamine. *Leach.*

*Four anterior legs* sub-equal, monodactyle, furnished with a filiform-subovate hand. *Antennæ* with their first joint shortest. *Eyes* oblong, not prominent, inserted behind the superior antennæ. *Tail* on each side with three double styles, and above on each side with one moveable style.

Sp. 1. *Spinosa*, segments of the abdomen behind, produced into spines.

Cancer *(gammarus)* spinosus.

*Montagu, Trans. Linn. Soc.* xi. 3.

Dexamine spinosa.

*Leach, Edin. Encycl.* vii. 433.

—— *Zool. Miscel.* ii. 24.

—— *Trans. Linn. Soc.* xi. 359.

Inhabits the sea of the western coasts of Britain.

Gen. 6. Leucothöe. *Leach.*

*Anterior pair of legs* didactyle, the thumb biarticulate; *second pair* with a dilated and compressed hand, furnished with a crooked thumb.

Sp. 1. *Articulosa.*

Cancer articulosus.

*Montagu, Trans. Linn. Soc.* vii. 71. tab. 6. f. 6.

Leucothöe articulosa.

*Leach, Edin. Encycl.* vii. 403.

—— *Trans. Linn. Soc.* xi. 358.

Inhabits the British Sea, but is very rare.

Division IV. *Subdivision* 1.

Gen. 7. Melita. *Leach.*

*Anterior pair of legs* monodactyle; second pair with the thumb inflexed on the palm. *Tail* on each side with an elongate foliaceous lamella.

Sp. 1. *Palmata.* Body blackish; antennæ and legs annulated with pale colour.

Cancer palmatus. *Montagu, Trans. Linn. Soc.* vii. 69.

Melita palmata.

*Leach, Edin. Encycl.* vii. 403.

—— *Trans. Linn. Soc.* xi. 358.

Plate XXI.

Inhabits the sea-shore on the Devonshire coast, under stones.

Gen. 8. Mæra. *Leach.* Crustacea.

*Four anterior legs* didactyle; thumb of the second pair bent on the side of the hand. *Tail* with no foliaceous appendices.

Sp. 1. *Grossimana.*

Cancer *gammarus* grossimanus.

*Montagu, Trans. Linn. Soc.* ix. 97. t. 4. f. 5.

Mæra grossimana.

*Leach, Edin. Encycl.* vii. 403.

—— *Trans. Linn. Soc.* xi. 359.

Inhabits the southern coast of Devonshire, beneath stones.

Division IV. *Subdivision* 2.

Gen. 9. Gammarus. *Latreille, Leach.*

*Superior antennæ* furnished at the base of the fourth joint with a little jointed seta. *Tail* above with bundles of spines.

* *Tail with the superior double styles, having the upper style process very short.*

Sp. 1. *Aquaticus.* Process between the antennæ rounded, obtuse.

Gammarus pulex.

*Leach, Edin. Encycl.* vii. 402—432.

Gammarus aquaticus.

*Leach, Trans. Linn. Soc.* xi. 359.

Inhabits ponds, ditches, and springs in great plenty. We formerly considered it to be the same with the *Gammarus pulex* of Latreille and Bosc, but, on examining the subject more closely, we find their figures, are those referred to by them, representing the hands much dentated within.

Sp. 2. *Marinus.* Process between the antennæ subacuminate.

Gammarus marinus. *Leach, Trans. Linn. Soc.* xi. 359.

Inhabits the sea on the southern coast of Devonshire in plenty.

** *Tail with the superior double styles, having the style processes subequal.*

Sp. 3. *Locusta.* *Eyes* lunate.

Cancer *gammarus* locusta.

*Montagu, Trans. Linn. Soc.* ix. 92.

Gammarus locusta.

*Leach, Edin. Encycl.* vii. 403.

—— *Trans. Linn. Soc.* xi. 359.

Inhabits the British Sea.

Sp. 4. *Campylops.* Eyes flexuous.

Gammarus campylops.

*Leach, Edin. Encycl.* vii. 403.

—— *Trans. Linn. Soc.* xi. 360.

Inhabits the sea about Loch Ranza, in the Isle of Arran, where we took a single pair of this interesting animal.

Gen. 10. Ampithöe. *Leach.*

*Superior antennæ* with no seta at the base of their fourth joint. *Tail* simple above. *Hands* ovate.

Sp. 1. *Rubricata.*

Cancer *gammarus* rubricatus.

*Montagu, Trans. Linn. Soc.* ix. 99.

Gammarus rubricatus.

*Leach, Edin. Encycl.* vii. 402.

Ampithöe rubricata.

*Leach, Edin. Encycl.* vii. 432.

—— *Trans. Linn. Soc.* xi. 360.

Inhabits the sea of the southern coast of Devon.

Gen. 11. PHERUSA. *Leach.*

*Superior antennæ* with no seta at the base of their fourth joint. *Tail* simple above. *Hands* filiform.

Sp. 1. *Fucicola.* Testaceous-cinereous, or gray-cinereous, mottled with reddish.

Pherusa fucicola.

*Leach, Edin. Encycl.* vii. 432.

—— *Trans. Linn. Soc.* xi. 360.

Plate XXI.

Inhabits fuci on the southern coast of Devonshire.

Division V. *Subdivision* 1.

Gen. 12. PODOCERUS. *Leach.*

*Eyes* prominent. *Four anterior legs* mondactyle.

Sp. 1. *Variegatus.* Body varied with red and white.

Podocerus variegatus,

*Leach, Edin. Encycl.* vii. 433.

—— *Trans. Linn. Soc.* xi. 361.

Inhabits the southern coast of Devonshire, amongst confervæ and corallines.

Gen. 13. JASSA. *Leach.*

*Eyes* not prominent. *Four anterior legs* monodactyle with oval hands; second pair with its internal edge dentated.

Sp. 1. *Pulchella.* Thumb of second pair of legs with its internal edge notched at the base; colour white painted with red.

Var. α. Hands of the second pair with an elongate obtuse tooth.

Var. β. Hands of the second pair with the internal edge tridentate.

Jassa pulchella.

*Leach, Edin. Encycl.* vii. 433.

—— *Trans. Linn. Soc.* xi. 361.

Inhabits the sea of southern Devon, amongst fuci.

Division V. *Subdivision* 2.

Gen. 14. COROPHIUM. *Latreille, Leach.*

Sp. 1. *Longicorne.*

Cancer grossipes. *Linn. Syst. Nat.* i. 1055.

Astacus grossipes. *Penn. Brit. Zool.* iv. pl. 16. fig. 31.

Corophium longicorne.

*Latr. Gen. Crust. et Insect.* i. 59.

*Leach, Edin. Encycl.* vii. 403—432.

—— *Trans. Linn. Soc.* xi. 662.

Inhabits the coast of the European Ocean. At low tide, it may be observed crawling amongst the mud. It is very common at the mouth of the river Medway, from whence we have received a vast number of specimens.

SECTION III.

A. Division I. *Subdivision* 1.

Gen. 15. PROTO. *Leach.*

*Second, third, and fourth pair of legs* appendiculated at their bases.

To this genus belongs *Squilla pedata*, and probably also *Ventricosa* of Müller, with *Cancer gammarus pedatus* of Montagu, which is probably the same with *S. pedata* of Müller. See *Transactions of the Linnean Society*, Vol. XI. page 6. tab. 11. fig. 6.

Gen. 16. CAPRELLA. *Lamarck, Latr. Bosc, Leach.*

*Second, third, and fourth pairs of legs* not appendiculated at their bases; the third and fourth pairs spurious, subgelatinous, and globose.

The animals composing this genus, inhabit the sea, living amongst sertulariæ and marine plants, moving geometrically like the larvæ of the *Phalænidea.*

The specific characters may be taken from the number and situation of the spines on the head and back, form of the second pair of legs, &c.

Sp. 1. *Phasma.* Hands of the second pair of legs narrow, their internal edge acutely notched backwards: back anteriorly with three spines, turning forwards.

Cancer phasma.

*Montagu, Trans. Linn. Soc.* vii. 66. tab. 6. f. 3.

Inhabits the southern coast of Devon.

*Astacus atomos* of Pennant, and *Squilla lobata* of Müller belong to the genus Caprella, of which we have some unpublished species.

A. Division I. *Subdivision* 2.

Gen. 17. LARUNDA. *Leach.*

CYAMUS. *Latreille, Bosc.*

PANOPE. *Leach.*

*Antennæ* four-jointed, upper ones longest. *Legs* compressed, with strong claws; the third and fourth pairs elongate, spurious, cylindric, without claws; the two anterior pairs monodactyle.

External uterus, or pouch of the female, composed of four valves.

Sp. 1. *Ceti.* Bases of the third and fourth pairs of legs with processes resembling the figure 6; the hands of the second pair of legs anteriorly with three obtuse teeth. Plate XXI.

Oniscus ceti.

*Linn. Syst. Nat.* i. 1060.

*Pall. Spec. Zool.* ix. 4. f. 14.

Squille de la baleine.

*De Geer, Mém. sur les Insect.* vii. pl. 42. f. 6. 7.

Pycrogonum ceti. *Fabr. Suppl. Ent. Syst.* 570.

Cyamus ceti. *Latr. Gen. Crust. et Insect.* i. 60.

Panope ceti. *Leach, Edinb. Encycl.* vii. 404.

Larunda ceti. *Leach, Trans. Linn. Soc.* xi. 364.

Inhabits whales, and, according to Latreille, it is also found on some species of the genus Scomber.

By the Greenland fishermen it is termed the whale-louse.

Division II.

Gen. 18. IDOTEA. *Fabr. Latr. Bosc, Leach.*

ASELLUS. *Olivier, Lamarck.*

ENTOMON. *Klein.*

*External antennæ* half the length of the body, or less; the third and fourth joints equal. *Body* ovate.

Sp. 1. *Pelagica.* Body linear-oval; tail rounded, the middle with a very obsolete tooth; antennæ one third of the length of the body.

Idotea pelagica. *Leach, Trans. Linn. Soc.* xi. 365.

Inhabits the Scottish Seas.

Mr Stevenson sent us this species from the Bell-Rock, and afterwards procured for us a large log, perforated by Limnoria terebrans, which contained a vast number of them in the deserted cavities formed by that animal. It was taken in the Firth of Forth by the Rev. Dr Fleming, in whose collection there are specimens.

Colour when alive ash-gray or fuscous, speckled with darker colour, and often variegated or mottled with white spots; legs pale.

The female seems to be very rare, as amongst four hundred specimens of the animal, one only of that sex was found.

Length one inch and a quarter.

Gen. 19. STENOSOMA. *Leach.*

*External antennæ* as long as the body, the third joint, longer than the fourth. *Body* linear.

Sp. 1. *Lineare.* Last segment of the tail somewhat narrowed at its base, and dilated towards its apex, which is truncate and notched.

Oniscus linearis.
*Penn. Brit. Zool.* iv. pl. 18. fig. 2.
Idotea hectica. *Leach, Edin. Encycl.* vii. 404.
Stenosoma hecticum.
*Leach, Edin. Encycl.* vii. 433.
Stenosoma lineare.
*Leach, Trans. Linn. Soc.* xi. 366.

Inhabits the European Ocean. It sometimes occurs in the Firth of Forth, and amongst the Hebrides.

B. Division III.

Gen. 20. ANTHURA. *Leach.*

*Antennæ* short subequal, inserted one after another in the same horizontal line, the internal ones a little longest. *Body* linear. *Tail* with the last joint but one very short, the last elongate, narrower, with two elongate lamellæ on each side.

Sp. 1. *Gracilis.* Lateral processes of the tail obliquely truncated.

Oniscus gracilis.
*Montagu, Trans. Linn. Soc.* ix. tab. 5. fig. 6.
Anthura gracilis.
*Leach, Edin. Encycl.* vii. 404.
——— *Trans. Linn. Soc.* ix. 366.

B. Division IV. *Subdivision* 1.

Gen. 21. CAMPECOPEA. *Leach.*

*Tail* with its last segment furnished on each side with a compressed, curved, appendage. *Body* six-jointed, the last joint of the same size with the others. *Antennæ* setaceous, upper ones longest, their peduncle biarticulate; the space between the antennæ very great. *Anterior claws* bifid (the others I have not seen).

Sp. 1. *Hirsuta.* Brown, the last joint of the body with a few faint blueish spots.

Oniscus hirsutus.
*Montagu, Trans. Linn. Soc.* vii. t. 6. f. 8.
Campecopea hirsuta.
*Leach, Edin. Encycl.* vii. 405.
——— *Trans. Linn. Soc.* xi. 367.

Inhabits the southern coast of Devonshire; but is rather rare. Length one eighth of an inch.

Gen. 22. NÆSA. *Leach.*

*Tail* on each side of the last segment with a strait, subcompressed process attached to a peduncle. *Body* six-jointed, the last joint largest. *Antennæ* setaceous, subequal; upper ones with a very large biarticulated peduncle, the first joint largest: space between the antennæ easily to be discerned. *Claws* bifid.

Sp. 1. *Bidentata.* Last segment of the body armed with two spines or teeth: colour cinereous, faintly streaked with blue, or reddish.

Oniscus bidentatus.
*Adams, Trans. Linn. Soc.* v. 8. t. 2. f. 3.
Næsa bidentata.
*Leach, Edin. Encycl.* vii. 405.
——— *Trans. Linn. Soc.* xi. 367.

Inhabits the coasts of Wales and Devonshire.

Division IV. *Subdivision* 2. *

Gen. 23. CYMODICE. *Leach.*

*Eyes* touching the anterior margin of the first segment of the body. *Body* seven-jointed. *Tail* at the base on each side with two sub-compressed but not foliaceous appendages, the exterior ones largest; the apex of the tail notched with a lamella in the centre. *Claws* bifid.

Sp. 1. *Truncata.* Apex of the tail truncate.

Oniscus truncatus.
*Montagu's MSS.*
*Leach, Trans. Linn. Soc.* xi. 303.
——— *Edin. Encycl.* vii. 433.

This species is very rare, and has been found but three times on the southern coast of Devonshire.

Gen. 24. DYNAMENE. *Leach.*

*Eyes* not reaching to the anterior margin of the first segment of the body. *Body* seven-jointed. *Tail* with two equal foliaceous appendages on each side of its base; the apex notched. *Claws* bifid.

Dynamene.
*Leach, Edinb. Encycl.* vii. 405.
——— *Trans. Linn. Soc.* xi. 308.

Gen. 25. SPHÆROMA. *Latreille, Leach.*

*Eyes* not reaching to the anterior margin of the first segment of the body. *Body* seven-jointed. *Tail* with its apex entire; the base on each side with two equal foliaceous appendages. *Claws* bifid.

Sp. 1. *Serrata.* Body smooth, unarmed; tail very smooth on each side, obliquely truncated; lamellæ elliptic, acute, the external ones externally serrated.

Oniscus globator.
*Pall. Spec. Zool. Fasc.* ix. tab. 4. fig. 18.
Cymothea serrata. *Fabr. Ent. Syst.* ii. 510.
Sphæroma cinerea. *Latr. Gen. Crust. et Insect.* i. 65.
Sphæroma serrata.
*Leach, Edinb. Encycl.* vii. 405.
——— *Trans. Linn. Soc.* xi. 303.

B. Division IV. *Subdivision* 2. **.

Gen. 26. ÆGA. *Leach.*

*Eyes* large, granulated, oblong, oblique, marginal. *Tail* with its appendages foliaceous.

Sp. 1. *Emarginata.* Tail with the last joint acuminate; the interior lamella internally obliquely truncated, externally emarginated. Plate XXI.

Æga emarginata. *Leach, Trans. Linn. Soc.* xi. 370.

B. Division IV. *Subdivision* 2. ***.

Gen. 27. EURYDICE. *Leach.*

*Eyes* distinct, simple, lateral. *Head* as broad as the first segment of the body.

Sp. 1. *Pulchra.* Tail with the last joint semioval; body cinereous, variegated with black.

Gen. 28. LIMNORIA. *Leach.*

*Head* as broad as first segment of the body. *Eyes* granulated.

Crustacea.

Sp. 1. *Terebrans*. Body cinereous; eyes pitchy-black.
Limnoria terebrans.
*Leach, Edinb. Encycl.* vii. 433.
—— *Trans. Linn. Soc.* xi. 370.

Inhabits the British Ocean, perforating buildings of wood, piles, &c. It is common at the Bell-Rock, and on the coasts of Suffolk and Yorkshire. It generally produces seven young ones.

Gen. 29. Cymothoa. *Fabr. Dald. Leach*, &c.

*Head* narrow and small. *Eyes* obsolete. *Body* with the first segment notched to receive the head.

Sp. 1. *Œstrum*.
Cymothoa œstrum. *Fabr. Ent. Syst.* ii. 505.

C. Division V.

Gen. 30. Apseudes. *Leach*.

Sp. 1. *Talpa*. Shell anteriorly sharp, rostriform, with three excavated longitudinal lines.
Cancer *gammarus* talpa.
*Mont. Tr. Linn. Soc.* ix. t. 4. f. 6.
Apseudes talpa.
*Leach, Edinb. Encycl.* vii. 404.
—— *Trans. Linn. Soc.* xi. 372.

Inhabits the British Sea.

D. Division VI. *Subdivision* 1.

Gen. 31. Janira. *Leach*.

*Claws* bifid. *Eyes* moderate lateral-subvertical. *Internal antennæ* shorter than the peduncle of the external ones.

Sp. 1. *Maculosa*. Body cinereous, maculated with fuscous.
Oniscus maculosus. *Montagu's MSS.*
Janira maculosa.
*Leach, Edinb. Encycl.* vii. 434.
—— *Trans. Linn. Soc.* xi. 373.

Inhabits the southern coast of Devonshire, amongst marine plants.

Gen. 32. Asellus. *Geoffroy, Olivier, Latreille, Bosc, Leach.*
Entomon. *Klein.*

*Claws* simple. *Eyes* minute, lateral. *Interior antennæ* of the length of the setiferous joint of the exterior ones.

Sp. 1. *Aquaticus*. Colour cinereous, either spotted with grey or whitish.
Oniscus aquaticus.
*Linn. Syst. Nat.* i. 1061.
Aselle d'eau douce.
*Geoff. Hist. des Insect.* ii. 672. pl. 22. fig. 2.
Squille asselle.
*De Geer, Mém. sur les Insect.* vii. 496. pl. 31. fig. 1.
Aselle ordinaire.
*Latr. Hist. Nat. des Crust. et des Insect.* vi. 359.
Asellus vulgaris.
*Bosc, Hist. Nat. des Crust.* ii. 170. pl. 15. fig. 7.
*Latr. Gen. Crust. et Insect.* i. 63.
*Leach, Edin. Encycl.* vii. 404.
Idotea aquatica. *Fabr. Suppl. Ent. Syst.* 303.
Entomon hieroglyphicum. *Klein, Dub.* fig. 5.
Asellus aquaticus.
*Leach, Trans. Linn. Soc.* xi. 373.

Inhabits ponds and ditches, and is generally considered a sign of the purity of the water.

Division VI. *Subdivision* 2.

Gen. 33. Jæra. *Leach.*

*Eyes* moderately large, situated between the sides and the vertex of the head.

Sp. 1. *Albifrons*. Cinereous; front whitish.
Oniscus albifrons. *Montagu's* MSS.
Jæra alifrons.
*Leach, Edinb. Encycl.* vii. 434.
—— *Trans. Linn. Soc.* xi. 373.

Inhabits marine plants, and beneath stones, on the southern coast of Devon.

Division VII. *Subdivision* 1.

Gen. 34. Ligia.
*Fabricius, Latreille, Bosc, Leach.*

*External antennæ* with the last joint composed of several other joints.

Sp. 1. *Oceanica*. Antennæ as long as the body; back subscabrose.
Ligia oceanica.
*Fabr. Suppl. Ent. Syst.* 301.
*Leach, Edinb. Encycl.* vii. 406.
Ligia scopulorum.
*Leach, Edinb. Encycl.* vii. 406.
Oniscus oceanicus.
*Linn. Syst. Nat.* i. 1061.

Inhabits the rocky shores of the European Ocean. The last joint of the antennæ varies much in the number of its segments, even in the same individual.

Division VII. *Subdivision* 2. * *a.*

Gen. 35. Philoscia. *Latreille, Leach.*

*External antennæ* with their bases naked. *Tail* abruptly narrower than the body.

Sp. 1. *Muscorum*. Body variegated; sometimes plain brick-red.
Oniscus muscorum. *Scop. Ent. Carn.* 1145.
Oniscus sylvestris. *Fabr. Ent. Syst.* iv. 397.
Philoscia muscorum.
*Latr. Gen. Crust. et Insect.* i. 69.
*Leach, Edinb. Encycl.* vii. 406.

Inhabits France, Germany, and England, under stones and mosses.

Gen. 36. Oniscus *of authors.*

*Antennæ* inserted beneath the anterior margin of the head, on a prominent part.

Sp. 1. *Asellus*. Above obscure cinereous, rough; the sides and a series of dorsal spots yellowish.
Oniscus asellus.
*Linn. Syst. Nat.* i. 1061.
*Latr. Gen. Crust. et Insect.* i. 70.
*Leach, Edinb. Encycl.* vii. 406.
—— *Trans. Linn. Soc.* xi. 375.
Oniscus murarius.
*Fabr. Suppl. Ent. Syst.* 300.

Inhabits rotten wood and old walls throughout the greater part of Europe.

It was formerly used in medicine, and was supposed to cure agues, consumptions, &c. but has now,

Crustacea.

like many other medicines, deservedly grown out of fashion, and is rejected from the modern pharmacopœias. It is commonly named *pig's louse*, *millipied* or *carpenter*.

Division VII. *Subdivision* 2. * *b*.

Gen. 37. Porcellio. *Latreille, Leach.*

*External antennæ* inserted on a prominence under the anterior margin of the head. *Tail* with its lateral styles conic, prominulous.

Sp. 1. *Scaber*. Body rough.
Oniscus asellus.
*Fabr. Suppl. Ent. Syst.* 300.
Porcellio scaber.
*Latr. Gen. Crust. et Insect.* i. 70.
*Leach, Edinb. Encycl.* vii. 406.
—— *Trans. Linn. Soc.* xi. 37.

Division VIII. *Subdivision* 2. **

Gen. 38. Armadillo. *Latr. Leach.*

*External antennæ* seven-jointed, inserted on a prominence in a cavity on each side of the head. *Tail* with the lateral styles not prominent.

Sp. 1. *Vulgaris*. Griseous lead-coloured; hinder margin of the segments whitish.
Oniscus armadillo.
*Linn. Syst. Nat.* i. 1062.
Armadillo vulgaris.
*Latr. Gen. Crust. et Insect.* i. 70.
*Leach, Edinb. Encycl.* vii. 406.
—— *Trans. Linn. Soc.* xi. 376.

Inhabits Europe, amongst moss and under stones. It is commonly named the *pill-millified*, and paves the way to the myriapoda, in general external appearance and in economy, allied to the Genus Glomeris.

*Genus of uncertain place.*

Gen. 39. Bopyrus. *Latr.*

## Class II.—MYRIAPODA.

Myriapoda.

This Class was proposed by Dr Leach in the *Edinburgh Encyclopædia*, Vol. VII. and has since been distinctly established, and its characters more decidedly shown, in a paper published in the eleventh volume of the *Transactions of the Linnean Society*.

By Linné the animals composing this group were denominated Scolpendræ and Juli, and were arranged with apterous insects. His pupil J. C. Fabricius, in the Supplement to his *Entomologia Systematica*, placed them in a particular class named Mitosata, * comprehending all the species, like Linné, under the generic appellations of Julus and Scolpendra. G. Cuvier, in his *Tableau Elémentaire*, arranged the Myriapoda with Insects, in which he was followed by A. M. C. Duméril, who has, however, adopted the new genera proposed by Latreille.

They were arranged in the older works of Latreille along with Insects; but in his last work he has placed them in a peculiar order of the class Arachnides, which he has denominated Myriapoda; and has divided them into two families, namely,

Fam. I. Chilognatha. Gen. 1. Glomeris. 2. Julus. 3. Polydesmus. 4. Pollyxenus.

Fam. II. Syngnatha. Gen. 5. Scutigera. 6. Scolopendra.

Lamarck arranged them with the Arachnides, into three genera, 1. Scolopenda; 2 Scutigera; 3 Julus; and in his last work, he had adopted a fourth genus, Pollyxenus.

Having given a slight sketch of what has been done by systematic writers, we may observe, that we differ from them merely in considering them as constituting a distinct class, and in disposing the species under some additional generic heads, which a minute examination of their structure has most fully warranted.

*Classification.*

All the Myriapoda have their head distinct from the body, furnished with two antennæ. *Mandibles* simple, incisive. All or most of the segments of the body furnished with two or four legs.

The nervous system is composed of a series of ganglia, one in each segment of the body; these ganglia are brought into communication with each other by a longitudinal bundle of nerves, or, as it is generally, but improperly, denominated, by a spinal marrow.

The two families established by Latreille, are adopted as Orders, and his names are retained.

Order I. Chilognatha. *Maxillæ* none. *Palpi* obscure. *Lip* simple. (*Antennæ* inserted on the upper margin of the head.)

Order II. Syngnatha. Maxillæ two, distinct, with their bases united. *Palpi, maxillary* two, filiform; *labial* two terminated by a little hook.

Order I. Chilognatha. †

Fam. I. Glomeridea. *Body* contractile into a globe. *Eyes* distinct.

Gen. 1. Glomeris.

Fam. II. Julidea. *Body* not contractile into a globe. *Eyes* distinct.

Genus 2. Julus.
3. Craspedosoma.

Fam. III. Polydesmidea. *Eyes* obsolete.

Genus 4. Polydesmus.

Family I. Glomeridea.

Gen. 1. Glomeris. *Latr. Dumér. Leach.*
Armadillo. *Cuvier.*

*Antennæ* with the two first joints shortest, the sixth largest including the last, which is very small. *Body* elongate-ovate, convex above, arched beneath; first segment a little semicircular lamina, the second

* In the *Entomologia Systematica* the Genus Oniscus was included in this Class.

† The Genus Pollyxenus of Latreille we have not seen. It is figured by Geoffroy, *Hist. des Insect.* ii. pl. 59. fig. 10—12.

Myriapoda. larger than the others; the last semicircular and arched. *Legs*, sixteen pairs.

Sp. 1. *Marginata*. Black, the margins of the segments luteous or orange.

Oniscus marginatus.
*Villers, Entom.* iv. 187. tab. 11. fig. 15.
Gloméris bordé.
*Latr. Hist. Nat. des Crust. et des Insect.* vii. 66.
Oniscus marginatus.
*Oliv. Encycl. Méth. Hist. Nat.* vi. p. 24.
Julus limbatus.
*Oliv. Encycl. Méth. Hist. Nat.* vii. p. 414.
Oniscus zonatus.

*Stewart, Elem. Nat. Hist.* ii. 307.
Glomeris marginata.
*Latr. Gen. Crust. et Insect.* i. 74.
*Leach, Edin. Encycl.* vii. 407.
——- *Trans. Linn. Soc.* xi.

Plate XXII.

Inhabits Britain, France, and Germany, under stones; but has generally been considered by British Naturalists as a variety of Armadillo vulgaris.

Family II. Julidea.

Gen. 2. Julus *of authors*.

*Body* serpentiform, cylindric. *Antennæ* with the second joint longer than the third. *Legs* a great many.

The British species of this obscure genus may be found described in the eleventh volume of the *Transactions of the Linnean Society*. The following species, which is the most common, will best serve as an example of the genus.

Sp. 1. *Sabulosus*. Black-cinereous, with two reddish dorsal lines; last joint mucronated; legs luteous.

Julus sabulosus.
*Linn. Syst. Nat.* i. 1065.
——*Fn. Sv.* ii. 2067.
*Fabr. Ent. Syst.* ii. 395.
*Latr. Gen. Crust. et Insect.* i. 76.
*Leach, Edinb. Encycl.* vii. 407.
——- *Trans. Linn. Soc.* xi.

Inhabits Europe, lurking beneath stones, especially in sandy places.

Gen. 3. Craspedosoma. *Leach*.

*Body* linear, depressed, the sides of the segments laterally prominent. *Antennæ* towards their extremities somewhat thicker, the second joint shorter than the third.

This genus was discovered by the late R. Rawlins, Esq., one of the most promising naturalists of this country.

* *Middle of the segments prominent.*

Sp. 1. *Raulinsii* Back fuscous-brown, with four lines of white spots; belly and legs reddish.

Craspedosoma Raulinsii.
*Leach, Edinb. Encycl.* vii. 407—434.
——- *Trans. Linn. Soc.* xi. 380.

Plate XXII.

Inhabits the neighbourhood of Edinburgh, where it occurs in some plenty under stones and amongst moss. It was first noticed by Mr Rawlins, the founder of the genus.

** *Hinder angles of the segments produced.*

Sp. 2. *Polydesmoides*. Body reddish-gray; belly pale; legs reddish, with their bases pale; produced angles of the body each furnished with a seta. Myriapoda.

Julus polydesmoides. *Montagu's* MSS.
Craspedosoma polydesmoides.
*Leach, Edinb. Encycl.* vii. 407—434.
——- *Trans. Linn. Soc.* xi. 380.

Plate XXII.

Inhabits Devonshire, under stones. It is common all along the borders of Dartmoor, and on the southern coast.

Family III. Polydesmidea.

Gen. 4. Polydesmus. *Latr. Dumér. Leach.*

*Antennæ* with the second joint scarcely longer than the first, and much shorter than the third. *Body* linear, the segments laterally compressed, margined. *Eyes* obsolete.

Sp. 1. *Complanatus*. Reddish cinereous, last segment of the body mucronated.

Julus complanatus.
*Linn. Syst. Nat.* i. 1065.
*Fabr. Ent. Syst.* ii, 393.
Polydesmus complanatus.
*Latr. Gen. Crust. et Insect.* i. 76.
*Leach, Edinb. Encycl.* vii. 408.
——- *Trans. Linn. Soc.* xi. 381.

Plate XXII.

Inhabits Europe, under stones.

Order II Syngnatha.

Fam. I. Cermatidea. *Body* with the segments each bearing four legs.

Genus 1. Cermatia.

Fam. II Scolopendridea. *Body* with each segment bearing two legs: *hinder legs* distinctly longer than the others.

Stirps 1. Legs on each side fifteen.

Genus 2 Lithobius.

Stirps 2. Legs on each side twenty-one.

Genus 3. Scolopendra.

——- 4 Cryptops.

Family III. Geophilidea. *Body* with each segment bearing two legs: hinder legs not distinctly longer than the others *Legs* many, varying in number in the same species.

Genus 5 Geophilus.

Family I Cermatidea.

Genus 1. Cermatia. *Illiger, Leach.*

Scutigera. *Lam. Latr. Dumér. Leach.*

*Legs* thirty

Sp 1. *Coleoptrata*. Body reddish-yellowish, with longitudinal lines and bars on the legs of blue black.

Scolopendra coleoptrata.
*Linn. Syst. Nat.* i. 1062.
*Fabr. Ent. Syst* ii. 389
Julus araneöides. *Pall. Spec. Zool. Fas.* ix. t. 4. f. 16.
Scutigera araneöides.
*Latr. Gen. Crust. et Insect.* i. 77.
Scutigera coleoptrata.
*Leach, Edinb. Encycl.* vii. 408.

Inhabits houses in the south of Europe. It is common also in Africa.

Family II. Scolopendridea.

Gen. 2. Lithobius. *Leach.*

*Antennæ* conic-setaceous (joints about forty-five), conic-setaceous, the two first joints largest. *Under*

*lip* anteriorly broadly notched, the margin very much denticulated. *Eyes* granulated.

Sp. 1. *Forpicatus.* Head broad; under lip entirely and deeply covered with impressed dots; legs testaceous-yellowish.

Scolopendra forpicata.

*Linn. Syst. Nat.* i. 1062.

*Fabr. Ent. Syst.* ii. 390.

Lithobius forpicatus.

*Leach, Edinb. Encycl.* vii. 408.

—— *Trans. Linn. Soc.* xi. 381.

Plate XXII.

Inhabits Europe, beneath stones.

The other species are described in the eleventh volume of the *Transactions of the Linnean Society of London.*

Gen. 3. Scolopendra *of authors.*

*Antennæ* conic-setaceous, composed of (seventeen subconic joints. *Mouth* covered by hemispheric galeæ. *Exterior palpi* with a double footstalk; the last joint internally compressed, and armed with two claws. *Mandibles* strong, corneous, without teeth. *Under lip* divided by a fissure, the anterior margin narrower, strait and denticulated. *Body* with the segments margined. *Anterior pair of legs* small, the *last pair* largest, with the inner edge of the first joint spinose. *Eyes* eight, four on each side of the anterior margin of the head, arranged in a rhomboidal form.

Of this genus we have no indigenous species. The genus contains several species which have been confounded together under the title of Scolopendra morsitans, to which the generic instead of the specific character has been applied.

* *Body with the segments nearly of equal size.*

Sp. 1. *Gigas.* Segments transversely-quadrate, with rounded angles, of ferruginous brown colour, luteous behind; antennæ, palpi, galeæ, and legs testaceous; legs (anterior pair excepted) with the first (and rarely the second) joint spinulose.

Scolopendra gigas. *Leach, Trans. Linn. Soc.* xi.

Locality unknown.

Fine specimens of this species are preserved in the cabinet of Professor Jameson of Edinburgh, and in the British Museum.

** *Body with the segments transverse, alternately longer and shorter; the fifth and sixth subequal.*

Sp. 2. *Alternans.* Hinder legs with the first joint rounded, and internally spinulose.

Scolopendra alternans.

*Leach, Trans. Linn. Soc.* xi. 383.

Plate XXII.

Locality unknown.

Sp. 3. *Subspinipes.* Hinder legs with the first joint subrounded, flat above, at the internal apex subspinose.

Scolopendra subspinosa.

*Leach, Trans. Linn. Soc.* xi.

Locality unknown.

British Museum.

Sp. 4. *Trigonopoda.* Hinder legs trigonate, the first joint above and below internally spiniferous.

Scolopendra trigonopoda.

*Leach, Trans. Linn. Soc.* xi.

Locality unknown.

British Museum.

*** *Segments of the body elongate, or subelongate, irregular, now longer, then shorter.*

Sp. 5. *Morsitans.*

Scolopendra morsitans *of authors.*

Inhabits India.

Gen. 4. Cryptops. *Leach.*

*Antennæ* conic-setaceous, composed of (seventeen) globose-subconic joints. *Under lip* not denticulated, anterior margin scarcely emarginate. *Hinder legs* with the first joint toothless. *Eyes* obscure.

Sp. 1. *Hortensis.* Testaceous-ferruginous; back deeper in colour; antennæ and legs hairy.

Scolopendra hortensis.

*Donovan, Brit. Ins.*

Cryptops hortensis.

*Leach, Edinb. Encycl.* vii. 408.

—— *Trans. Linn. Soc.* xi.

Plate XXII.

Inhabits gardens in and near Exeter. It has likewise been found near Plymouth, in Devonshire.

Family III. Geophilides.

Gen. 5. Geophilus. *Leach.*

*Eyes* obscure. (*Lip* divided by a fissure?) *Mandibles* strong. *Antennæ* cylindric in some, towards the apex gradually somewhat narrower in others; composed of (fourteen) subcylindric joints, a little narrower at their base.

* *Antennæ with short joints.*

Sp. 1. *Carpophagus.* Head, antennæ, and arms fulvescent; body violet, anteriorly yellowish; legs pale yellowish.

Var. B. Body obscurely subviolet-testaceous, anteriorly subtestaceous.

Geophilus carpophagus.

*Leach, Trans. Linn. Soc.* xi. 384.

Inhabits Devonshire, in garden fruit; it is not uncommon.

Sp. 2. *Subterraneus.* Body yellow, head subferruginous.

Scolopendra subterranea.

*Shaw, Trans. Linn. Soc.* ii. 7.

Geophilus subterraneus.

*Leach, Trans. Linn. Soc.* xi. 385.

Inhabits the earth. Is very common in England.

Sp. 3. *Acuminatus.* Body ferruginous, anteriorly gradually narrower; head anteriorly and the legs paler.

Geophilus acuminatus.

*Leach, Trans. Linn. Soc.* xi. 386.

Inhabits moss and beneath the ground. It is rare.

** *Antennæ with elongate joints.*

Sp. 4. *Longicornis.* Body yellow; head ferruginous; antennæ long.

Geophilus longicornis.

*Leach, Trans. Linn. Soc.* xi. 386.

Plate XXII.

Inhabits the earth and under stones.

Obs. Scolopendra electrica of Linné, belongs to this genus.

## Class III.—ARACHNIDES.

From *αραχνη*, a *spider*, and *ειδος*, *resemblance*; a class of animals formerly arranged with insects, but first shown to be distinct by the celebrated Lamarck, and established as such, by Latreille and Cuvier.

Of the history of the Arachnides little can be said; we shall therefore content ourselves with giving a general view of the ideas entertained by authors. Linné arranged all of these animals with which he was acquainted with apterous insects, under the generic titles, Phalangium, Aranea, Acarus and Scorpio; and in this disposition he was followed by Cuvier.

Lamarck, in his *Systême des Animaux sans Vertébres*, has included amongst the Arachnides, the Myriapoda, and certain animals which we have considered as forming a subclass of insects, as shall be hereafter mentioned; and he has disposed what we consider as genuine Arachnides, into two divisions.

I. *Mouth furnished with mandibles and with maxillæ.*

Genus 1. Scorpio, 2. Aranea, 3. Phrynus, 4. Galeodes, 5. Phalangium, 6. Chelifer, 7. Elaïs, 8. Trombidium.

II. *Mouth furnished with a rostrum or haustellum.*

Genus 9. Hydrachna, 10. Bdella, 11. Acarus, 12. Pycnogonum, 13. Nymphum.

Duméril, in his *Zoologie Analytique*, has placed the Arachnides with the apterous insects. He arranges the genus, 1. Ixodes, *Latr.* with Pediculus and Pulex; the other genera he has placed in a peculiar family; 2. Aranea, 3. Mygale, 4. Phrynus, 5. Scorpio, 6. Chelifer, 7. Galeodes, 8. Phalangium.

Lamarck, in his *Extrait du Cours*, &c. has placed the Arachnides with some genuine insects and Myriapoda, but he has formed for them a separate order, which he terms Arachnides palpati, and disposes them into the following little groups of genera.

I. Pycnogonides.

Genus 1. Nymphum, 2. Phoxichilus, 3. Pycnogonum.

II. Acarides.

* *Parasiticæ.*

a. *Six legs.*

Genus 4. Astoma, 5. Leptus, 6. Caris.

b. *Eight legs.*

Genus 7. Uropoda, 8. Argas, 9. Ixodes, 10. Acarus.

** *Vagebundæ.*

a. *Land.*

Genus 11. Oribata, 12. Smaris, 13. Cheyletus, 14. Bdella, 15. Erythræus, 16. Trombidium.

b. *Aquatic.*

Genus 17. Elais, 18. Limnocharis, 19. Hydrachna.

III. Phalangides.

Genus 20. Siro, 21. Trogulus, 22. Phalangium, 23. Galeodes.

IV. Scorpionides.

Genus 24. Chelifer, 25. Scorpio, 26. Thelephonus, 27. Phrynus.

V. Araneides.

Genus 28. Aranea, 29. Mygale.

*Classification.*

The following classification is that lately published in the eleventh volume of the *Transactions of the Linnean Society*. It may not be improper to observe, that, from the Arachnides of Latreille, we have not only removed the *Tetracera* and *Myriapoda* (the first being referable to the *Crustacea*, the second to a new class), but also the *Parasita* and *Thysanura*, which form a subclass of genuine insects, and have added to the Arachnides the genus *Nycteribia*, which agrees with them in general structure.

Subclass I. Cephalostomata. Mouth situated in the front of the head.

Subclass II. Notostomata. Mouth situated on the back.

### Subclass I. CEPHALOSTOMATA.

A. *Legs with coxæ, thighs, tibiæ, and tarsi, distinct in form.*

Order I. Podosomata. *Body* four-jointed, and formed as it were of the junction of the coxæ. *Mouth* tubular. *Eyes* four, placed on a common tubercle. *Legs* eight.

Order II. Polymerosomata. *Body* composed of a series of segments; abdomen not pedunculated. *Mouth* furnished with didactyle mandibles and with maxillæ. *Eyes* two, four, six, or eight. Legs eight.

Order III. Duomerosomata. *Body* composed of two segments, the abdomen pedunculated. *Mouth* furnished with mandibles, and with maxillæ. *Eyes* six or eight. *Legs* eight.

B. *Legs, with the coxæ, thighs, tibiæ, and tarsi, not distinct from each other in form.*

Order IV. Monomerosomata. *Body* formed but of one segment. *Mouth* rostriform, or in some furnished with maxillæ and mandibles. *Legs* eight or six.

### Order I. Podosomata.

The singular animals which compose this order inhabit the sea. The females are furnished with two palpiform organs inserted at the base of the rostrum, on which parts they carry their eggs, attached in globular masses.

The legs are composed of three-jointed coxæ, one-jointed thighs, two-jointed tibiæ and tarsi, the latter parts furnished with claws.

Family I. Pycnogonideæ. *Mandibles* none.

Genus 1. Pycnogonum.

2. Phoxichilus.

Family II. Nymphonideæ. *Mandibles* two, biarticulate, didactyle.

Genus 3. Ammothea.

4. Nymphum.

Family I. Pycnogonideæ.

Gen. 1. Pycnogonum *of authors.*

*Legs* rather strong; coxæ with subequal joints; tibiæ with the first joint largest; tarsi with the first joint very small; claws simple, strong, acute.

*Egg-bearing organs* ten-jointed, the last joint very acute, unguiform, attached to the first joint of the body at the base of the rostrum.

Sp. 1. *Balænarum.* Plate XXIII.

Arachnides. Pycnogonum balænarum.

*Fabr. Ent. Syst.* iv. 416.
*Latr. Gen. Crust. et Insect.* i. 144.
*Leach, Edin. Encycl.* vii. 413. pl. 221. fig. 2.
—— *Trans. Linn. Soc.* xi. 388.

Inhabits the European Ocean. It is not uncommon in the Plymouth Sound, where it is taken by the trawl-fishers.

Gen. 2. Phoxichilus. *Latr. Leach.*

*Legs* very slender; *coxæ* with the middle joint longest, subclavate; *tibiæ* with the first joint shorter; *tarsi* with the first joint very small; claws double, unequal, the longer one acute.

*Egg-bearing organs* seven-jointed, the last joint tuberculiform, inserted at the base of the rostrum, one on each side, and attached to the first segment of the body.

The specific characters of none of the species are yet ascertained. To the genus, however, belong Pycnogonum spinipes, *Oth. Fabr. Fn. Grœn.* 232. and Phalangium hirsutum, *Montagu, Trans. Linn. Soc.* ix. tab. 5. fig. 7.

Family II. Nymphonideæ.

Gen. 3. Ammothea. *Leach.*

*Mandibles* much shorter than the rostrum, with equal joints, the fingers arcuate, and meeting at their tips. *Palpi* nine-jointed, the third joint very long. *Legs* slender; *coxæ* with the middle joint longest; *tibiæ* with the first joint somewhat shortest; *tarsi* with the first joint small; *claws* double, unequal.

*Egg-bearing organs* nine-jointed, inserted under the first legs, behind the rostrum.

Sp. 1. *Carolinensis.* Body entirely brown, testaceous; back with three trigonate tubercles.

Ammothea Carolinensis.

*Leach, Zool. Miscel.* i. 34. tab. 13.
—— *Trans. Linn. Soc.* xi.

Plate XXIII.

Inhabits the sea about Southern Carolina.

Gen. 4. Nymphum. *Lamarck, Leach.*
Nymphon. *Fabricius, Latreille.*
Pycnogonum. *Müller.*

*Mandibles* longer than the rostrum, with equal joints, the fingers curved, meeting along their whole length, and abruptly hooked at their extremities. *Palpi* six-jointed, the second joint elongate, the sixth very small. *Legs* very slender, coxæ with the middle joint longest; tibiæ with the second joint rather longest; tarsi with the first joint somewhat shortest, claws simple.

*Egg-bearing organs* ten-jointed, inserted behind the rostrum, almost under the anterior pair of legs.

Sp. 1. *Gracile.* Cinereous, thighs cylindric.

Nymphum gracile.

*Leach, Zool. Miscel.* i. 45. tab. 19. fig. 1.

Plate XXIII.

Inhabits the British seas everywhere; but as it never attains the size of the *phalangium,* misnamed by Linné *grossipes* (which is figured by Ström in his history of Sondmor, 208. tab. 2. fig. 16.), we are doubtful if it be the same species; but as the Linnean name is so ridiculously inapplicable, little fault can be found with the more appropriate name for which it has been exchanged.

Sp. 2. *Femoratum.* Reddish, thighs dilated and compressed.

Nymphum femoratum.

*Leach, Zool. Miscel.* i. 45. tab. 19. fig. 2.

Inhabits the shores on the southern coast of Devon.

Order II. Polymerosomata.

Fam. I. Sironeæ. *Palpi* simple. *Mandibles* didactyle.

Genus 5. Siro.

Fam. II. Scorpionideæ. *Palpi* arm-shaped. *Mandibles* didactyle. *Legs* alike.

*Stirps* 1. *Tail* none. *Eyes* two or four. *Pecten* none.

Genus 6. Obisium.
7. Chelifer.

*Stirps* 2. *Tail* elongate, articulated, terminated by a curved sting. *Eyes* six or eight. *Pecten* one on each side of the base of the abdomen.

Genus 8. Scorpio.
9. Buthus.

Fam. III. Tarantulideæ. *Mandibles* monodactyle. *Palpi* arm-shaped. *Anterior* legs shaped like antennæ; six hinder ones alike, simple. *Eyes* eight.

*Stirps* 1. *Tail* filiform. *Palpi* didactyle.

Genus 10. Thlephonus.

*Stirps* 2. *Tail* none. *Palpi* terminated by a moveable hook.

Genus 11. Tarantula.

Family I. Sironeæ.

Gen. 5. Siro. *Latreille, Leach.*

*Mandibles* two, two-jointed, cylindric, compressed, their points armed with a forceps. *Palpi* two, five-jointed, joints elongate, the second longest. *Body* oval. *Eyes* two, placed one in each side of the thorax, on an erect peduncle. *Legs* elongate, filiform; tibiæ and tarsi two-jointed, the latter parts terminated by an arcuate claw.

Sp. 1. *Rubens.* Pale red, legs paler.

Siro rubens.

*Latr. Gen. Crust. et Insect.* i. 143.
*Leach, Edinb. Encycl.* vii. 416.
—— *Trans. Linn. Soc.* xi. 390.

Plate XXIII.

Inhabits moss at the roots of trees and in woods.

Family II. Scorpionideæ.

The animals composing this fami y constitute a most natural group.

*Stirps* 1.

Gen. 6. Obisium. *Illiger, Leach.*

*Body* cylindric. *Thorax* composed of one segment. *Mandibles* porrect. *Eyes* four.

Sp. 1. *Trombidioides.* Second joint of the arms elongate; fingers long and strait.

Chelifer Trombidioides.

*Latr. Gen. Crust. et Insect.* i. 133.

Obisium Trombidioides.

*Leach, Edinb. Encycl.* vii. 428.
—— *Trans. Linn. Soc.* xi. 391.

Plate XXIII.

Inhabits France and England, under stones.

Gen. 7. Chelifer. *Geoffroy, Leach.*

*Thorax* composed of three parts. *Mandibles* short. *Eyes* two.

Sp. 1. *Fasciatus.* Hands oval; segments of the abdomen bordered with whitish.

Chelifer fasciatus. *Leach, Trans. Linn. Soc.* ix.

Inhabits beneath the bark of willow and other trees.

Arachnides. It sometimes occurs near London. It is mentioned by Geoffroy (*Hist. des Insect.* ii. 618.)

Plate XXIII.

*Stirps* 2.

Gen. 8. SCORPIO *of authors.*

Eyes six.

Sp. 1. *Europæus.* Pecten with nine teeth; hands angulated, subcordate; wrists unidentate; body obscure brown; legs and last joint of the tail brownish-yellow.

Scorpio Europæus.

*Villers, Entom.* iv. 131. tab. 2. f. 11.
*Latr. Gen. Crust. et Insect.* i. 131.
*Leach, Edinb. Encycl.* vii. 429.
——— *Trans. Linn. Soc.* xi. 391.

Inhabits the south of Europe.

Gen. 9. BUTHUS. *Leach.*

Eyes eight.

Sp. 1. *Occitanus.* Pecten with twenty-eight teeth; body yellowish; tail longer than the body, with elevated granulated lines; no point beneath the sting.

Scorpio occitanus.

*Amoreaux, Jour. de Phys.* an. 1789.
*Latr. Gen. Crust. et Ins.* i. 132.
*Leach, Edinb. Encycl.* vii. 428.

Buthus occitanus. *Leach, Trans. Linn. Soc.* xi. 391.

Inhabits southern Europe; it occurs in France and in Portugal.

Family III. TARANTULIDEÆ.

*Stirps* 1.

Gen. 10. THELYPHONUS. *Latreille, Leach.*

*Maxillæ* subtriangular, large, meeting within. *Palpi* very thick, terminated by a didactyle hand.

*Body* elongate. *Thorax* ovate, with two eyes on its anterior margin towards the middle, and three on each side, placed in a triangle.

Sp. 1. *Proscorpio.*

Phalangium caudatum. *Linn. Syst. Nat.* i. 1029.
Tarantula caudata. *Fabr. Ent. Syst.* ii. 433.
Thelyphonus proscorpio.

*Latr. Gen. Crust. et Ins.* i. 130.
*Leach, Edinb. Encycl.* vii. 428.
——— *Trans. Linn. Soc.* xi.

Inhabits Southern America.

*Stirps* 2.

Gen. 11. TARANTULA. *Brown, Fabricius, Leach.*

PHRYNUS. *Olivier, Lam. Fabr. Hermann.*

*Maxillæ* obverse-conic, divergent; internal apex produced, compressed, and rounded. *Palpi* terminated by a moveable, horny, bent claw.

*Body* depressed. *Thorax* broad, reniform, or lunate, with two eyes about the middle of its anterior margin, and three on each side, placed in a triangle.

Sp. 1. *Lunata.* Palpi nearly three times the length of the body; apex of the third joint with four spines, the two upper ones strongest.

Tarantula lunata.

*Fab. Ent. Syst.* ii. 433.
*Leach, Edin. Encycl.* vii. 428.
——— *Trans. Linn. Soc.* xi. 392.

Phrynus lunatus. *Latr. Gen. Crust. et Insect.* i. 128.

Inhabits the East Indies.

Order III. DUOMEROSOMATA.

Fam. I. SOLPUGIDEÆ. *Eyes* four. *Anus* simple.

Genus 12. SOLPUGA. Arachnides.

Fam. II. PHALANGIDEÆ. *Eyes* two. *Anus* simple.

Genus 13. PHALANGIUM.
14. OPILIO.

Fam. III. ARANEIDEÆ. *Eyes* six or eight. *Anus* with nipples for spinning.

*Stirps* 1. *Legs* simple. *Hinder* eyes not placed on the anterior and superior part of the thorax, nor forming an irregular hexagon. *The two exterior nipples* of the anus longer than the others, and projecting. *Lip* not advancing between the maxillæ nor prominent, but as long as broad.

* *Eyes eight. Mandibles projecting.*

Genus 15. MYGALE.
16. ATYPUS.
17. ERIODON.

** *Mandibles perpendicular. Eyes six.*

Genus 18. SEGESTRIA.
19. DYSDERA.

*** *Mandibles perpendicular. Eyes eight.*

Genus 20. FILISTATA.
21. DRASSUS.
22. CLOTHO.
23. CLUBIONA.
24. ARANEA.
25. AGELENA.
26. ARGYRONETA.

*Stirps* 2. *Legs* simple. *Hinder eyes* not placed on the anterior and superior of the thorax, nor forming an irregular hexagon. *Nipples* of the anus short and nearly equal, of a conic form. *Lip* nearly semicircular, broader than long, and projecting between the maxillæ. (*Eyes* eight).

* *Eyes not describing the segment of a circle. Maxillæ straightened towards their extremities, but not dilated.*

Genus 27. SYCTODES.
28. THERIDION.
29. LATRODECTUS.
30. PHOLCUS.

** *Eyes not describing the segment of a circle. Maxillæ strait with their points dilated.*

Genus 31. ULOBORUS.
32. TETRAGNATHA.
33. LINYPHIA.
34. EPEIRA.
35. NEPHILA.

*** *Eyes describing the segment of a circle.*

Genus 36. EPISENUS.
37. MICROMMATA.
38. THOMISUS.

*Stirps* 3. *Legs* not formed for leaping. *Hinder eyes* placed on the anterior and superior part of the thorax, forming an irregular hexagon.

* *Anterior legs longest.*

Genus 39. OXYOPES.
40. STORENA.
41. CTENUS.

** *Hinder pair of legs longest.*

Genus 42. LYCOSA.
43. DOLOMEDES.

*Stirps* 4. *Legs* formed for leaping. (*Eyes* eight. *Thorax* never carinated).

Genus 44. ERESUS.

Genus 45. SALTICUS.

46. ATTUS.

Family I. SOLPUGIDEÆ.

Gen. 12. SOLPUGIDEÆ.

*Lichtenst. Fabr. Herbst, Leach.*

GALEODES. *Olivier, Lamarck, Latreille.*

RHAX. *Bermann.*

*Eyes* placed on a common tubercle. *Mandibles* very large, strait. *Palpi* very large, formed like legs, the last joint simple. *Body* elongate.

Sp. 1. *Arachnoides.* Pale-yellowish, mixed with cinereous.

Solpuga arachnoides.

*Lichtenst. Catal. Hamb.* 1797, 151, 196.

Solpuga araneoides.

*Fabr. Suppl. Ent. Syst.* 294.

Galeodes araneoides.

*Oliv. Encycl. Méth. Hist. Nat.* vi. 590.

*Latr. Gen. Crust. et Insect.* i. 135.

Inhabits the Cape of Good Hope.

Family II. PHALANGIDEÆ.

Gen. 13. PHALANGIUM of authors.

*Eyes* placed in a common peduncle. *Mandibles* corneous, subcylindric, compressed, biarticulate, inflexed or geniculated at the second joint, the apex of which bears a forceps with equal fingers. *Palpi* formed like legs terminated by a hook. *Body* more or less oval. *Second pair of legs* almost six times the length of the body; *tarsi* all capillary, very slender, the first joints elongate, four times (or more) longer than broad.

Sp. 1. *Opilio. Latr. Gen. Crust. et Insect.* i. 157.

Male, Phalangium cornutum.

*Linn. Syst. Nat.* i. 1028.

*Fabr. Ent. Syst.* ii. 430.

Female, Phalangium opilio.

*Linn. Syst. Nat.* i. 1027.

*Fabr. Ent. Syst.* ii. 429.

Inhabits Europe, on walls and rocks.

Gen. 14. OPILIO.

*Eyes* placed on a common peduncle. *Mandibles* corneous, subcylindric, compressed, biarticulate, inflexed or geniculated at the second joint, the apex of which has a forceps with equal fingers. *Palpi* formed like legs, terminated by a hook. *Body* more or less oval. *Second pair of legs* three or four times the length of the body, the fourth and following joints a little elongate, twice as long as broad.

Sp. 1. *Histrix.*

Phalangium histrix.

*Latr. Gen. Crust. et Insect.* i. 140.

Inhabits France and England.

Family III. ARANEIDEÆ.

The animals composing this most natural family, are familiarly denominated spiders, and, as we have before mentioned, were included by Linné, Fabricius, and other authors, in one genus, which they called Aranea; but as the species are very numerous, they were obliged to divide them into sections, which they distinguished by the situation of their eyes. These organs are immoveable, and consist each of a single lens, which deprives them of the faculty of seeing in every direction.

The Araneideæ are by far the most interesting animals of that class of which they form the type; and consequently their habits and structure excited the attention of naturalists at a very early period.

Aristotle and Pliny were acquainted with those species that have the power of darting out long threads. *Vide Aristotelis Historia Animalium*, lib. ix. cap. 89. and *Plinii Hist. Naturalis*, lib. xii. cap. 74.

Spiders frequently change their skins, and their skins are often found in their webs, being dry and transparent, with their mandibles attached to them. When about to cast their covering, they suspend themselves in some corner, and creep out of a crack which takes place on their back, gradually withdrawing their legs from the skin, as if from a glove. They have likewise the power of reproducing their legs; the mode in which this takes place, was made known to us by Sir Joseph Banks, and which we shall relate as nearly as possible in the words of that accurate observer of nature.

As he was writing one evening in his study, one of the web-spinning spiders, of more than the middle size, passed over some papers on the table, holding a fly in its mouth. Much surprised to see a spider of this description walking about with its prey, and being struck with somewhat unusual in its gait, he caught it and placed it within a glass for examination; when instead of eight, he perceived that it had but three legs, which accounted for the inability of the creature to spin its web; but the curious circumstance of its having changed its usual economy, and having become a hunting instead of a spinning spider, as well as a wish to learn whether its legs would be renewed, induced him to keep the animal in the glass, from whence it could not escape, and to observe its conduct.

On the following morning the animal eat two flies, given to it, by sucking out the juices, but left the carcasses entire. Two or three days afterwards, it devoured the body and head of a fly, leaving only the wings and legs. After this time, it sometimes sucked and sometimes eat the fly given to it. At first it consumed two flies in a day, but afterwards not more than one in two days. Its excrement, which it voided, was at first of a milky-white colour, but afterwards the white had a black spot in the centre, of a more solid appearance than the surrounding fluid.

Soon after its confinement, it attempted to form a web on the side of the vessel, but performed the business very slowly and clumsily, from the want of the proper number of legs. In about a fortnight it had completed a small web, upon which it generally sat.

A month after having been caught, it shed its skin, leaving the slough on the web. After this change five new legs appeared, not half as long as the other three legs, and of very little use to the animal in walking. These new members, however, extended themselves a little in three days, and became half as long as the old ones. The web was now increased, and the animal continued immoveably sitting on it in the day time, unless drawn from it, or attracted by a fly thrown to it as its usual provision.

Twenty-nine days afterwards, it again lost its skin, leaving the slough hanging in the web, opposite to a hollow cell it had woven, so as to prevent it from

being completely seen when lodged in it. The legs were now larger than before the change of skin, and they grew somewhat longer still in three or four days, but did not attain the size of the old legs.

The animal now increased its web, and being put into a small bowl, as a more commodious residence, soon renewed a better web than the first. In this state it was left on the first of November. No farther observations have yet been made on the subject.

The principal use of the *Aranëideæ*, in the economy of nature, seems to be that of preventing the too great increase of insects.

The palpi of the different sexes should be carefully described, as they seem to afford some most excellent subsidiary generic characters.

*Stirps* 1. *

Gen. 15. Mygale. *Walckanäer, Latreille, Leach.*

*Labium* very small and quadrate, inserted under the base of the maxillæ. *Palpi* attached to the apex of the jaws. *Eyes* on each side geminated.

A. *Claws of the tarsi, with a few very obscure, or with no denticulations beneath.*

* *Last joint of the tarsi and palpi with a brush of hair.*

Sp. 1. *Avicularia.* (Bird-catching Mygale). Blackish, very hairy, the hairs elongate: palpi and legs with ferruginous tips; tarsi broad; claws not exserted. (*Palpi* of the male globose, produced into a very long, very slender hook).

Aranea avicularia.
*Linn. Syst. Nat.* i. 1034.
*Fabr. Ent. Syst.* ii. 424.

Mygale avicularia.
*Latr. Gen. Crust. et Insect.* i. 83.
*Leach, Edin. Encycl.* vii. 420.

Inhabits South America.

** *Palpi and tarsi without any brush.*

Sp. 2. *Cæmentaria.* Ferruginous brown; mandibles blackish; carina and margin of the thorax paler.

Mygale cæmentaria.
*Latr. Gen. Crust. et Insect.* i. 84.
*Leach, Edin. Encycl.* vii. 421.

Inhabits the South of France. It is described by Dorthes in the second volume of the *Transactions of the Linnean Society*, tab. 17. fig. 6.

B. *Claws of the tarsi internally much dentated.*

Sp. 3. *Calpeiana.*

Mygale calpeina.
*Walck. Tab. des Aran.* 5.
*Latr. Gen. Crust. et Insect.* i. 85.
*Leach, Edin. Encycl.* vii. 421.

Gen. 16. Atypus. *Latreille, Leach.*

Oletera. *Walckanäer.*

*Eyes* on each side geminated. *Lip* very small and quadrate, inserted under the base of the maxillæ. *Palpi* inserted at the external base of the maxillæ, which are dilated at that part.

Sp. 1. *Sulzeri.* Black and shining; mandibles very long and strong; thorax nearly quadrate; plain behind, abruptly elevated before; the two middle eyes placed on an eminence; back of the abdomen coriaceous and more shining; joints of the legs whitish.

Atypus.
*Latr. Nouv. Diction. d'Hist. Nat.* tab. 24. p. 133.

Atypus sulzer.
*Latr. Gen. Crust. et Insect.* i. 85.
*Leach, Edin. Encycl.* vii. 421.

Oletère dittorme. *Walck. Tab. des Aran.* 7.

Plate XXIII.

Inhabits France and England. In the latter country it was discovered by Dr Leach near Exeter, and he has twice obtained specimens that occurred near London.

Gen. 17. Eriodon. *Latreille, Leach.*

Missulena. *Walckanäer.*

*Lip* linear, esserted between the maxillæ. *Palpi* inserted at the external base of the maxillæ, which are dilated at that part. *Eyes* disposed somewhat like the letter H.

This genus was first established by Latreille, in the *Noveau Dictionnaire d'Histoire Naturelle*, xxiv. p. 133.

Sp. 1. *Occatorius.*

Missulène herseuse. *Walck. Tab. des Aran.* 8.

Eriodon occatorius.
*Latr. Gen. Crust. et Insect.* i. 86.
*Leach, Edin. Encycl.* vii. 421.

Inhabits Notasia. Discovered by Le Sueur and Peron.

*Stirps* 1. **

Gen. 18. Segestria.
*Latreille, Walckanäer, Leach.*

*Maxillæ* strait, longitudinal, with the base thickened, dilated externally, somewhat wedge-shaped, the middle longitudinally convex. *Lip* elongate-quadrate, longer than broad, the middle longitudinally convex or subcarinated. *Legs*, the first pair longest, rest in proportion, the second, then the fourth, the third pair being shortest. *Eyes* placed in a transverse line, the extremities somewhat recurved.

Sp. 1. *Senoculata.* Thorax blackish-brown; abdomen oblong, griseous, with a longitudinal band of blackish spots; legs pale brown with obscure bands.

Aranea senoculata. *Fabr. Ent. Syst.* ii. 426.

Segestria senoculata.
*Walck. Tab. des Aran.* 48.
*Latr. Gen. Crust. et Insect.* i. 89.
*Leach, Edin. Encycl.* vii. 421.

Inhabits rocks and old buildings. It is common in France, near Paris, and in England it is not rare.

*Segestria cellaria* has once been found at Plymouth in a cellar, and is now in Dr Leach's collection.

Gen. 19. Dysdera. *Latreille, Walckanäer, Leach.*

*Maxillæ* strait, longitudinal, with the base thickened and externally dilated at the insertion of the palpi; the apex internally obliquely truncated, and thence externally acutely terminated. *Palpi* with the first joint short and nearly obsolete. *Lip* elongate, quadrate, gradually narrowing towards its point. *Eyes* forming a horse-shoe, the open part in front. *Legs* with the first, then the fourth, then the second pair longest; the third shortest. *Claws* with a little brush beneath.

Sp. 1. *Eythrina.* Mandibles and thorax sanguineous; legs lightly coloured; abdomen soft, greyish yellow and silky.

Aranea Erythrina. *Fourcroy, Fn. Paris*, ii. 224.
Dysdera Erythrina.
*Latr. Gen. Crust. et Insect.* i. 90.
*Walck. Tab. des Aran.* 47.
*Leach, Edinb. Encycl.* vii. 421.
Plate XXIII.

Inhabits the south of France, and England, beneath stones. It is rare in the latter country, but has been taken in Devonshire, near Plymouth and Exeter, and near London. *Aranea Hombergii* of Scopoli, is merely a variety of this species.

*Stirps* 1. ***

Gen. 20. Filistata. *Latreille.*

*Eyes* placed on an uneven elevation, the four anterior ones forming a semicircle, open in front; the four hinder ones disposed in pairs, in nearly the same transverse line. *Maxillæ* much inclined towards the lip, with no groove at the insertion of the palpi. *Palpi* inserted in the lower side of the maxillæ. *Lip* much longer than broad. *Legs* with the fourth pair larger than the first pair.

This genus contains but one species. *Filistata testacea* of Walckanäer's MS. Of this animal, which was discovered near Marseilles, we have seen no description.

Gen. 21. Drassus. *Walckanäer, Latreille, Leach.*
Gnaphosa. *Latreille.*

*Palpi* inserted under the lateral and external margin of the maxillæ towards their middle. *Maxillæ* longitudinal, arcuated, gradually becoming broader from the base towards the middle, somewhat concave internally, smooth externally, their middle impressed, the points bent inwards above the lip, and obliquely truncated within. *Lip* elongate, ovate-quadrate, or rather oval; the base transversely truncated, inclosing the maxillæ. *Legs* with the first, and afterwards the second pair longest.

* *Lip somewhat oval; the external side of the maxillæ much bent and arched.*

Sp. 1. *Melanogaster.* Mandibles blackish; thorax and legs obscure brown; thighs light reddish-brown; abdomen cinereous-brown and silky.
Drassus melanogaster.
*Latr. Gen. Crust. et Insect.* i. 87.
Drassus lucifagus.
*Walck. Tab. des Aran.* 45.

Inhabits France and England, under stones.

** *Lip ovate-quadrate.*

Sp. 2. *Ater.* Entirely black.
Drassus ater.
*Latr. Gen. Crust. et Insect.* i. 87.
*Leach, Edin. Encycl.* vii. 422.

Inhabits the vicinity of Paris, and near London, beneath stones.

Gen. 22. Clotho. *Walckanäer, Latreille, Leach.*

*Maxillæ* much inclined towards the lip, with no groove at the insertion of the palpi. *Lip* not much longer than broad. *Feet* with the fourth, the second, then the third longest. *Eyes* close together, disposed four and four in two lines, bent backwards in somewhat a concentric manner; those of the hinder line disposed in pairs.

Sp. 1. *Durandii.* Thorax rusty brown, margined with pale yellow; abdomen black, with five red spots arranged 2, 2, 1; legs livid brown.
Clotho Durandii.
*Latr. Gen. Crust. et Ins.* vol. iv. append.
*Leach, Edin. Encycl.* vii. 422.

Inhabits Montpellier, building its web amongst stones.

Gen. 23. Clubiona. *Latreille, Walckanäer, Leach.*

*Maxillæ* strait and longitudinal; the basis a little dilated externally; the apex rounded and obliquely truncated on the inside. *Lip* elongate, quadrate, gradually narrowing towards the point. *Legs*, the first or the fourth pair longer than the second pair.

* *The two outermost eyes on either side neither placed very close together, nor inserted on a distinct prominence. (The maxilla in all with an incrassated base; the fourth pair of feet (rarely the first) longest.)*

Sp. 1. *Lapidicola.* Thorax and mandibles pale reddish; feet very light red; abdomen ash-grey coloured.
Clubiona lapidicola.
*Walck. Tab. des Aran.* 46.
*Latr. Gen. Crust. et Insect.* i. 91.
*Leach, Edin. Encycl.* vii. 422.

Inhabits France and England, under stones, constructing a globular cell of the size of a common hazel nut, in the centre of which are deposited a vast number of pale yellowish eggs, agglutinated into a spherical mass.

The mandibles of the male are porrect, and rather more than half of the length of the thorax; those of the female rather vertical.

** *The two external eyes on each side placed rather close to each other. (Maxillæ not always thickened at their base; the first and then the second pair of legs longest.)*

A. Maxillæ somewhat thickened at their base, and transversely impressed before the middle.

Sp. 2. *Nutrix.* Ungulæ black; thorax and mandibles light red; legs very light red; abdomen yellowish green, with an obscure longitudinal band.
Clubiona nutrix.
*Walck. Tab. des Aran.* 43.
*Latr. Gen. Crust. et Insect.* i. 92.
*Leach, Edin. Encycl.* vii. 422.

Inhabits the environs of Paris; it is common in a place called Sevres, building a nest amongst the leaves of the Eryngium campestre. Mandibles of the male stronger than those of the female.

It has once occurred in England, near Cheltenham.

B. Maxillæ not thickened at their base; front not transversely impressed.

Sp. 3. *Atrox.* Brown; legs pale; tibiæ with dark spots; middle of the back of the abdomen, with a somewhat quadrate black spot, margined with yellow.
Clubiona atrox.
*Walck. Tab. des Aran.* 44.
*Latr. Gen. Crust, et Insect.* 93.
*Leach, Edin. Encycl.* vii. 422.
Aranea atrox.
*De Geer, Mém. sur les Insect.* vii. 253. pl. 14. fig. 24, 25.

Inhabits old walls and fissures of rocks. It is very common in Britain and France. A tolerable figure

 is given in the work of Dr Lister on *British Spiders*, p. 68. fig. 21.

Gen. 24. ARANEA *of authors.*

TEGENERIA. *Walckanäer.*

*Maxillæ* strait and longitudinal, with their internal angle distinctly truncate, diameter equal, apex rounded. *Lip* elongate, nearly quadrate, longer than broad, towards the superior angles a little narrower. *Legs*, the anterior pair about the same length with the fourth pair; third pair shortest. *Eyes* disposed in two transverse lines near each other, and bent backwards.

Sp. 1. *Domestica.* Livid-cinereous; thorax of the *male* immaculate; of the *female* on each side with longitudinal blackish band; abdomen blackish, middle of its back with a longitudinal, maculose, dentated band, and the lateral lineolæ livid.

Aranea domestica.

*Fabr. Ent. Syst.* ii. 412.
*Linn. Syst. Nat.* i. 1031.
*Latr. Gen. Crust. et Insect.* i. 96.
*Leach, Edin. Encycl.* vii. 423.

Tegeneria domestica.

*Walck. Tab. des Aran.* 49.

Inhabits houses in Europe: spinning its web in a place where there is a cavity, such as the corner of a room. The mode of constructing the web is curious. Having chosen a convenient situation, she fixes one end of her thread to the wall, and passes on to the other side, dragging the thread along with her till she arrive at the other side, where she fixes the other end of it. Thus she passes and repasses until she has made as many parallel threads as are necessary; she then crosses these by other threads. This net is intended for the capture of her prey, and, in addition to it, the animal prepares a cell for herself, where she remains concealed, and on the watch. Between the cell and the net, the spider builds a bridge of threads, which, by communicating with the threads of the large net, both gives her intelligence when any thing touches the web, and enables her to pass quickly in order to seize it.

Gen. 25. AGELENA. *Walckanäer.*

*Maxillæ* strait and longitudinal, their internal angle slightly truncate; diameters equal, apex rounded. *Lip* not longer than broad, towards the superior angle a little narrower. *Legs* moderately long, the anterior and fourth pairs of nearly equal length, the third pair shortest. *Eyes* disposed in two transverse lines near to each other, and bent backwards.

Sp. 1. *Labyrinthica.* Griseous-pale-reddish; thorax on each side with a blackish longitudinal line; abdomen black, above and on each side with white oblique lines forming obtuse angles, running together anteriorly in pairs; the weaving appendices or nipples conic, elongate.

Aranea labyrinthica.

*Linn. Syst. Nat.* i. 1031.
*Fabr Ent. Syst.* ii. 418.
*Latr. Gen. Crust. et Insect.* i. 95.
*Leach, Edin. Encycl.* vii. 423.

Agelena labyrinthica.

*Walckanäer, Tab. des Aran.* 51.

Inhabits the fields. It is very common in most parts of Europe during the summer months. In Britain it is most abundant in the autumn. It spins a horizontal web on the ground, in which it watches for its prey, consisting principally of flies and other dipterous insects. The spider itself lives in a funnel-shaped cavity, often extending below the surface of the ground.

Gen. 26. ARGYRONETA. *Latreille, Walckanäer, Leach.*

*Maxillæ* short, strait, elongate-quadrate, the sides of nearly equal diameters; anteriorly convex; the apex rounded. *Lip* short, shorter than the maxillæ; of a narrow elongate-triangular form; the anterior aspect convex; the apex obtuse or truncate. *Legs*, the first, the fourth pair longest; the second pair shortest. *Eyes* with the four middle ones forming a quadrangle, the two on each side set obliquely and subgeminated.

Sp. *Aquatica.* Blackish-brown; abdomen black velvety, with some impressed dots on its back.

Aranea aquatica.

*Linn. Syst. Nat.* i. 1036.
*Fabr. Entom. Syst.* ii. 418.

Argyroneta aquatica.

*Latr. Gen. Crust. et Insect.* i. 95.
*Walck. Tab. des Aran.*
*Leach, Edin. Encycl.* vii. 423.

Inhabits Europe, frequenting slow running waters and ditches, in which it spins a web most beautifully constructed under the water, in which it lives, being surrounded by air, which shines through the water with a silvery lustre. The eggs are deposited in a globose silky bag. It is extremely common in most of the ditches round London, and may be observed, especially in the beginning of the summer, building its nest beneath the water, or running along the lines by which it is suspended.

*Stirps* 2. *

Gen. 27. SYCTODES. *Latreille, Walckanäer, Leach.*

*Maxillæ* oblique and longitudinal, covering the sides of the lip; their bases thickened, the apex internally obliquely truncated. *Lip* somewhat quadrate, the base a little contracted. *Legs* with the fourth, then the first pair longest; the third pair shortest.

Sp. 1. *Thoracica.* Pale reddish-white, spotted with black; thorax large and somewhat orbicular, elevated roundly behind; abdomen lighter in colour, and subglobose.

Syctodes thoracica.

*Walck. Tab. des Aran.* 79.
*Latr. Gen. Crust. et Ins.* i. 99. tab. 5. fig. 4.
*Leach, Edinb. Encycl.* vii. 423.

Inhabits Paris, in houses. It has twice occurred near Dover, but both the individuals were females.

Gen. 28. THERIDIUM.

THERIDION. *Walckanäer, Latreille, Leach.*

*Maxillæ* with an oblique direction covering the sides of the lip, converging towards their points; of equal breadth; the internal apex obtuse, or obliquely truncated. *Lip* small, triangular or semicircular; the apex truncate or subrounded. *Legs* elongate, the first, then the fourth pair longest. *Eyes* with four in the centre, forming a quadrangle, the under

ones placed on a common elevation; two others on each side geminated, and situated on a common elevation.

Sp. 1. *Sisiphum.* Rufous; abdomen globose, with white lines.

Theridion sisiphum.

*Latr. Gen. Crust. et Insect.* i. 97.

*Walck. Tab. des Aran.* 74.

*Leach, Edinb. Encycl.* vii. 423.

Inhabits Europe, in the corners of buildings, walls and rocks. It is figured by Lister, t. 14. f. 14.

Gen. 29. Latrodectus. *Walckanäer, Latreille.*

*Maxillæ*, with an oblique direction covering the sides of the lip, converging towards their points; of equal breadth; the internal apex truncate or subrounded. *Lip* small, triangular, or semicircular; the apex truncate or rounded. *Legs* elongate, the first then the second pair largest. *Eyes* placed four and four, in two transverse, strait and parallel lines.

Sp. 1. *Tredecim-guttatus.* Black, abdomen globose, with thirteen sanguineous spots.

Aranea, 13-guttata.

*Rossi, Fn. Etrus.* ii. 136. tab. 9. fig. 10.

*Fabr. Ent. Syst.* ii. 409.

Latrodecte Malmignatte. *Walck. Tab. des Aran.* 81.

Theridion tredecim-guttatum.

*Latr. Gen. Crust. et Insect.* i. 98.

*Leach, Edin. Encycl.* vii. 424.

Latrodectus, 13-guttatus.

*Latr. Considerat.* 424.

Inhabits Italy, and is not uncommon in the plains of that country.

Gen. 30. Pholcus. *Walckanäer, Latreille, Leach.*

*Maxillæ* oblique, covering the side of the lip, converging from the base to the apex; apex internally truncated. *Lip* transversely quadrate, the lateral angles of the apex rounded and somewhat margined. *Legs* very long and very slender; the first, then the second and fourth (nearly equal) longest. *Eyes* inserted on a tubercle, two geminated, and placed transversely in the middle; three on each side amassed in a triangle, one larger than the rest.

Sp. 1. *Phalangioides.* Pale-livid; abdomen elongate, cylindric oval, very soft, obscure cinereous; tip of the tibiæ and thighs with a pale ring of whitish colour.

Pholcus phalangiöides.

*Walck. Tab. des Aran.* 80.

*Latr. Gen. Crust. et Insect.* i. 99.

*Leach, Edin. Encycl.* vii. 424.

Aranea Pluchii.

*Scopol. Ent. Carn.* 1120.

Aranea opilionides.

*Schrank, Enum. Ins. Aust.* 1103.

Aranea phalangioides.

*Fouri. Ent. Paris*, ii. 213.

Inhabits houses in Europe; in the western parts of England it is extremely common. Its body vibrates like that of a tipulideous insect.

*Stirps* 2. **

Gen. 31. Uloborus. *Latreille, Leach.*

*Eyes* equal and very minute, disposed in two transverse lines, the first nearly strait, or scarcely bent backwards, the two middle eyes a little closer than the others; the posterior line bent forwards. *Maxillæ* strait, broad and inversely triagonal, the side broader than the apex. *Lip* very broad and semicircular. *Legs* with the first pair much the largest, then the fourth and afterwards the second, the third being consequently the smallest.

Sp. 1. *Walckanäcrius.* Pale reddish yellowed; thorax and abdomen silky, back white; abdomen oblong banded with fasciculi of hairs: legs banded with darker rings.

Uloberus Walckanäerius.

*Latr. Gen. Crust. et Insect.* i. 110.

*Leach, Edinb. Encycl.* vii. 424.

Inhabits the pines of Germany and France, in which it constructs its web.

Gen. 32. Tetragnatha. *Latreille, Leach.*

*Eyes* subequal, disposed in two strait and almost parallel transverse lines, the four middle ones forming nearly a regular quadrangle. *Maxillæ* strait, elongate and narrow, almost equally broad; the apex externally dilated and round: *Lip* semicircular and somewhat notched. *Legs* very long and very slender, the first pair longest, then the second, afterwards the fourth.

Sp. 1. *Extensa.* Reddish, abdomen oblong, golden green, with the sides and two lines below yellowish; the middle below longitudinally black.

Aranea extensa.

*Linn. Syst. Nat.* i. 1034.

*Fabr. Ent. Syst.* ii. 407.

Tetragnatha extensa.

*Latr. Gen. Crust. et Insect.* i. 101.

*Walck. Tabl. des Aran.* 68.

*Leach, Edinb. Encycl.* vii. 424.

Inhabits Europe, frequenting moist places, in which it constructs a vertical web, sitting on it with its legs extended.

Gen. 33. Linyphia. *Latreille, Walckanäer, Leach.*

*Eyes* with the four middle ones disposed in an irregular quadrangle; the eyes on each side geminated, and placed obliquely. *Maxillæ* nearly strait, inversely-suboval. *Lip* semicircular. *Legs* elongate and slender, the first pair longest, then the second, then the third.

Sp. 1. *Triangularis.* Pale reddish, inclining to yellow; thorax with a black dorsal line, bifid in front; abdomen oval, inclining to globose, with spots and angulated bands of brown and white; legs immaculate.

Linyphia triangularis.

*Latr. Gen. Crust. et Insect.* i. 100.

*Walck. Tabl. des Aran.* 70.

*Leach, Edinb. Encycl.* vii. 424.

Inhabits hedges in Europe, constructing its web on genistæ and pines.

Gen. 34. Epëira. *Walckanäer, Latreille, Leach.**

*Eyes* with the four middle ones placed on an abruptly formed tubercle, in the form of a quadrangle, the two anterior ones largest and most distant; the

* This genus, as defined by Latreille, requires much division into other genera: That author has divided the genus into sections, most of which would form good genera.

lateral eyes on each side subgeminated, and placed obliquely on a tubercle. *Maxillæ* subcircular, internally membranaceous. *Lip* semicircular, short with the point membranaceous. *Legs* moderately long, hispid, the thighs rather strong, the first pair largest, then the second, afterwards the fourth pair.

*Thorax* inversely elongate-subcordate, anteriorly broadly truncated. *Abdomen* subglobose, large, much broader than the thorax.

Sp. 1. *Diadema.* Reddish; abdomen globose-oval, with an elevated angle on each side of its base, dorsal band broad, triangular, dentated, darker, with a triple cross of luteous white dots or spots, and with four impressed dots disposed in a quadrangle.

Aranea Diadema.
*Linn. Syst. Nat.* i. 1030.
Araignée à croix.
*De Geer, Mém. sur les Insect.* vii. 218. pl. ii. f. 3.
Epëira Diadema.
*Walck. Tab. des Aran.* lviii.
*Latr. Gen. Crust. et Insect.* i. 106.
*Leach, Edinb. Encycl.* vii. 424.

Inhabits Europe. It frequents the borders of woods, rocks and gardens, and is well known in Britain by the names Sceptre or Diadem-spider.

Gen. 35. Nephila. *Leach.*

*Eyes* with the four middle ones placed on a gradually formed elevation, in the form of a quadrangle, the two anterior ones rather largest; the lateral ones on each side placed on a tubercle, subgeminated and set obliquely. *Maxillæ* elongate, with their base narrow, their apex truncate. *Lip* elongate, rather narrower at their base, the apex abruptly subacuminate. *Legs* elongate, slender, somewhat hairy, the first pair longest, then the second, then the fourth.

*Thorax* elongate-quadrate, anteriorly abruptly narrower, notched behind. *Abdomen* elongate, not or scarcely broader than the thorax.

Sp. 1. *Maculata.* Blackish; thorax fuscous-ferruginous; coxæ and base of the palpi croceous-luteous; abdomen luteous, the belly and sides infuscate; the latter with lines, the former with spots of white.

Aranea maculata. *Fabr.* 2. 134. t. 110.
Nephila. *Leach, Zool. Miscel.*

Inhabits China.

*Stirps* 3. ***

Gen. 36. Episenus. *Walckanäer, Latreille, Leach.*

*Eyes* forming the segment of a circle; of nearly an equal size, placed on an eminence. *Maxillæ* strait and longitudinal, the base a little dilated, the apex rounded. *Lip* very semicircular, much broader than long. *Legs* much lengthened; the anterior and then the fourth pair of legs longest; the third pair shortest.

Sp. 1. *Truncatus.* Thorax condiform, a little longer than broad, anteriorly acute; above obscure dark brown, beneath reddish brown; abdomen pyramidal, brown anteriorly, margined, behind truncated; third pair of legs whitish, the others brown, points of the first and fourth with white bases.

Episenus truncatus.
*Latr. Gen. Crust. et Insect.* i. 126.
*Leach, Edinb. Encycl.* vii. 425.

Inhabits the vicinity of Turin.

Gen. 37. Micrommata. *Latreille, Leach.*
Sparassus. *Walckanäer.*

*Eyes* subequal, disposed nearly in a semicircle, and surrounded by hairs. *Maxillæ* strait, quadrate-suboval, the longitudinal angle anteriorly; the internal side with a concave base, the apex obliquely truncated. *Lip* short and semicircular. *Legs* elongate; fourth longest, then the second, which are a little shorter than the first; the tips of the tarsi beneath furnished with a little double brush.

Sp. 1. *Smaragdina.* Bright green; back of the abdomen with dark longitudinal band; (that of the male with three longitudinal red lines.)

Micromate.
*Latr. Nouv. Dict. d'Hist. Nat.* 24. tab. p. 135.
Aranea smaragdula.
*Fabr. Ent. Syst.* ii. 412.
Sparassus smaragdulus.
*Walck. Tabl. des Aran.* 39.
Micrommata smaragdina.
*Latr. Gen. Crust. et Insect.* i. 115.
*Leach, Edin. Encycl.* vii. 426.

Gen. 38. Thomisus. *Walckanäer, Latreille, Leach.*
Heteropoda. *Latreille.*
Misumena. *Latreille.*

*Eyes* generally subequal, placed in two transverse lines in a kind of semicircle. *Maxillæ* oblique, covering the side of the lip, and in some degree converging; the internal apex truncate. *Lip* somewhat oval, or nearly quadrate, generally longer than broad. *Legs*, the first and second pair longest; the second pair rather longest; the third and fourth pair of legs much less, sometimes one being largest, sometimes the other.

The mandibles of the animals composing this genus, are either perpendicular or somewhat inflexed, in many conical, with very short claws.

* *Thorax convex, cordiform, the sides, especially behind, abruptly sloping, anteriorly broadly truncate; the largest legs not double the length of the body; the first and second pair much thicker than the others, sometimes one, sometimes the other being longest. The first joint of the tarsi, with several moveable little spines, in a single or in a double series, the claws of the tarsi naked. Lip sometimes oval, the apex truncate or obtuse. Apex of the maxilla wedge-shaped.*

Sp. 1. *Citrens.* Thorax at the insertion of the eyes transversely elevated; the sides anteriorly produced and prominent; eyes equal; abdomen roundish-triangonal, broader behind, with a red line on each side; body yellowish-citron-coloured.

Thomisus citreus.
*Walck. Tabl. des Aran.* 21.
*Latr. Gen. Crust. et Insect.* i. 111.
*Leach, Edinb. Encycl.* vii. 426.

Inhabits Europe, living in flowers. It is very common in Britain; the male is rare, smaller than the female, of a brown colour, banded with yellowish-green.

** *Thorax convex, cordiform, the sides, especially behind, abruptly sloping, the anterior part broadly truncated; the larger legs not twice the length of the body, all of nearly an equal*

*degree of thickness; the hinder four not much shorter; the anterior with four little spines; the claws of all the tarsi scarcely visible. Lips somewhat oval; the apex truncate or obtuse. Maxillæ at their points wedge-shaped.*

Sp. 2. *Lynceus.* Lateral eyes largest, placed on an eminence, the tubercles of the hinder ones thickest; body pale yellowish-grey, variegated with punctures and spots of a blackish colour; abdomen very large, of a triangular-oval form, broader behind.

Thomisus lynceus.
*Latr. Gen. Crust. et Insect.* i. 112.
*Leach, Edinb. Encycl.* vii. 426.

Inhabits France and Scotland. Latreille considers it to be much allied to *Thomisus onustus* of Walckanäer.

*** *Thorax depressed, somewhat oval, very obtuse before; the larger legs not twice the length of the body: all the legs of equal thickness; the tarsi hairy beneath, the first joint with a few little spines; the apex with two brushes under the claws; abdomen oblong; the maxillæ beyond the insertion of the palpi, nearly of an equal breadth, distinctly and abruptly truncated; lip somewhat quadrate; hinder eyes distant.*

Sp. 3. *Oblongus.* Pale-yellowish, with white hairs above; abdomen somewhat cylindrical, with obscure longitudinal lines.

Thomisus oblongus.
*Walck. Tabl. des Aran.* 38.
*Latr. Gen. Crust. et Insect.* i. 113.
*Leach, Edinb. Encycl.* vii. 426.

Inhabits France, Denmark, and England, on plants.

**** *Thorax depressed, cordiform, anteriorly truncated; the four anterior legs more than double the length of the body; the under parts of the tarsi generally hairy, always furnished with two little brushes under the claws; maxillæ short, much inflexed above the lip, nearly of an equal breadth beyond the insertion of the palpi; apex abruptly truncated; lip nearly quadrate, broad; the second pair of legs longest.*

A. *Tarsi hairy beneath. Eyes disposed in two nearly parallel lines; the third pair of legs shorter than the fourth.*

Sp. 4. *Regia.* The four lateral eyes largest; body pale-dirty yellow, inclining to red; thorax, with the anterior margin, and a posterior band yellowish-grey, the hinder band margined with black above.

Aranea regia. *Fabr. Ent. Syst.* ii. 408.
Thomisus leucosia.
*Walck. Tabl. des Aran.* 36.
*Latr. Gen. Crust. et Insect.* i. 113.
*Leach, Edinb. Encycl.* vii. 426.

Inhabits the Isle of France.

B. *Tarsi scarcely hairy beneath. Eyes disposed in a semicircle; third pair of legs longer than the fourth.*

Sp. 5. *Venatorius.* Yellowish-red; abdomen yellow-grey, clouded with ash-grey; legs spotted with black.

Aranea venatoria. *Linn. Syst. Nat.* i. 1035.

Thomisus venatorius.
*Latr. Gen. Crust. et Insect.* i. 114.
*Leach. Edinb. Encycl.* vii. 427.

Inhabits the American Islands.

*Obs.* Aranea venatoria of Fabricius, is the same with the Mygale nidulans of Walckanäer.

C. *Tarsi scarcely hairy beneath. Eyes placed in a semicircle. Third pair of legs longer than the fourth.*

Sp. 6. *Levipes.* Body grey, spotted with black; abdomen plain, rhomboidal.

Aranea levipes.
*Linn. Syst. Nat.* i. 1037.
*Fab. Ent. Syst.* ii. 413.
Thomisus tigrinus.
*Latr. Gen. Crust. et Insect.* i. 114.
*Walck. Tabl. des Aran.* 34.
Thomisus levipes.
*Leach, Edinb. Encycl.* vii. 427.

Inhabits Europe; it resides on the branches of trees, and runs with great celerity.

*Stirps 3.* *

Gen. 39. OXYOPES. *Latreille, Leach.*
SPHASUS. *Walckanäer.*

*Maxillæ* strait, longitudinal and elongate, of an equal breadth from the base to the apex, which is externally gradually arcuated, internally obliquely truncated. *Lip* oblong-quadrate. *Legs* long and slender; the first pair longest, then the fourth and second, which are nearly of equal length; *tarsi* short; *claws* exserted, with no brush beneath. *Eyes* disposed in four transverse lines, forming an elongate hexagon.

Sp. 1. *Variegatus.* Body hairy and grey, variegated with red and white; legs pale, reddish, spotted with brown; the tibial spines elongate.

Oxyope.
*Latr. Nouv. Dict. d'Hist. Nat.* tom. xxiv. tabl. p. 135.
Spasus heterophthalmus.
*Walck. Tab. des Aran.* xix.
Oxyopes variegatus.
*Latr. Gen. Crust. et Insect.* i. 116.
*Leach, Edin. Encycl.* vii. 427.

Inhabits France.

Gen. 40. STORENA. *Walckanäer, Latreille, Leach.*

*Maxillæ* much longer than the lip, which they cover. *Lip* oval and lengthened. *Eyes* disposed in three transverse lines, forming a nearly equal sided hexagon.

Sp. 1. *Cœrulea.*

Storène bleue. *Walckanäer.*
*Latreille, Considerat.* 424.

Gen. 41. CTENUS. *Walckanäer, Latreille, Leach.*

*Maxillæ* strait. *Lip* very much shorter than the maxillæ. *Eyes* disposed in three transverse lines, forming an angulated curved line.

Sp. 1. *Ambiguus.*

Ctène douteux.
*Walckanäer.*
*Latreille, Consider.* 424.

*Stirps 3.* **

Gen. 42. LYCOSA. *Latreille, Walckanäer, Leach.*

*Maxillæ* strait, anteriorly convex; externally

towards the side, somewhat arcuated, internally slightly margined, gradually narrowing towards the base; the apex obliquely truncated, forming almost an inverted triangle. *Lip* elongate, quadrate. *Legs* strong, the fourth pair longest, then the second; the third shortest.

Sp. 1. *Tarentula.* Body above cinereous-fuscous; mandibles and palpi towards their middles ferrugineous, their tips black; thorax with a radiated dorsal line and margins griseous; abdomen anteriorly above with trigonal spots, behind with arcuate, transverse streaks of black, bordered with white; beneath bright saffron colour, with a transverse black band; thighs and tibiæ beneath rufous-white, with two black spots.

Aranea tarentula.
*Linn. Syst. Nat.* i. 1035.
*Fabr. Ent. Syst.* ii. 425.

Lycosa tarentula.
*Walck. Tabl. des Aran.* xi.
*Latr. Gen. Crust. et Insect.* i. 119.
*Leach, Edinb. Encycl.* vii. 427.

Inhabits the south of Europe. This species is the celebrated Tarentula spider, of which such marvellous accounts have been given by travellers, who have described its bite as generally fatal, and to be curable only by music, the effects of which were, to cause the patient to dance until a profuse perspiration was produced, by which a certain cure was effected.

The name tarentula is derived from Tarentum (now Taranto), in the kingdom of Naples, near which place they were supposed to be found in the greatest plenty. It is figured in Albin's spiders, tab. 39.

Sp. 2. *Saccata.* Above smoky-black, clouded with cinereous villosity; carina of the thorax obscure, reddish, with a cinereous villous line; base of the abdomen with a little bundle of griseous hairs; legs livid-red, with blackish spots.

Lycosa saccata.
*Walck. Tabl. des Aran.* 13.
*Latr. Gen. Crust. et Insect.* i. 120.
*Leach, Edinb. Encycl.* vii. 427.

Inhabits Europe. It is very common in Britain; the female may be observed in gardens, carrying her bag of eggs, of a green colour. Palpi, mandibles and anterior margin of the thorax livid red in the female, black in the male.

Gen. 43. Dolomedes.
*Latreille, Walckanäer, Leach.*

*Maxillæ* strait, oval-quadrate, the apex externally rounded, internally obliquely truncated. *Lip* somewhat square, the diameters nearly equal, the points of the angles rounded. *Legs* elongate, the fourth pair longest, then the second, the third shortest: *Claws* exserted without brushes below.

Sp. 1. *Mirabilis.* Pale reddish, covered with greyish down; thorax heart-shaped, anteriorly, abruptly sloping; the anterior angles and dorsal line whitish; abdomen conical, suboval, back darker.

Aranea saccata.
*Linn. Syst. Nat.* i. 1036.

Dolomedes mirabilis.
*Walck. Tabl. des Aran.* 16.
*Latr. Gen. Crust. et Insect.* i. 117.
*Leach, Edin. Encycl.* vii, 427.

Aranea Listeri.
*Scopol. Ent. Carn.* 1093?

Aranea obscura.
*Fabr. Ent. Syst.* ii. 419.

Inhabits the woods of Europe. The female carries about her eggs inclosed in a dirty orange-coloured or whitish bag; this economy is common to the whole genus.

*Stirps* 4.

Gen. 44. Eresus. *Walckanäer, Latreille, Leach.*

*Maxillæ* strait, longitudinal, subcuneiform, the apex broader, externally rounded, internally obliquely truncated. *Legs* strong, short, formed for leaping; the fourth pair longest, then the first; the third pair shortest, a little shorter than the second. *Eyes* disposed in two quadrangles, one quandrangle inclosed by another.

Sp. 1. *Moniligerus.* Black; abdomen above cinnabar-coloured, with four or six black dots, arranged in two longitudinal lines; joints of the legs whitish; hinder sides of the thorax, the thighs, and the first joint of the four hinder legs pale-cinnabar.

Eresus cinnabarinus.
*Walck. Tabl. des Aran.* 21.
*Latr. Gen. Crust. et Insect.* i. 122.
*Leach, Edin. Encycl.* vii. 428.

Aranea moniligera.
*Villers, Ent.* iv. 128. tab. 11. f. 8.

Aranea quadriguttata.
*Rossi, Fn. Etrusc.* ii. 135. pl. 1. f. 8, 9.

Inhabits France, Germany, and England.

Gen. 45. Salticus. *Latreille, Leach.*
Attus. *Walckanäer.*

*Maxillæ* strait, longitudinal, subrhomboidal, or inverse-cuneate-ovate. *Lip* elongate suboval, the apex obtuse. *Palpi* clavate. *Thorax* truncate-ovate or parallelogrammic. *Eyes* disposed in the form of a horse-shoe, the two middle ones largest. *Legs* thick and short; the first pair thickest and not longer than the fourth pair; the second and the third pairs of nearly an equal length, and shorter than the two other pairs.

Sp. 1. *Scenicus.* Black; margin of the thorax covered with white down; abdomen short ovate, above with a reddish-gray pubescence, with three transverse arcuate lines, and the anus white; the first band basal and entire, the others acutely bent anteriorly, and interrupted in their middle.

Aranea scenica.
*Linn. Syst. Nat.* i. 1035.
*Fabr. Ent. Syst.* ii. 422.

Atte paré. *Walck. Tabl. des Aran.* 24.

Salticus scenicus.
*Latr. Gen. Crust. et Insect.* i. 123.
*Leach, Edin. Encycl.* vii. 428.

Inhabits walls and palings. It is found in most parts of Europe, and is called in Britain the Hunting-spider.

Palpi of the female whitish; legs of the same sex reddish-gray, with darker spots. Male with very large mandibles.

Gen. 46. Attus. *Walckanäer.*
Salticus. *Latreille, Leach.*

*Maxillæ* strait, longitudinal, subrhomboidal or

inversely cuneate-ovate. *Lip* elongate, suboval, with the apex obtuse. *Palpi* filiform. *Thorax* elongate, narrow, subconic. *Eyes* disposed in the form of a horse-shoe; the two middle eyes largest. *Legs* slender, elongate, the first pair thickest and not longer than the fourth pair; the second and third pairs of nearly an equal length, and shorter than the two other pairs.

This genus we have separated from Salticus, with which it was placed by Latreille; and we have given it the name applied by Walckanäer to both these genera, which he did not think distinct from one another.

Sp. 1. *Formicarius.* Thorax anteriorly black, behind red; abdomen fuscous, with a white spot on each side; legs red.

Attus formicarius.
*Walck. Tabl. des Aran.* 26.
Salticus formicarius.
*Latr. Gen. Crust. et Insect.* i. 124.
*Leach, Edin. Encycl.* vii. 428.
Araignée fourmi.
*De Geer, Mém. sur les Insect.* vii. 293. tab. 18. fig. 1, 2.

Inhabits Europe, residing on plants and walls. It is very rare in Scotland, and has not been observed in England.

Order IV. MONOMEROSOMATA.

SECTION I.

*Legs formed for walking.*

A. *Mouth with mandibles.*

Fam. I. TROMBIDIDEÆ. *Palpi* porrect, and furnished at their extremities with a moveable appendage.

*Stirps* 1. *Eyes* two placed on a pillar. *Body* apparently divided into two parts by a transverse line; the anterior division bearing the eyes, mouth and four anterior legs.

Genus 47. TROMBIDIUM.
48. OCYPETE.

*Stirps* 2. *Body* not divided by a transverse line. *Palpi* with the under part of their last joint furnished with a moveable appendage. *Eyes* sessile.

Genus 49. ERYTHRÆUS.

Fam. II. GAMMASIDEÆ. *Palpi* porrect, simple.

Genus 50. GAMMASUS.

Fam. III. ACARIDEÆ. *Mouth* furnished with mandibles. *Palpi* simple, very short, not porrected.

Genus 51. ORIBITA.
52. NOTASPIS.
53. ACARUS.

B. *Mouth furnished with a rostrum.*

Fam. IV. IXODIDEÆ. *Eyes* obscure or concealed.

*Stirps* 1. *Palpi* and *Rostrum* exserted.

Genus 54. ARGAS.
55. IXODES.

*Stirps* 2. *Palpi* and *Rostrum* hidden.

Genus 56. UROPODA.

Fam. V. CHEYLETIDEÆ. *Eyes* distinct.

*Stirps* 1. *Palpi* distinct.

Genus 57. CHEYLETUS.
58. SMARIS.
59. BDELLA.

*Stirps* 2. *Palpi* concealed.

Genus 60. SARCOPTES.

SECTION II.

*Legs formed for swimming.*

Fam. I. EYLÄIDEÆ. *Mouth* furnished with mandibles.

Genus 61. EYLÄIS.

Fam. II. HYDRACHNIDEÆ. *Mouth* without mandibles.

Genus 62. HYDRACHNA.
Genus 63. LINNOCHARES.

Section I. A.

Family I. TROMBIDIDEÆ. *Stirps* 1.

Gen. 47. TROMBIDIUM *of authors. Legs* eight.

Sp. 1. *Tinctorium.* Body subquadrate, coccineous, immaculate, very tomentose and hairy; the hairs setaceous, elongate, bearded.

Acarus tinctorius. *Linn. Syst. Nat.* i. 1025.
Trombidium tinctorium.
*Fabr. Ent. Syst.* ii. 398.
*Latr. Gen. Crust. et Insect.* i. 145.
*Leach, Edin. Encycl.* vii. 416.

Inhabits Guinea: It is often preserved in collections, and is probably a common animal. Its colour is destroyed by alcohol.

Gen. 48. OCYPETE. *Leach.*

*Legs* six.

Sp. 1. *Rubra.* Red; back with a few long hairs, the legs with many short hairs of a rufous-cinerescent colour; eyes black-brown.

Ocypete rubra. *Leach, Trans. Linn. Soc.* xi.
——— *Edinb. Encycl.* vii. 434.

This curious little animal, which is not larger than a grain of small sand, is parasitic, and is frequently to be found on the largest tipularidous insects, adhering to their legs. We have obtained no less than sixteen specimens from one insect.

Family I. *Stirps* 2.

Gen. 49. ERYTHRÆUS. *Latreille, Leach.*

*Palpi* with their moveable appendage subcheliferous. *Hinder legs* longest, then the first.

Sp. 1. *Phalangioides.* Legs very long, the last joint broad, compressed; body obscure-red, with a dorsal band of orange-yellow.

Erythræus phalangioides.
*Latr. Gen. Crust. et Insect.* i. 146.
*Leach, Edin. Encycl.* vii. 416.

Inhabits Europe, running on the ground with great rapidity.

Family II. GAMMASIDEÆ.

Gen. 50. GAMMASUS. *Latreille, Leach.*

*Body* depressed, the skin of the back partly or entirely coriaceous.

* *Anterior portion of the back, and a triangular part behind, coriaceous.*

Sp. 1. *Coleoptratorum.* Coriaceous parts of the back fuscous; anterior pair of legs a little longer than the hinder ones.

Gammase des Coléoptères.
*Latr. Hist. Nat. des Crust. et des Insect.* vii. 399.
Gammasus coleoptratorum.
*Latr. Gen. Crust. et Ins.* i. 147.
*Leach, Edin. Encycl.* vii. 415.

Arachnides. Acarus coleoptratorum.

*Linn. Syst. Nat.* i. 1026.

*Fabr. Ent. Syst.* iv. 432.

Inhabits the excrements of horses and oxen, often attaching itself to Scarabæi, Histeres, &c. in great numbers; we have counted nearly one hundred on Scarabæus stercorarius (the common Dorbeetle).

** *Back entirely coriaceous.*

Sp. 2. *Marginatus.* Ovate, brown; belly coriaceous, the sides alone membranaceous and whitish; anterior legs nearly twice the length of the body.

Gammasus marginatus.

*Latr. Gen. Crust. et Insect.* i. 148.

*Leach, Edin. Encycl.* vii. 415.

Inhabits dung and dead animals.

Family III. Acarideæ.

Gen. 51. Oribita. *Latreille, Leach.*

*Body* covered by a coriaceous skin; anterior part rostrated; the produced part inclosing the organs of mastication. *Abdomen* subglobose. *Tarsi* with claws.

Sp. 1. *Geniculata.* Fuscous-castaneous, shining, hairy; legs pale-fuscous; thighs subclavate.

Acarus geniculatus. *Linn. Syst. Nat.* i. 1025.

Oribita geniculata.

*Latr. Gen. Crust. et Insect.* i. 149.

*Leach, Edin. Encycl.* vii. 415.

Inhabits trees and beneath stones. It is common in Sweden, Germany, and England.

Gen. 52. Notaspis. *Hermann.*

*Body* covered by a coriaceous skin, the anterior part rostrated, the produced part inclosing the organs of mastication. *Abdomen* subglobose, the sides anteriorly with a wing-like process. *Tarsi* with claws.

Sp. 1. *Humeralis.* Abdomen blackish-chesnut; the produced parts membranaceous.

Mitte à rebord.

*De Geer, Mém. sur les Insect.* vii. 133? pl. 8. fig. 6.

Oribita humeralis.

*Latr. Gen. Crust. et Ins.* i. 150.

*Leach, Edin. Encycl.* vii. 415.

Inhabits moss, and beneath stones. It is not uncommon in the southern parts of Devonshire.

Gen. 53. Acarus *of authors.*

*Body* soft. *Mouth* naked. *Tarsi* with a pedunculated vesicle at their extremities.

Sp. 1. *Domesticus.* White, with two brown spots; body ovate, the middle coarctate, with very long hairs; legs equal.

Ciron du fromage. *Geoff. Hist. des Insect.* ii. 622.

Mitte domestique.

*De Geer, Mém. sur les Insect.* vii. 88. pl. 5. fig. 1—4.

Acarus siro.

*Linn. Syst. Nat.* i. 1024.

*Fabr. Ent. Syst.* iv. 430.

*Leach, Edin. Encycl.* vii. 415.

Acarus domesticus.

*Latr. Gen. Crust. et Insect.* i. 150.

Tyroglyphus.

*Latr. Préc. des Caract. Génér. des Insect.* 185.

Inhabits houses, living in cheese and flower that have been kept too long.

Section I. B.

Family IV. Ixodideæ. *Stirps* 1.

Gen. 54. Argas. *Latreille, Leach.*

Rhynchoprion. *Hermann.*

*Palpi* short, conic, four-jointed.

Sp. 1. *Marginatus.* Pale-yellowish, or fleshy violet, margined; with very short squamulæ, with branched blood-vessels.

Acarus marginatus. *Fabr. Ent. Syst.* iv. 427.

Argas reflexus.

*Latr. Gen. Crust. et Insect.* i. 155.

*Leach, Edin. Encycl.* vii. 414.

Plate XXIII.

Inhabits houses in France, sucking the blood of doves.

Gen. 55. Ixodes. *Latreille, Leach.*

Cynorhæstes. *Hermann.*

*Palpi* equally broad, longer than broad.

Dr Leach has written a paper on the British species of this genus, in the eleventh volume of the *Transactions of the Linnean Society.*

Sp. 1. *Ricinus.* Scutus rounded, smaller; with the vagina of the rostrum, and the legs fuscous; abdomen varying in colour.

Acarus ricinus.

*Linn. Syst. Nat.* i. 1023.

*Fabr. Ent. Syst.* iv. 425.

Idodes ricinus.

*Latr. Gen. Crust. et Insect.*

*Leach, Edin. Encycl.* vii. 414.

—— *Trans. Linn. Soc.* xi.

Inhabits Europe, attaching itself to dogs. In Britain it is called the Dog ticque.

Family IV. *Stirps* 2.

Gen. 56. Uropoda. *Latreille, Leach.*

*Body* oval, orbiculate; back corneous, clypeiform, the disc being gradually convex; beneath flat. *Anus* produced into a long filiform peduncle (by which it adheres to coleopterous insects). *Legs* very short, pressed close to the body, the first pair shortest, the second rather longer, the third distinctly longer, the fourth pair longest.

Sp. 1. *Vegetans.* Brown, very smooth, shining.

Mitte vegetative.

*De Geer, Mém. sur les Insect.* vii. 123. pl. 7. fig. 15.

*Latr. Hist. Nat. des Crust. et Insect.* vii. 381, *et* viii. pl. 67. f. 8.

Uropoda vegetans.

*Latr. Gen. Crust. et Insect.* i. 158.

*Leach, Edin. Encycl.* vii. 414.

Inhabits France and England, attaching itself to the legs, abdomen, and elytra of histeres, aphodii, &c. by its pedunculated anus.

Family V. Cheyletideæ. *Stirps* 1.

Gen. 57. Cheyletus. *Latreille, Leach.*

*Palpi* brachiiform, very thick, their points falcate.

Sp. 1. *Eruditus.* Body brownish.

Acarus eruditus.

*Schr. Enum. Insect. Aust.* 1058. tab. 2. fig. 1.

Cheyletus eruditus.

*Latr. Gen. Crust. et Ins.* i. 153.

*Leach, Edin. Encycl.* vii. 414.

Inhabits books and Musæa.

Gen. 58. Smaris. *Latreille, Leach.*

*Palpi* small, filiform, strait, simple. *Eyes* two. *Anterior legs* longest.

Sp. 1. *Sambuci.*

Acarus sambuci. *Schr. Enum. Ins. Austr.* 1085.

Smaris sambuci.

*Latr. Gen. Crust. et Insect.* i. 153.

*Leach, Edinb. Encycl.* vii. 414.

Inhabits the trunks of trees, especially those of the Elder.

Gen. 59. Bdella. *Latreille, Lamarck.*

Scirus. *Hermann.*

*Palpi* small, filiform, long, geniculated, the apex setigerous. *Eyes* four. *Hinder legs* longest.

Sp. 1. *Rubra.* Body coccineous, legs paler, rostrum longer than the thorax.

Bdelle rouge.

*Latr. Hist. Nat. des Crust. et des Insect.* viii. 53. pl. 67. fig. 7.

Bdella rubra.

*Lam. Syst. des Anim. sans Vertéb.* 179.

*Latr. Gen. Crust. et Insect.* i. 154.

*Leach, Edin. Encycl.* vii. 414.

Inhabits Europe, under stones. It is the *Pince rouge* of Geoffroy, and is probably the *Acarus longicornis* of Linné.

Family V. *Stirps* 2.

Gen. 60. Sarcoptes. *Latreille, Leach.*

Sp. 1. *Scabiei.* Subrotundate; legs short, reddish; four hinder ones, with a very long seta, the plantæ of the four anterior ones terminated by a swelling.

Mitte de la Gale.

*De Geer, Mém. sur les Insect.* ii. 622.

Le Ciron de la Gale.

*Geoff. Hist. des Insect.* ii. 622.

Acarus Scabiei. *Fabr. Ent. Syst.* iv. 430.

Sarcopte de la Gale.

*Latr. Hist. Nat. des Crust. et des Insect.* viii. 55. *et* vii. pl. 66.

Sarcoptes scabiei.

*Latr. Gen. Crust. et Insect.* i. 152.

*Leach, Edin. Encycl.* vii. 413.

Inhabits the ulcers of the itch. *Acarus exulcerans* of Linné is probably this animal, or is at least referable to the same genus.

### Section II.

Family I. Elyaideæ.

Gen. 61. Elyäis. *Latreille, Lamarck, Leach.*

*Mandibles* depressed, armed at their joints with a claw. *Palpi* elongate-conic, arcuate. *Eyes* four.

Sp. 1. *Extendens.* Body rounded, shining, smooth, red, immaculate; hinder legs strait.

Eläis extendens.

*Lam. Syst. des Anim. sans Vertéb.* 177.

*Latr. Gen. Crust. et des Insect.* i. 158.

*Leach, Edinb. Encycl.* vii. 413.

Hydrachna extendens.

*Müll. Hydr.* 62. tab. 9. f. 4.

Trombidium extendens.

*Fabr. Ent. Syst.* ii. 406.

Inhabits stagnant waters.

Family II. Hydrachnideæ.

Gen. 62. Hydrachna. *Müll. Oliv. Latr. Leach.*

*Palpi* subcylindric, porrect, arcuate-inflexed, four-jointed, the last acute, unguiform. *Mouth* produced into a conic rostrum. *Body* globose. *Legs* fimbriated with hairs, and situated at equal distances from one another.

Sp. 1. *Geographica.* Black, with coccineous spots and dots.

Hydrachna geographica.

*Müll. Hydr.* 59. tab. 8. fig. 3—5.

*Latr. Gen. Crust. et Insect.* i. 159.

*Leach, Edinb. Encycl.* vii. 413.

Inhabits waters that flow gently. It is a most beautiful animal, and is very common in some parts of Britain.

Gen. 63. Limnochares. *Latreille, Leach.*

*Palpi* incurved, the apex acute simple. *Mouth* with a very short rostrum. *Body* depressed. *Legs* short, the four hinder ones remote. *Eyes* two.

Sp. 1. *Holosericea.* Body ovate, red, rugose, soft; eyes black.

Acarus aquaticus.

*Linn. Syst. Nat.* i. 1025.

La tique rouge satinée aquatique.

*Geoff. Hist. des Insect.* ii. 625.

Mitte satinée aquatique.

*De Geer, Mém. sur les Insect.* i. 149. pl. 9. 15—17.

Trombidium aquaticum.

*Fabr. Ent. Syst.* ii. 399.

Limnochares holosericea.

*Latr. Gen. Crust. et Insect.* i. 160.

*Leach, Edinb. Encycl.* vii. 413.

Inhabits the waters of Europe. It is very common in most of our ponds during the summer months. It varies much in colour, but is generally found of a bright red or greyish-red colour, and of all the intermediate varieties of shade.

Fabricius says that it deposits its eggs on Nepæ (water-scorpions), and that they are of a red colour.

---

*Arachnideous Genera of uncertain situation.*

Gen. 64. Trogulus. *Latreille.*

*Body* ovate-elliptic, depressed. *Eyes* two, placed on the back, but not on a common tubercle. *Legs* eight, elongate, filiform, the second pair longest, then the fourth, which is scarcely shorter; the third and fourth afterwards: *tarsi* with a horny claw. *Mandibles* cylindric, compressed, elongate, biarticulate, geniculated, the last joint didactyle, the fingers equal, towards their points unidentate. *Palpi* filiform, a little longer than the mandibles, geniculated, five-jointed, the last furnished at its point with a very minute corneous claw.

For a more detailed character of this genus, see Latreille's *Genera Crustaceorum et Insectorum*, Vol. I. p. 141. where it is placed next to Phalangium. In his last work, Latreille has grouped it with Siro, and has put it in the second division of his family Phalangita.

Sp. 1. *Nepæformis.* Obscure-cinereous or earth-coloured; middle of the back of the abdomen and the sides obsoletely subcarinated; external apex of the first joint of the tarsi produced.

Phalangium tricarinatum.

*Linn. Syst. Nat.* i. 1029.

Acarus nepæformis.

*Scopol. Ent. Carniol.* 1070.

 Phalargium carinatum.

*Fabr. Ent. Syst.* ii. 431.

Trogulus nepæformis.

*Latr. Gen. Crust. et Insect.* i. 142. tab. 6. f. 1.

*Leach, Edinb. Encycl.* vii. 416.

Inhabits France and Germany, lurking under stones.

Gen. 65. CELLULARIA. *Montagu.*

The singular animal, that forms the type of the genus *Cellularia*, was discovered by Montagu, and described by him in the first volume of the *Memoirs of the Wernerian Natural History of Edinburgh*, page 191, and, as we have never seen it, we must extract the description given by that ingenious zoologist.

" Ovate-oblong, smooth, glossy white, with eight short legs, furnished with several joints and terminated by bristles, two on each side approximating and near to the anterior end, the others similarly disposed, about one third of its length from the posterior end; of the posterior legs, the hindermost pair is furnished with a very long bristle, the other pair usually with two; the anterior legs possess several bristles each. No other appendages were discernible under the best constructed microscope, not even the mouth or eyes could be clearly ascertained; but beneath, at the anterior end, and from whence the fore legs arise, there are four light depressions, surrounded by dark lines, in the two hindermost of which is a dark spot, but had not the appearance of the eyes; behind this part is usually a fold in the skin, in which there is an independent motion; the feet were also observed to be in continual alternate motion, whilst under the microscope.

" Size of the cheese mite.

" As far as I have hitherto observed, this animal is peculiar to the gannet, and does not appear to inhabit any other part than the cellular membrane. In some subjects it is found in considerable numbers, together with its ova; and no instance has occurred in which it has not appeared more or less in every specimen dissected.

" To class this animal with any of the Linnean genera, is impossible; nor am I acquainted with any genus in the arrangement of any more modern systematic writers, in which it could with propriety be placed. Under these circumstances, I propose giving it a distinct place in the system of nature, under the title of CELLULARIA *Bassani*, with the following generic characters: head thorax and abdomen united; no eyes, antennæ, palpi nor proboscis; legs eight, the four posterior remote from the four anterior; feet unarmed, but furnished with bristles."

Gen. 66. CARIS. *Latreille, Leach.*

" *Legs* six. *Palpi* subconic, porrect, four-jointed, of the length of the rostrum. *Rostrum* conic, porrect. *Body* coriaceous, depressed, suborbiculate." *Latreille.*

Sp. 1. *Vespertilionis.* Body fuscous.

La tique de la chauve-souris?

*Geoff. Hist. des Insect.* ii. 627.

Caris vespertilionis.

*Latr. Gen. Crust. et Insect.* i. 161.

*Leach, Edinb. Encycl.* vii. 413.

Inhabits bats (vespertilionidea).

Gen. 67. LEPTUS. *Latreille.*

" *Legs* six. *Palpi* short, subconic. *Mouth* with a porrected rostrum. *Body* soft, generally oval." *Latreille.*

Can this be synonymous with our genus *Ocypete?*

Sp. 1. *Phalangii.* Body oval, coccineous, anteriorly subcapitate, with two black eyes and a subconic rostrum; first joint of the palpi very much incrassated; legs subequal.

Pediculus coccineus. *Scopol. Ent. Carn.* 1055.

Mitte des Faucheurs.

*De Geer, Mém. sur les Insect.* vii. 117. pl. 7. f. 5.

Acarus Phalangii. *Fabr. Ent. Syst.* iv. 433.

Leptus Phalangii.

*Latr. Gen. Crust. et Insect.* i. 162.

*Leach, Edin. Encycl.* vii. 413.

Inhabits Phalangium opilio.

Gen. 68. ASTOMA. *Latreille.*

" *Legs* six. *Mouth* beneath, nearly obsolete; parts of the mouth not visible. *Body* soft, oval. *Legs* very short." *Latreille.*

Sp. 1. *Parasiticum.* Body coccineous, the middle slightly contracted.

Mitte parasite.

*De Geer, Mém. sur les Insect.* vii. 118. pl. 7. fig. 7.

Astoma parasiticum.

*Latr. Gen. Crust. et Insect.* i. 162.

Inhabits flies and other insects.

Latreille placed the three last mentioned genera in a family which he named *Micropthira;* and, in the *Edinburgh Encyclopædia*, Dr Leach put them in a particular tribe, named *Hexapoda*, under which he arranged all the Arachnides that have six legs.

## Subclass II. NOTOSTOMATA.

This subclass contains the genera *Nycteribia* of Fabricius and Latreille, *Phthiridium* of Hermann.

We shall simply give references to one species, and a definition of the genus containing it.

Genus 69. PHTHIRIDIUM. *Hermann.*

NYCTERIBIA. *Latreille.*

*Abdomen* of one sex two-jointed, terminated by two cylindric processes, bearing setæ; of the other sex six-jointed.

Sp. 1. *Hermanni.*

Plate XXIII. represents the sexes of this species, with a leg highly magnified.

Phthiridium biarticulatum.

*Hermann, Mém. Apterol.* 124. pl. 6. fig. 1.

Celeripes vespertilionis.

*Montagu, Trans. Linn. Soc.* ix. 166, note.

Nycteribia vespertilionis.

*Montagu, Trans. Linn. Soc.* xi. 11. tab. 3. fig. 5.

Inhabits the lesser and greater horse-shoe bats of England.

OBS. *Nycteribia vespertilionis* of Latreille most probably is referable to a distinct genus.

## CLASS IV.—INSECTA.

Insecta, so named from in *into*, and seco *to cut*. This term was applied to these animals by the Latins; by the Greeks they were named Entoma (ἔντομα), from ἐν, *into*; and τεμνω, *to cut*. Insects were so named, because their bodies are composed of many joints or segments, on which account several of the ancient and older naturalists placed them with the classes *Crustacea*, *Myriapoda*, *Arachnides*, and *Vermes*.

Insects constitute the most considerable portion of animated nature, on which account they become interesting, and very worthy of philosophic investigation; and consequently, from the earliest period, of which any authentic records remain, the study of them has obtained a very great portion of attention.

The oldest records on this subject are to be found in the sacred writings, where mention is made of locusts, flies, and caterpillars; and it is probable that Moses had acquired some knowledge of insects from the Egyptian sages, as his writings abound with passages relating to insects.

Hippocrates, as we are told by Pliny, wrote on insects, and the writings of the earlier Greek and Latin philosophers quoted by Pliny, afford extracts of his labours.

Aristotle, in his *History of Animals*, has devoted a very considerable portion of his attention to insects, which he called ἔντομα, and has described their general external structure with great accuracy; but we cannot enter into a detail of what was done by this great man, who has laid the foundation of the modern systems; and we must also pass over in silence, the little that has been observed by Ælian, Democritus, Aristamachus, and others of less note, and state generally that Pliny, in the eleventh book of his *Historia Naturalis*, treats of insects; but his observations are copies chiefly from the works of Aristotle. From the time of this author, until the overthrow of the Roman empire, the study seems to have been totally disregarded.

Sorry as we feel at being under the necessity of omitting to trace the rise of this interesting science, yet we shall give a sketch of the systems of every writer, that the rise of the *systematic* part may be rendered clear to every one interested with that branch of the science, which is the foundation on which the natural history is built.

Aldrovandus in 1602, published a very voluminous work, *De Animalibus Insectis*, in which he divides insects into *Terrestrial* and *Aquatic*.

In 1612, Woolfang Frenzius published *Historia Animalium Sacra*, which contains some new observations, and a distribution of insects into *Aërial*, *Aquatic*, and *Terrestrial*.

Swammerdam, who published his *Historia Insectorum Generalis* in 1669, divided genuine insects into, 1*st*, Those which, after leaving the egg, appear under the form of the perfect insect, but have no wings, which parts are afterwards produced; 2*dly*, Those insects which appear, when hatched from the egg, under the form of a larva (caterpillar), which, when full grown, changes into a chrysalis, where it remains until its parts are fit to be developed; 3*dly*, Those who, having attained the pupa (chrysalis or nympha) state, do not divest themselves of their skin. His other division refers to animals of the classes *Arachnides*, *Crustacea*, and *Myriapoda*, and the whole of his work contains much valuable observation on the structure and economy of these animals.

In 1735, Linné published the first edition of his *Systema Naturæ, sive Regna tria Naturæ Systematice proposita per classes, ordines, genera, et species*, in which work insects are distributed into four orders, according to the number and form of their wings.

1. Coleoptera.
2. Angioptera.
3. Hemiptera.
4. Aptera.

With the last order he included Crustacea, Arachnides, Myriapoda, Vermes, and certain Zoophytes; but in subsequent editions of this work, he separated the Vermes, as Aristotle had done before him, and established them as a class distinct from insects.

Schæffer in 1741 published a valuable work, under the title *Icones Insectorum circa Ratisbonam Indigenorum*. The classification proposed by this author differs entirely from that of Linné, and approaches in some respects that proposed by Geoffroy; yet it is so far distinct, that, being a system of considerable repute, it may not be amiss to give an outline of it in this place. He divides insects into seven Orders, which he terms Classes.

I. Coleoptero-macroptera. Insects with long crustaceous elytra.

II. Coleoptero-microptera. Insects with short crustaceous elytra.

III. Coleoptero-hymenoptera. Insects with half crustaceous elytra.

IV. Hymeno-Lepidoptera. Insects with transparent wings.

V. Hymeno-gymnoptera. Insects with naked membranaceous wings.

VI. Diptera. Insects with two wings.

VII. Aptera. Insects without wings, amongst which spiders, &c. were comprehended.

In 1764, Geoffroy published his most valuable system of insects, under the title, *Histoire Abrégée des Insectes*, &c. in which these animals are arranged into six sections:

I. Coleoptera. Wings covered with elytra; mouth with jaws.

II. Hemiptera. Upper wings resembling elytra; mouth bent under the thorax.

III. Tetraptera alis farinaceis. Wings four, covered by little scales.

IV. Tetraptera alis nudis. Wings four, naked, membranaceous.

V. Diptera. Wings two. Haltares or balancers, under the origin of the wings.

Insecta.

VI. Aptera. Wings none.

Like his predecessors, Geoffroy included Crustacea, &c. under the title Aptera.

In 1780, Linné produced the twelfth edition of his *Systema Naturæ;* and, as this was the last systematic work of that illustrious naturalist, we shall state his entomological arrangement. He divides insects into seven orders, deducing the characters from the wings, but he still retained the *Crustacea, Myriapoda*, and *Arachnides*, amongst the apterous insects.

Order I. Coleoptera (from κολεὸς, *a sheath*, and πτερὸν, *a wing*), including those insects having crustaceous shells or elytra, which shut together and form a longitudinal suture down the back. In many, the abdomen is wholly covered by these elytra; in others partially.

Order II. Hemiptera (from ἥμισυ, *half*, and πτερὸν). These animals have their elytra half crustaceous, and half membranaceous, or of a matter intermediate between leather and membrane.

Order III. Lepidoptera (from λεπὶς, *a scale*, and πτερὸν). Insects with four wings imbricated with scales.

Order IV. Neuroptera (from νεῦρον, *a nerve*, and πτερὸν). Insects with four transparent wings, reticulated with nerves.

Order V. Hymenoptera (from ὑμὴν, *a membrane*, and πτερὸν). Insects with four naked membranaceous wings.

Order VI. Diptera (from δυω, *two*, and πτερὸν). Insects with two wings.

Order VII. Aptera (from ἀ, without, and πτερὸν). Insects destitute of wings.

In 1776, J. C. Fabricius, a pupil of Linné, published a new system of entomology, under the title *Systema Entomologiæ*, in which the principles of a new mode of classification, founded on the organs of deglutition and mastication, is for the first time developed. This system, which has undergone several modifications, is named the *Cibarian System*, of which we shall say more, when speaking of the most improved form in which it has been given to the world.

Scopoli, in 1777, published his *Introductio ad Historiam Naturalem*, in which work he divides insects into five tribes, under the singular appellations of, 1. *Swammerdami-lucifuga*, 2. *Geoffroy-gymnoptera*, 3. *Roeselii-lepidoptera*, 4. *Reaumurii-proboscidea*, 5. *Frischii-Coleoptera;* identifying each tribe by the name of that author who has, in his opinion, been most successful in the explanation of that to which his name is attached.

The *Lucifuga* includes the lice; *Gymnoptera*, his *halterata*, *aculeata* and *caudata:* *Lepidoptera*, the moths and butterflies; *Proboscidea*, he has divided into terrestrial and aquatic, and the *Coleoptera* he divides into those inhabiting water, and those the land.

In 1793, P. A. Latreille published his *Precis du Caractéres des Genres*, in which he divided insects into, 1. *Coleoptera*, 2. *Orthoptera*, 3. *Hemiptera*, 4. *Neuroptera*, 5. *Lepidoptera*, 6. *Suctoria*, 7. *Thasynoura*, 8. *Parasita;* and under the further terms, *Acephala, Entomostraca, Crustacea, and Myriopoda*, he has comprehended the *Crustacea, Myriapoda*, and *Arachnides*.

Insecta.

In 1798, J. C. Fabricius produced his last general systematic work, his *Supplementum Entomologiæ Systematicæ*, which presents an outline of his system in its latest state; and which, being the result of much knowledge, demands a considerable portion of attention. In this work he divides genuine insects into the following Orders, which he named Classes. The omitted classes are referable to Crustacea, Myriapoda, and Insecta, as already shown.

Class I. Eleuterata. Maxillæ naked, free, bearing palpi.

Class II. Ulonata. Maxillæ covered by an obtuse galea, or mouth-piece.

Class III. Synistata. Maxillæ elbowed at their base, and connected with the labium.

Class IV. Piezata. Maxillæ corneous, compressed, often elongate.

Class V. Odonata. Maxillæ corneous, dentated. *Palpi* two.

Class XI. Glossata. Mouth with a spiral tongue reflexed between the palpi.

Class XII. Ryngota. Mouth with a rostrum and articulated sheath.

Class XIII. Antliata. Mouth with an inarticulate haustellum.

In the "*Entomologie Helvetique*," a work published in 1798, Clairville, its author, has arranged insects in the following manner:

* PTEROPHORA; mandibulata. With wings and jaws.

Section 1. Elytroptera. Wings crustaceous.
2. Deratoptera. Wings coriaceous.
3. Dictyoptera. Wings reticulated.
4. Phleboptera. Wings veined.

** PTEROPHORA; haustellata. With wings and an haustellum.

5. Halteriptera. Wings with poisers.
6. Lepidoptera. Wings with powder.
7. Hemimeroptera. Wings partly obscure, partly diaphanous.

*** APTERA; haustellata. Without wings; with a sucker.

8. Rophoptera. Sucker sharp.

**** APTERA; mandibulata. Without wings; with jaws.

9. Pododunera. Legs formed for running.

In 1800, Cuvier, with the assistance of Duméril, published his *Anatomie Comparée*, in which the organization of insects is treated of at great length.

In 1801, J. B. Lamarck produced his *Systême des Animaux sans Vertèbres*, in which work he has separated the Crustacea from Insects, and proposed the Arachnides as a separate and distinct class. Some of the animals which we conceive to be genuine insects, he has placed with the Arachnides, the rest he distributes into the following Orders:

* *With mandibles and jaws.*

Order I. Coleoptera. Two wings, folded transversely, and covered by coriaceous elytra.

Order II. Orthoptera. Two strait wings, folded longitudinally, and covered by submembranaceous cases, or elytra.

Order III. Neuroptera. Four naked, reticulated, membranaceous wings.

** *With mandibles and with a kind of proboscis.*

Order IV. Hymenoptera.

*** *No mandibles. A trunk or sucker.*

Order V. Lepidoptera. Four membranaceous wings covered with fine powder-like scales; tongue spiral.

Order VI. Hemiptera. Two wings, covered by semimembranaceous elytra.

Order VII. Diptera. Two naked wings, with balancers at their base.

Order VIII. Aptera. No wings. Mouth with an articulated trunk.

In the same year, in 1806, P. A. Latreille published his *Genera Crustaceorum et Insectorum*, in which he has denominated the true insects *Insecta Pterodicera*; and has arranged them in the following manner:

Century I. ELYTHROPTERA.

Elytra two, covering the wings entirely.

Cohors I. Odontota.

Mouth with mandibles, maxillæ, and lip. Wings folded.

Order I. Coleoptera. Wings transversely folded. Elytra crustaceous.

Order II. Orthoptera. Wings longitudinally folded. Elytra coriaceous.

Cohors II. Siphonostoma.

Order III. Hemiptera. Mouth with an articulated beak, sheathing the haustellum, formed of three setæ. Wings extended; elytra generally semicoriaceous or semimembranaceous, one decussating the other.

Century II. Gymnoptera.

Wings naked.

Cohors I. Odontota.

Mouth with mandibles, maxillæ, and lip. Wings four.

Order IV. Neuroptera. Wings reticulated, most generally equal. Maxillæ not sheathing the sides of the lip.

Order V. Hymenoptera. Wings veined, hinder ones smallest. Maxillæ sheathing the sides of the lip.

Cohors II. Siphonostoma.

Mouth tubular, formed for sucking.

Order VI. Lepidoptera. Wings four, imbricated with scales. Mouth with a spiral tongue, formed of two laciniæ; haustellum none.

Order VII. Diptera. Wings two, with haltares or balancers at their base. Mouth with a proboscis, including an haustellum that is composed of one part, or at least only geniculated at its base.

Order VIII. Suctoria. Wings and balancers none. Body formed of a series of rings. Thorax not distinct from the base of the abdomen. Mouth with a rostrum articulated from its origin, with two external valves at the base.

Latreille has retained the same general arrangement in his last work, *Considerations Génerales sur l'Ordre Naturelle, &c.* but he has rejected the divisions into legions, centuries, and cohortes.

Duméril, in his *Zoologie Analytique*, arranges insects into eight orders, the last of which also comprehends the classes Arachnides and Myriapoda.

In 1812, De Lamarck published a little work, entitled *Extrait de Cours de Zoologie du Muséum d'Histoire Naturelle*, in which he has continued the general arrangement published by him in 1801.

In 1815, Vol. IX. of the *Edinburgh Encyclopædia* was published, in which Dr Leach has given the following arrangement of insects into orders, and has added to them the *Parasita* and *Thysanoura*, which Latreille placed with the Arachnides.

INSECTA.

Subclass I. AMETABOLIA.

Insects undergoing no metamorphosis.

Order I. Thysanura. Tail armed with setæ.

Order II. Anophura. Tail without setæ.

Subclass II. METABOLIA.

Insects undergoing metamorphosis.

Century I. ELYTHROPTERA.

Insects with elytra.

Cohors I. Odontostomata.

Mouth with mandibles.

* *Metamorphosis incomplete.*

Order III. Coleoptera. Wings transversely folded. Elytra crustaceous, covering the wings, their suture strait.

** *Metamorphosis nearly coarctate.*

Order IV. Strepsiptera. Wings longitudinally folded. Elytra coriaceous, not covering the wings.

*** *Metamorphosis semi-complete.*

Order V. Dermaptera. Wings longitudinally and transversely folded. Elytra somewhat crustaceous, abbreviated, with the suture strait.

Order VI. Orthoptera. Wings longitudinally folded. Elytra coriaceous, the internal margin of one elytron covering the same part of the other.

Order VII. Dictyoptera. Wings longitudinally folded twice or more. Elytra coriaceous, nervose, one decussating the other obliquely.

Cohors II. Siphonostomata.

Mouth with an articulated rostrum.

Order VIII. Hemiptera. Elytra somewhat crustaceous, or very coriaceous; towards the apex generally membranaceous, horizontal, one decussating the other obliquely. (Metamorphosis semi-complete.)

Order IX. Omoptera. Elytra entirely coriaceous, or membranaceous, and meeting obliquely, with a strait suture. (Metamorphosis semi-complete, or incomplete.)

Century II. MEDAMOPTERA.

Insects without wings or elytra.

Order X. Aptera. Mouth with a tubular sucking rostrum. (Metamorphosis incomplete.)

Century III. GYMNOPTERA.

Insects with wings, but with no elytra.

Cohors I. Glossostomata.

Mouth with a spiral tongue.

Order XI. Lepidoptera. Wings four, imbricated with scales.

Cohors II. Gnathostomata.

Mouth with maxillæ and lip.

Insecta.

Order XII. Trichoptera. Wings four, membranaceous, the pterygostia hairy.

Cohors III. Odontostomata.

Mouth with mandibles, maxillæ, and lip.

Order XIII. Neuroptera. Four highly-reticulated wings, generally of an equal size. (Anus of the female without a sting, or compound oviduct.)

Order XIV. Hymenoptera. Four venose wings, hinder ones smallest. (Anus of the female with a sting, or compound oviduct.)

Cohors IV. Siphonostomata.

Mouth tubular, formed for sucking.

Order XV. Diptera. Wings two, with balancers at their base.

The above arrangement is liable to various objections. We shall endeavour to define the orders in a more intelligible and simple manner.

*Classification.*

All genuine insects have six legs; a head distinct from their body, and furnished with two antennæ: they all are produced from eggs. Some undergo no metamorphosis, others but a partial change, whilst the remainder pass through three stages of existence, after having been hatched from the egg.

The peculiarities of every order will be mentioned under its proper head, in the article Insecta; but we shall here proceed with the systematic arrangement into orders.

Subclass I. AMETABOLIA.

Insects undergoing no metamorphosis.

Order I. Thysanoura. Tail armed with setæ.

Order II. Anoplura. Tail without setæ.

Subclass II. METABOLIA.

Insects undergoing metamorphosis.

Order III. Coleoptera. Wings two, transversely folded, covered by two crustaceous or hard coriaceous elytra, meeting (generally) with a strait suture. Mouth with mandibles. (Metamorphosis incomplete.) Plate XXIV.

Order IV. Dermaptera. Wings two, longitudinally and transversely folded. Elytra subcrustaceous, abbreviated, with the suture strait. Mouth with mandibles. (Metamorphosis semi-complete.) Plate XXIV.

Order V. Orthoptera. Wings two, longitudinally folded, covered by two coriaceous elytra, the margin of one elytron covering the same part of the other. Mouth with mandibles. (Metamorphosis semi-complete.) Plate XXIV.

Order VI. Dictyoptera. Wings two, longitudinally folded, twice or more, covered by two coriaceous elytra, one elytron decussating the other obliquely. Mouth with mandibles. (Metamorphosis semi-complete.) Plate XXIV.

Order VII. Hemiptera. Wings two, covered by two crustaceous or coriaceous elytra (the tips of which are generally membranaceous), horizontal, one decussating the other obliquely. Mouth with an articulated rostrum. (Metamorphosis semi-complete.) Plate XXIV.

Order VIII. Omoptera. Wings two, covered by two elytra, which are entirely coriaceous or membranaceous; meeting obliquely with a strait suture. Mouth with an articulated rostrum. (Metamorphosis semi-complete, or incomplete.) Plate XXIV.

Order IX. Aptera. No wings, or elytra. Mouth with a tubular, jointed, sucking rostrum. (Metamorphosis incomplete.)

Order X. Lepidoptera. Wings four, membranaceous, covered with meal-like scales. Mouth with a spiral tongue. (Metamorphosis incomplete.) Plate XXV.

Order XI. Trichoptera. Wings four, membranaceous; the pterigostia or wing-bones hairy. Mouth with maxillæ and lip. (Metamorphosis incomplete.) Plate XXV.

Order XII. Neuroptera. Wings four, membranaceous, generally of equal size; with numerous decussating pterigostia, resembling a net-work. Mouth with mandibles, maxillæ, and lip. (Metamorphosis incomplete or semi-complete.) Plate XXV.

Order XIII. Hymenoptera. Wings four, membranaceous, the hinder ones always smallest; the pterigostia not decussating each other, so as to resemble a net-work. Mouth with mandibles, maxillæ, and lip. (Metamorphosis incomplete.) Plate XXV.

Order XIV. Strepsiptera. Wings two, longitudinally folded. *Mouth* with mandibles. (Metamorphosis subcoarctate.) Plate XXIV.

Order XV. Diptera. *Wings* two, with haltares or balancers at their base. Mouth tubular, formed for sucking. (Metamorphosis incomplete or subcoarctate.) Plate XXV.

The generic characters of insects, and their distribution into families and stirpes, will be given under the article Insecta, which see.

## CLASS V.—Vermes.

Vermes.

The Vermes comprehend all those annulose animals which have no distinct head, no antennæ, and no legs. Many of them inhabit the sea, others fresh water, and some few damp places, or even under the earth. Their classification is not understood; an extensive field is therefore open to any naturalist, who may hereafter have time, inclination, and opportunity to study them.

Lamarck and others have arranged them, from the position of their respiratory organs, into two orders, which we have adopted; but the arrangement of the genera appears to be very artificial, although well calculated to assist the views of the student.

Order I. Cryptobranchia. Organs of respiration concealed, or internal.

Order II. Gymnobranchia. Organs of respiration naked, or external.

Order I. Cryptobranchia.

A. *Body* rounded, furnished with little spines.

Genus 1. Lumbricus, 2. Thalessema.

B. *Body* rounded or flattened; each extremity furnished with a sucker.

Genus 3. PONTOBDELLA, 4. HIRUDO.

C. *Body* flattened, naked, smooth; extremities without suckers.

Genus 5. PLANARIA.

D. *Body* flattened; sides with setæ.

Genus 6. NAÏS.

A.

Gen. 1. LUMBRICUS *of authors.*

*Body* naked, long, cylindric, articulated; rings fleshy, contractile; with short fasciculæ of spines; anterior extremity conic; posterior extremity somewhat flattened, obtuse.

One species only has been accurately determined by naturalists. This species is hermaphrodite, and deposits its eggs. There is an excellent paper on its structure, by De Montegre, published in the first volume of the *Mémoirs du Muséum d'Histoire Naturelle.*

Sp. 1. *Terrestris* of authors. Plate XXVI.

This is the common earth-worm, whose use, in the economy of nature, seems to be, that of rendering the earth more porous, by its innumerable holes, and thus facilitating the growth of vegetables, which it manures by the leaves, &c. that it draws into its haunts.

Gen. 2. THALESSEMA. *Cuvier,* &c.

*Body* with its hinder extremity much thicker than the anterior, which resembles a conic funnel; neck with two hooks below.

The *Thalessemæ* inhabit the shores of the sea.

Sp. 1. *Aquatica.*

B.

The animals of this section are denominated *Leeches* or *Blood-suckers.* One of the genera inhabits the sea, the other fresh-water.

Gen. 3. PONTOBDELLA. *Leach.* (SEA-LEECH.)

*Body* oblong, round, slightly contractile; both extremities (especially the anterior extremity) attenuated; skin subcoriaceous.

Sp. 1. *Spinulosa.* Body Spinulose.

Plate XXVI.

This species is common in the North British seas, adhering to skates, whence it is commonly called *skate-sucker.* When bruised it emits a dark liquor, which stains of a beautiful purple colour.

Gen. 4. HIRUDO *of authors.* (LEECH.)

*Body* oblong, more or less flattened, very contractile; anterior extremity very gradually attenuated; skin tough.

Sp. 1. *Medicinalis.* (Common leech.)

Plate XXVI.

This species inhabits rivers and lakes. It is the common leech used by medical people.

C.

Gen. 5. PLANARIA. *Müll.* &c.

*Body* horizontally depressed, subgelatinous; *mouth* terminal; *belly* with two openings beneath; one for generation; the other for the passage of the excrement.

The species are numerous, and of various shapes: They inhabit fresh waters; some have one, two, three, four, or even no eyes; some have tentacules, others none. On this account, as Cuvier observes, they should be distributed under several generic heads.

D.

Gen. 6. NAÏS. *Müller,* &c.

*Body* naked, long, slender, somewhat depressed, articulated; *sides* with long setæ, disposed in bundles.

Sp. 1. *Proboscidea.* Reddish, mouth produced, filiform.

Inhabits fresh waters. Its mode of generation is curious. The last joint of the body by degrees separates and forms an entire animal.

OBS. The other *Naides* of authors (at least those whose economy is known) deposit eggs. This genus may therefore be divided hereafter, when the exact structure of each species shall have been accurately determined.

Order II. GYMNOBRANCHIA.

A. *Body* free.

a. *Mouth with jaws.*

Genus 7. NEREIS.

b. *Mouth without jaws; labial palpi distinct.*

Genus 8. AMPHINOME, 9. APHRODITA, 10. LEPIDONOTUS.

c. *Mouth without jaws; labial palpi none.*

Genus 11. ARENICOLA.

B. *Body* inclosed within a tube.

a. *Tube composed of fragments of shell or sand; head with tentacules.*

Genus 12. TEREBELLA, 13. AMPHITRITE.

b. *Tube composed of fragments of shell or sand; head without tentacules.*

Genus 14. CISTENA.

c. *Tube testaceous, open at each end.*

Genus 15. DENTALIUM.

d. *Tube testaceous, open at its anterior end only.*

Genus 16. SERPULA, 17. SPIRORBIS.

A. a.

Gen. 7. NEREÏS *of authors.*

*Body* composed of rings; rings on each side with processes of various forms in the different species. *Mouth* with tentacules.

The Nereïdes are often called *Sea-centipieds,* from their general resemblance to the Scolopendridea. They require to be investigated. Their tentacules vary in number, in proportion, and in situation. The characters for division are therefore very obvious. Their mouth varies very much in the structure of its parts, in the size of its jaws, in the form of the lateral processes, &c.

Sp. 1. *Margaritacea.* Body pearly; terminated by two long setæ; tentacules eight; head trilobate; exterior lobes, with their points attenuated and very slightly knobbed; middle lobe with two little incurved processes.

Plate XXVI.

This species is common at the Bell-Rock, and is subject to great variation in colour; being sometimes greenish-bronze, at other times with a purple line running down the middle of its back.

A. b.

The three genera of this division form a natural group.

Vermes.

Gen. 8. Amphinome. *Bruguière, &c.*

*Organs of respiration* long, plumose.

Sp. 1. *Tetraedra.*

Aphrodita rostrata. *Pallas.*

Gen. 9. Aphrodita *of authors.*

*Organs of respiration* short, covered. *Back* membranaceous, naked; *sides* very bristly; bristles intermingled with silky down.

Sp. 1. *Aculeata* of authors.

Inhabits the European Ocean. It is often named the sea-mouse by our fishermen.

Gen. 10. Lepidonotus, new genus.

*Organs* of respiration short, covered. *Back* covered by a double series of scales.

This genus contains many species: We possess about eleven kinds found on our coasts.

Sp. 1. *Clavatus.*

Aphrodita clava.

*Montagu, Trans. Linn. Soc.* ix. tab. 7.

Inhabits the British Seas.

A. c.

Gen. 11. Arenicola. *Lamarck, &c.*

*Body* round, each extremity rounded, obtuse; *posterior extremity* narrowest; *anterior extremity* with tubercles on each side terminated by setæ; *organs of respiration* placed externally behind the tubercles of the middle of the body.

Sp. 1. *Carbonaria.* Body coal-black.

Inhabits the Firth of Forth at the Black Rocks, near Leith, under stones. Plate XXVI.

Sp. 2. *Tinctoria.* Body yellowish inclining to cinereous, beautifully banded with blue; organs of respiration blood-red; tail greenish.

Inhabits the sand of the sea, in which it burrows, and is extracted by the fishermen, who use it as a bait for fish. When living the tail secretes a fluid which stains the fingers of a fine yellow colour.

Lumbricus marinus of Linné belongs to this genus, of which we possess two other indigenous species.

B. a.

Gen. 12. Terebella. *Linné, &c.*

*Body* cylindric. *Tentacules* capillary, numerous.

This genus has been confused with Amphitrite, by several authors. The Linnean character "tentacula capillaria" will however apply to this alone.

Sp. 1. *Lapidaria.* Linné.

Inhabits the Mediterranean.

Gen. 13. Amphitrite. *Müller, &c.*

*Body* annulated. *Tentacules* acuminate, plumose, numerous.

Vermes.

Sp. 1. *Volutacornis.* Tentacules convoluted; stem with long ciliated fibres on one side, spirally turned two or three times.

Amphitrite volutacornis.

*Montagu, Trans. Linn. Soc.* xi. 81. tab. 7. fig. 10.

Inhabits the southern coast of Devon, where it was first discovered by Montagu. Plate XXVI.

B. b.

Gen. 14. Cistena, new genus.

*Mouth* with two pectinated scales, of a brilliant golden colour. Plate XXVI.

Sp. 1. *Pallassii.*

Nereis cylindraria.

*Pall. Miscel. Zool.* 181. tab. ix. fig. 3.

Sabella tubiformis.

*Penn. Brit. Zool.* iv. 148. tab. 92. fig. 163.

Nereis conchilega.

*Penn. Brit. Zool.* iv. 47.

Inhabits the sandy shores of Britain.

B. c.

Gen. 15. Dentalium *of authors.*

*Head* with tentacules. *Tubes* slightly bent.

The species of this genus are distinguished by the sculpture of their shelly tubes.

Sp. 1. *Entalis* of authors.

Inhabits the European Ocean.

B. d.

Gen. 16. Serpula *of authors.*

*Tentacules* forming two bundles.

The species of this genus are very numerous, and are but little known; they are to be distinguished by their shelly tubes.

Gen. 17. Spirorbis. *Daudin, &c.*

*Tentacules* six in number, resembling palpes.

The *Spirorbes* form an extensive genus, the species of which are distinguished by their shells.

The classification of the *Vermes*, as we have before observed, is so very imperfectly understood, that the above enumeration of the genera can be of use only to the student.

The other genera formed by Montagu and Fleming, will be given in the article Zoology, their situation in the system not having been determined by an examination of the animals. (v.)

Anquetil.

ANQUETIL (LEWIS PETER), a French historian, was born at Paris, on the 21st of January 1723. At the age of seventeen, he entered the congregation of St Genevieve, where he taught theology and literature with ability and success. He afterwards became Director of the academy at Rheims; and, in 1759, he was appointed Prior of the abbey de la Röe, in Anjou. Soon after this, he was sent, in the capacity of Director, to the college of Senlis. In 1766, he obtained the Curacy or Priory of Chateau-Renard, near Montargis, which he exchanged, at the commencement of the Revolution, for the Curacy of La Villette, in the neighbourhood of Paris. During the reign of terror, he was imprisoned at St Lazare. On the establishment of the National Institute, he was elected a member of the second class, and was soon afterwards employed in the office of the minister for foreign affairs. Endowed with a robust constitution, which was preserved by a natural equality of temper, and general moderation in diet, Anquetil was capable of very laborious exertions, and is said to have passed ten hours every day, regularly, in study. When upwards of eighty, he still meditated extensive literary undertakings; but he was carried off by death, in the midst of his projects and researches, on the 6th of September 1808, in the eighty-fourth year of his age. On the evening previous to this event, he is reported to have said to one of his friends, "Come and see a man who is dying full of life."

As an author, M. Anquetil does not stand very high in the ranks of literature. He possessed more industry in research, than ability or judgment in execution. His style is censurable in many respects, and he appears to have been almost entirely destitute of the critical discernment and philosophical sagacity, which are requisite to form the character of a good historian. The following is a list of his principal works. 1. *Histoire Civile et Politique de la ville de Reims*, 1756-57, 3 vols. 12mo. The history is brought no farther down than 1657; a fourth volume should have been added, but it never appeared. Anquetil is said to have written this work in concert with one Felix de la Salle, and it is, perhaps, the best of all his productions. 2. *Almanach de Reims*, 1754, in 24mo. 3. *L'Esprit de la Ligue, ou Histoire Politique des Troubles de France, pendant les 16 et 17 siècles*, 1767, 3 vols. 12mo. This work has been frequently reprinted. 4. *Intrigue du Cabinet sous Henri IV. et sous Louis XIII. terminée par la Fronde*, 1780, 4 vols. 12mo. 5. *Louis XIV. sa Cour et le Regent*, 1789, 4 vols. 12mo; reprinted in 1794, 5 vols. 12mo. 6. *Vie du Marechal Villars, ecrit par lui-même, suivie de Journal du la Cour de 1724 à 1734*, Paris, 1787, 4 vols. 12mo; reprinted in 1792. 7. *Precis de l'Histoire Universelle*, 1797, 9 vols. 12mo; reprinted in 1801 and 1807, in 12 vols. 12mo. This work has been translated into English, Spanish, and Italian. 8. *Motifs des Guerres et des Traités de Paix de la France, pendant les regnes de Louis XIV. Louis XV. et Louis XVI.* 1798, 8vo. 9. *Histoire de France, depuis les Gaules jusqu' à la fin de la Monarchie*, 1805 *et seqq.* 14 vols. 12mo. This work was composed in haste, and is of no great value. 10. *Notice sur la vie de M. Anquetil du Perron.* M. Anquetil likewise wrote several papers in the Memoirs of the Institute. See *Biographie Universelle*. (H.)

Anquetil. Du Perron.

ANQUETIL DU PERRON (ABRAHAM HYACINTH), brother of the subject of the preceding article, was born at Paris, on the 7th of December 1731. Having distinguished himself as a student at the university of that city, and acquired a considerable knowledge of the Hebrew language, he was invited to Auxerre by M. de Caylus, then the Bishop of that diocese. This prelate made him study theology, first at the academy of his diocese, and afterwards at that of Amersfort, near Utrecht; but Anquetil had no desire to embrace the ecclesiastical vocation, and devoted himself with ardour to the study of the different dialects of the Hebrew, and of the Arabic and Persian. Neither the solicitations of M. de Caylus, nor the hopes of rapid preferment, had the power to detain him at Amersfort, after he thought he had acquired every thing that was to be learnt there. He returned to Paris, where his diligent attendance at the Royal Library, and his ardour in the prosecution of his favourite studies, attracted the attention of the Abbé Sallier, keeper of the manuscripts, who introduced him to the acquaintance of his associates and friends, whose united exertions procured for him a small salary, as student of the oriental languages. He had scarcely received this appointment, when, having accidentally laid his hands on some manuscripts in the *Zend*, he formed the project of a voyage to India, with the view of discovering the works of Zoroaster. At this period, an expedition was preparing at the port of L'Orient, which was destined for India. M. du Perron, however, applied in vain, through his protectors, for a passage; and seeing no other means of accomplishing his plan, he enlisted as a common soldier, and set out from Paris, with a knapsack on his back, on the 7th of November 1754. His friends procured his discharge; and the minister, affected by this romantic zeal for science, granted him a free passage, a seat at the captain's table, and a salary, the amount of which was to be fixed by the governor of the French settlements in India. After a passage of nine months, Anquetil landed, on the 10th of August 1755, at Pondicherry. Here he remained no longer than was necessary to make himself master of the modern Persian, and then hastened to Chandernagore, where he thought to acquire the Sanscrit. But in this he was deceived; and he was on the point of returning, when a serious complaint threatened his life. He had scarcely escaped from this danger, when war was declared between France and England; Chandernagore was taken; and Anquetil resolved to return to Pondicherry by land. After a journey of one hundred days, in the course of which, he encountered many adventures, and suffered many hardships, he arrived at Pondicherry. Here he found one of his brothers who had arrived from France, and embarked with him for Surat; but, with the view of exploring the country, he landed at Mahe, and proceeded on foot. It was at Surat that he succeeded, by perseverance and address in his intercourse with the native Priests, in acquiring a sufficient knowledge of the languages, to enable him to translate the Dictionary,

Anquetil Du Perron.

called the *Vedidad-Sade*, and some other works. From thence he proposed going to Benares, to study the languages, antiquities, and sacred laws of the Hindoos; but the capture of Pondicherry obliged him to return to France. He accordingly embarked on board an English vessel, and landed at Portsmouth, in the month of November 1761. After spending some time in London, and visiting Oxford, he set out for Paris, where he arrived on the 4th of May 1762, without fortune, or the desire of acquiring any; but esteeming himself rich in the possession of an hundred and eighty oriental manuscripts, besides other curiosities. The Abbé Barthelemy, and his other friends, procured for him a pension, with the title and appointments of Interpreter for the oriental languages at the royal library. In 1763, the Academy of the *Belles Lettres* received him among the number of its associates; and from that period, he devoted himself to the arrangement and publication of the materials he had collected during his eastern travels. In 1771, he published a work in three volumes 4to, under the title of *Zend-Avesta*, containing collections from the sacred writings of the Persians, among which are fragments of works ascribed to Zoroaster; and he accompanied this work with an account of the life of that sage. This publication must be considered as constituting a very important accession to our stores of oriental literature. A recent historian, and very competent judge, refers to the *Zend-Avesta*, as certainly the most authentic source from which we can derive information regarding the religion and institutions of the great Persian legislator. (Sir John Malcolm's *Hist. of Persia*, Vol. I. p. 193, Note.) To the *Zend-Avesta* M. Du Perron prefixed a discourse, in which he treated the University of Oxford, and some of its learned members, with ridicule and disrespect. Mr (afterwards Sir William) Jones replied to these invectives in an anonymous letter, addressed to the author, written in French, with uncommon force and correctness of style, but at the same time, with a degree of asperity which could only be justified by the petulance of M. Du Perron. In 1778, he published his *Legislation Orientale*, in 4to; a work in which he controverts the system of Montesquieu, and endeavours to prove, that the nature of oriental despotism has been misrepresented by most authors; that in the empires of Turkey, Persia, and Hindostan, there are codes of written law, which equally bind the prince and subject; and that, in these three empires, the inhabitants possess both moveable and immoveable property, which they enjoy with perfect security. His *Recherches Historiques et Geographiques sur l'Inde*, appeared in 1786, and formed part of Thieffenthaler's *Geography of India*. They were followed, in 1789, by his treatise *De la Dignité du Commerce et de l'etat du Commerçant*. The Revolution seems to have greatly affected him. During that period, he abandoned society, shut himself up in his study, and devoted himself entirely to literary seclusion. In 1798, he published *L'Inde en Rapport avec l'Europe*, &c. in 2 vols. 8vo; a work which is more remarkable for its virulent invectives against the English, and for its numerous misrepresentations, than for the information which it contains, or the soundness of the reflections which it conveys. The spirit of the work, indeed, may be ascertained from the summary of its contents, stated in the title-page, in which the author professes to give a detailed, accurate, and terrific picture of the English Machiavelism in India; and he addresses his work, in a ranting, bombastic dedication, to the *Manes* of Dupleix and Labourdonnais. In 1804, he published a Latin translation from the Persian of the *Oupnek'hat*, or *Upanischada*, i. e. "Secrets which must not be revealed," in 2 vols. 4to. On the re-organization of the Institute, M. Anquetil was elected a member, but soon afterwards gave in his resignation. He died at Paris on the 17th of January 1805.

Anquetil Du Perron || Ant.

Besides the works we have already enumerated, M. Anquetil read to the Academy several memoirs on subjects connected with the history and antiquities of the East. At the time of his death, he was engaged in revising a translation of the *Travels of Father Paulin de St Barthelemy in India;* which work was continued by M. Silvestre de Sacy, and published in 1808, in 3 vols. 8vo. He also left behind him a great number of manuscripts, among which, his biographers particularly notice the translation of a Latin treatise *on the Church*, by Doctor Legros, in 4 vols. 4to.

From the preceding narrative, our readers will be enabled to form some notion of the character of Anquetil Du Perron. Among his countrymen, he is regarded as one of the most learned men of the eighteenth century. He certainly distinguished himself by a very ardent and disinterested zeal in the prosecution of those studies to which he dedicated the labours of a long life; but the lustre of his literary character was obscured by a very absurd vanity, and the most inveterate prejudices. In a Discourse addressed to the Asiatic Society at Calcutta, in 1789, Sir William Jones speaks of him, as "having had the merit of undertaking a voyage to India, in his earliest youth, with no other view than to recover the writings of Zeratust (Zoroaster), and who would have acquired a brilliant reputation in France, if he had not sullied it by his immoderate vanity and virulence of temper, which alienated the good-will even of his own countrymen." In the same Discourse, he affirms, that M. Anquetil most certainly had no knowledge of the Sanscrit.—See *Biographie Universelle. Monthly Rev.* Vol. LXI. Lord Teignmouth's *Life of Sir William Jones*. (II.)

Progress of this branch of Entomology.

ANT. The history of a tribe of insects so long celebrated for their industry and frugality, and for the display of that sagacity which characterizes some of the higher orders of animals, is peculiarly calculated to occupy the attention of modern naturalists. The ancients, indeed, had often noticed the habits and economy of the ant; but their accounts, at all times deficient in accuracy from the want of precise definitions and logical arrangement of the objects they describe, are, in this instance, so mixed up with fanciful notions, and chimerical doctrines, and so coloured by the vivid imagination and credulity of the narrators, as to have retarded rather than advanced the progress of real knowledge. Aristotle and Pliny report, for instance, that the labours of ants are in a great measure regulated by the phases

Ant.

of the moon; and the latter mentions a species found in the northern parts of India, whose size was said to equal that of the wolves of Egypt, whose colour was the same as that of a cat, and whose occupation in winter consisted in digging up gold from the bowels of the earth; while the inhabitants in the summer, robbed them of their treasures, after having decoyed them, by stratagem, from their nests. Great mistakes have prevailed, even in later times, from the circumstance of the larvæ of ants bearing a resemblance to grains of corn, which it was supposed these insects hoarded up as a provision for winter consumption. The form of the eggs and of the larvæ, and the attention paid to them by the ants, were described by Dr King in the 23d Number of the *Philosophical Transactions*; but Leuwenhoeck was the first who distinguished, with precision, the different forms which the insect assumes in the several stages of its growth. He traced the successive changes from the egg to the larva, the nymph, and the perfect insect. Swammerdam pursued his scrutiny into these successive developements with greater minuteness; and, unrivalled in the act of microscopic dissection, discovered the wonderful encasement of all the parts of the future ant, at every preceding stage; and showed that it appears under such different forms only from the nature of its envelopes, each of which, at the proper period, is in its turn cast off. Linnæus (*Memoirs of the Royal Academy of Sciences at Stockholm*, Vol. II.) ascertained some of the leading facts with regard to the distinction between the sexes, and determined that the ants which are furnished with wings, are the only individuals that exercise the sexual functions. Several particulars, with regard to the economy of ants, were published by Mr Gould, in a book entitled "An account of English Ants," of which an abstract is given in the *Philosophical Transactions* for 1747, by the Rev. Dr Miles. The facts are there stated with tolerable correctness; but some errors have been committed by following too closely the analogy with bees. Geoffroy (*Histoire des Insectes qui se trouvent aux environs de Paris*), though a good naturalist on other topics, is a bad authority on the subject of ants. The most complete series of observations on the natural history of these insects, is that for which we are indebted to the celebrated Swedish entomologist De Geer (*Mémoires pour servir à l'histoire des Insectes*), an observer on whose fidelity the most implicit reliance may be placed.

In the *Encyclopédie Méthodique*, under the article *Fourmi*, Olivier has drawn up an able statement of all the material facts that had been established by preceding naturalists, without, however, adding any original observations of his own, excepting the description of five or six undescribed species. A full account of the habits of those ants, which for a long period infested the Island of Martinique, is contained in some of the earlier numbers of the *Journal de Physique*, (Vols. IX. and X.) The author of these memoirs, M. Barboteau, has given many curious details on this subject, and has cited a number of facts on various authorities; and the account might now be swelled by the reports of subsequent travellers in different parts of the world; but these statements are often made upon slender authority, and are too much tinctured with the marvellous to admit of much credit being attached to them. The narrative given to us by Bonnet, in the second volume of his *Observations sur les Insectes*, of the proceedings of a colony of ants, which had established itself in the head of a large thistle, and which he transported into his house, is highly interesting; but it elucidates only a few points of their economy, and leaves us to regret that so patient and indefatigable an observer had not bestowed more of his attention to the study of this tribe of insects. In the *Philosophical Transactions* for 1790, we find an interesting memoir on the Sugar Ant, a species which, for a period of ten years, committed dreadful ravages in the sugar plantations throughout the whole Island of Grenada. The most methodical account of this tribe of insects that has yet appeared, is that of Latreille, in his *Histoire Naturelle des Fourmis*, published at Paris in 1802; a work which alone would have secured the reputation of the author as an able and scientific naturalist. His merit is particularly conspicuous in the clearness and accuracy of his descriptions of each species, and the luminous method of arrangement which he has adopted in their classification. He gives an account of one hundred species, which he had himself observed, and of twenty-four which he has described from the reports of others; these he distributes into nine natural families, according to the situation and structure of the antennæ, and the form of the abdominal scales. But the work which contains the most copious collection of facts relative to the habits and economy of ants, is that of Mr P. Huber, of Geneva, entitled *Traité des moeurs des Fourmis Indigénes*, published in 1810. By means of an apparatus, which he contrived so as to admit of his obtaining a view, whenever he pleased, of the inmost recesses of their habitation, he was enabled to observe what was going on in the interior of the nest, and to investigate, with success, some of the most important and interesting features of their history. The results of his researches, as they are reported in his work, are highly curious and instructive, and open a wide field of speculation and inquiry to the philosophical entomologist. They have not only elucidated many obscure points with regard to one tribe of insects, but have disclosed some general views of the instincts and faculties of this order of the creation, which are totally new, and must tend, in a considerable degree, to exalt our conceptions of the inexhaustible powers and resources of nature.

Economy and Policy of Ants.

Having thus pointed out the principal sources of information in this department of entomology; we shall proceed to give an outline of the leading facts that have been ascertained relative to the economy and domestic policy of these remarkable insects.

Functions of the Neuters.

In common with many tribes of hymenopterous insects, ants present the remarkable peculiarity of a threefold distinction of sex among the individuals of the same species; a circumstance which is met with in no other order of the animal kingdom, and which appears, as far as observation has extended, to be totally excluded from the plan of the vegetable

Ant.

creation. Besides males and females, there exists an apparently intermediate order of *neuters*, which are also denominated labouring or working ants. The neuters, thus exempted from every sexual function, exercise, on the other hand, all the other offices necessary for the existence and welfare of the community to which they belong; it is they who collect supplies of food, who explore the country for this purpose, and seize upon every animal substance, whether living or dead, which they can lay hold of, and transport to their nest. It is they who construct every part of their dwelling-place, who attend to the hatching of the eggs, to the feeding of the larvæ, and to their removal, as occasion may require, to different situations favourable to their growth and developement; and who, both as aggressors and as defenders, fight all the battles of the commonwealth, and provide for the safety of their weaker and more passive companions. Thus all the laborious and perilous duties of the state are performed solely by this description of ants, who act the part of Helots in these singularly constituted republics of insects. We find, however, on closer examination, that, in all probability, this anomaly in point of sex is more apparent than real; and that, however different in external conformation to the productive females, they nevertheless originally and essentially belong to the same sex. There is every reason to believe that the developement of the sexual organs in the former is the consequence of some difference in the circumstances in which the larva is placed during its growth. That such is the case with bees, is now perfectly well established; and the analogy of bees with ants, in many points of physiology, must be admitted as a strong argument in corroboration of this theory. In all the essential features of internal structure, the supposed neuters agree with the female, and differ from the male of the same species. In all hymenopterous insects, which are armed with stings, a difference exists in the two sexes, as to the number of articulations composing the antennæ; those of the female consisting of fewer pieces than those of the male. The accurate observations of Mr Kirby *(Monographia Apum)*, have determined that in the bee the antennæ of the male have fifteen articulations, while those of the female and the neuter have only fourteen. In the ant, likewise, we find thirteen articulations in the male, and twelve only in the female; and likewise only twelve in the neuter. In the male ant the abdomen has seven rings, in the female and neuter only six. In the two latter classes the head is broader, and the mandibles very large and powerful, compared with those of the male, and are furnished with serrated edges, and a sharp and often hooked point. The external sexual organs of the female and of the neuter are so nearly similar in appearance, that Latreille declares he was unable to perceive the least difference between them. On the other hand, it is to be observed, that, in the neuter, the principal deviation from the model of the female consists in the absence of wings; a circumstance which, as it regards the organs of locomotion only, is one of subordinate importance in the economy; and their presence may, without difficulty, be conceived to be connected with a certain condition of the sexual organs, as are the horns of the deer, and the beard in the human species. But although of so little consequence in a physiological point of view, it is a circumstance materially affecting their external condition. It dooms them to severe toil and exertion in traversing the ground, and in climbing up the steep paths that may lie in their route; while their more luxurious and favoured associates are fluttering in the spacious realms of air in search of amusement, and wafted to the objects of their gratification on the light breezes of the summer.

**Sensitive Powers of Ants.**

Ants appear to be endowed with a greater share of muscular strength than almost any other insect of the same size. Of this we have sufficient proofs in the vivacity of their movements, the incessant toil which many undergo, the great loads which they are seen to carry, often exceeding ten or twelve times their own weight, and the agility which they exert in making their escape from danger. This high degree of irritability is conjoined, apparently, with a corresponding share of the power of sensation; a power which is manifested in their susceptibility to a variety of impressions capable of affecting the organs of sense. They have a quick perception of all changes of temperature, as well as of other conditions of the atmosphere; and are readily, and disagreeably, affected by moisture. In the perfection of the sense of sight they seem to be nearly on a level with other insects; and the males and females are provided with both the descriptions of eyes peculiar to this class, namely, the composite and the simple eyes. The labouring ants, indeed, who never fly, are frequently destitute of the latter kind: a circumstance which appears to confirm the suspicion that has often been entertained, that the simple eyes are chiefly instrumental in the vision of distant objects. Latreille describes two species of ants, in which he could not discover the least appearance whatsoever of eyes, although he employed a high magnifying power in examining them. One of these (the *Formica cæca*) is a foreign species, inhabiting the forests of Guiana, and of which the history is therefore little known. The other (the *Formica contracta*) is met with in the vicinity of Paris. It always conceals itself during the day, under stones, or in obscure recesses, where no light can penetrate; and emerges from its retreat only during the night. It is much less social in its habits than other ants, collecting in groupes only of about a dozen individuals, and appears to be far inferior in sagacity to the rest of the tribe.

Ants possess a considerable acuteness of smell, a sense which appears to be useful not only in directing them to their food, but also, as Bonnet first remarked, in enabling them to follow by the scent the tract of their companions. If the end of the finger be passed two or three times across the line of their march, so as to brush off the odorous particles with which the ants who had already passed that way may have impregnated the track, those who follow immediately stop on arriving at the place where the experiment has been made, and afterwards direct their course irregularly, till they have passed over the space touched by the finger, when they soon find the path, and proceed with the same confidence as before.

Bonnet repeated this experiment frequently, and always with the same result. Latreille has endeavoured to discover the seat of smell, which had long been suspected to reside in the antennæ. He, with this view, deprived several labouring ants of these organs, and replaced them near their nests. When thus mutilated, they wandered to and fro in all directions, as if they were delirious, and utterly unconscious of where they were going. Some of their companions were seen to notice their distress, and approaching them with apparent compassion, applied their tongues to the bleeding wounds of the sufferers, and anointed them with a liquor, which they caused to flow from their own mouths. This trait of sensibility was repeatedly witnessed by Latreille, while he was observing their actions with a magnifying lens.

It is indeed evident that, in all insects, the antennæ are organs of the greatest utility in conveying impressions from external objects. But in the ant, independently of their importance as organs of touch, they appear to be of still greater consequence to the welfare of the individual, and of the community to which it belongs, by being the chief instruments which enable them to communicate to one another intelligence in which they are mutually interested, and on which they are called upon immediately to act. Mr Huber, to whom we are indebted for a variety of curious observations on this subject, has given the name of *Language Antennal* to this species of intercourse. The situation of the antennæ, which are placed in front of the head, their great mobility, their peculiar mechanism, which presents a series of phalanges having great freedom of play, and endowed with exquisite sensibility, conspire to fit them admirably for the function which he assigns to them,—that of producing a variety of different impressions, when applied in different ways to the antennæ, or other parts of those ants, with which they come in contact. Thus the signal of danger, which consists in the ant which gives the alarm striking its head against the corselet of the other, is propagated from ant to ant with astonishing quickness, throughout the whole society. For a few minutes a general ferment prevails, as if they were deliberating what measures to pursue; but their resolution is soon formed, and they are ready to rush in a body against the enemy. Any small animal that is discovered to have insolently invaded their repose, is certain of falling a victim to their resentment; unless he can make a precipitate retreat, which he seldom effects without being covered with the bites of these furious insects. They are not, however, equally jealous of the intrusion of every kind of insect, for woodlice are often found in the interior of the nest, to whom, according to Latreille, they offer no molestation. Ants appear to be incapable of emitting sounds, so as to communicate with one another at a distance: and there is, indeed, no evidence that they possess the sense of hearing. The consideration of the sense of taste naturally comprehends that of their food, to which we shall therefore next proceed.

Their Food; and Depredations.

Very erroneous opinions were prevalent with regard to the food of ants, which have often been supposed to consume corn, and to do great injury to plants by devouring their roots or stems. The truth is, that they are chiefly carnivorous insects, preying indiscriminately on all the softer parts of animals, and especially the viscera of other insects. These, indeed, they will often attack when alive, and overpower by dint of numbers; either devouring their victim on the spot, or dragging it a prisoner into the interior of the nest. If, however, the game should be too bulky to be easily transported, they make a plentiful meal, and exert, like the bee, a power of disgorging a portion, and of imparting it to their companions at home: and it appears that they are even able to retain at pleasure the nutricious juices unchanged for a considerable time. The rapidity with which they consume, and in fact anatomize the carcasses of any small bird or quadruped that happens to fall in their way, is well known; and furnishes an easy method of obtaining natural skeletons of these animals, by placing their dead bodies in the vicinity of a populous ant hill. In hot climates, where they multiply to an amazing extent, their voracity and boldness increase with their numbers. Bosman, in his description of Guinea, states that, in one night, they will devour a sheep, leaving it a fine skeleton; while a fowl is for them only the amusement of an hour. In these situations, they will venture to attack even living animals of considerable size. Rats and mice often become their victims. The sugar ants of Grenada cleared every plantation which they visited of rats and other vermin, which they probably effected by attacking their young. Poultry, or other small stock, could not be raised without the greatest difficulty; and the eyes, nose, and other emunctories of the bodies of dying or dead animals, were instantly covered with them. They generally, indeed, begin their attacks on the most sensible parts, which have the finest cuticle: and accumulating in great numbers about the nostrils, destroy the animal by interrupting respiration. Negroes with sores had difficulty in keeping the ants from assailing them. Their power of destruction keeping pace with their increase of numbers, it is hardly possible to assign limits to either; and the united hosts of this diminutive insect have often become formidable to man himself. A story is related by Prévost, in his *Histoire Général des Voyages*, of an Italian missionary, resident in Congo, who was awaked by his negroes in great alarm at the house being invaded by an immense army of ants, which poured in like a torrent, and before he could rise, had already mountted upon his legs. They covered the floor and passages, forming a stratum of considerable depth. Nothing but fire was capable of arresting their progress. He states that cows have been known to be devoured in their stalls by these daring devastators. Smith, in his *Voyages to Guinea*, reports that at Cape Corse the castle was attacked by legions of ants, who were preceded by thirty or forty, apparently acting as guides. It was at day break when they made this incursion, entering first by a chapel, on the floor of which some negro servants were lying. Assailed by this new enemy, they fled with precipitation, and gave the alarm to their master, who, on awaking, could hardly recover from his astonishment at beholding the advancing multitude, which extended for a quarter of a mile before him. There was not much

Ant.

time for deliberation; and a happy expedient was adopted of putting a long train of gunpowder across the line of their march, and extending it to their flanks, which had already began to deploy, and, setting fire to the whole, millions were destroyed at one blow, which so intimidated the rest, that the whole army retreated in disorder, and did not renew the attack.

Descriptions of ant hills of immense size abound in books of travellers who have visited tropical regions. Mr Campbell (*Account of Travels in South Africa*, published in 1815) observed in the district of Albany, at the Cape, an ant hill, five feet high, and twelve in circumference. In the forests of Guiana, according to M. Malouet, they attain the height of from fifteen to twenty feet; and, when viewed from a distance on these widely extended savannahs, resemble the rude huts of savages: but they contain a race more ferocious than the savage or the tiger himself, and cannot be approached by men without the utmost danger of being devoured. When new settlers, who are clearing the country, meet with any of these in their progress, they must immediately desist from their task, and even abandon the neighbourhood, unless they can speedily destroy the enemy in the very heart of the citadel which protects him, and from which he is able to pour an overwhelming number of combatants. The only method of accomplishing this, is to dig a trench all round the ant hills, and, after having filled it with dry wood, and set fire to it on every side by lighting it quickly in different places, so as to cut off all retreat to the ants, to batter down the edifice with cannon. The ants, thus scattered, soon perish in the flames.

The chief, if not the only vegetable substance which is at all alluring to their appetite is *sugar*. They not only eat it in substance, but are fond of all fluids that contain it in any quantity,—such as the secretions which exude from many trees, and compose what has been termed the honey-dew; and the saccharine juice, which is excreted from the bodies of many of the insects belonging to the genus Aphis. This latter species of food they appear to relish above all others; it resembles honey in its qualities, and is sucked with avidity from the insect which yields it, and which appears in no respect to suffer from the operation. Boissier de Sauvages was the first who noticed this singular fact; and Mr P. Huber has ascertained a number of curious circumstances attending it. He conceives that the liquor is given out voluntarily by the aphis, at the solicitation of the ant, who, for this purpose, strikes it gently and repeatedly with its antennæ, using the same motions as it does when caressing its young; and remarks that the aphis retains this liquor for a longer time, where the ants are not at hand to receive it. A single aphis may often be seen surrounded by three or four ants, who are feeding on the honey, and deriving from it a plentiful meal. It does not appear that the aphis uses any exertion to avoid the ants, who are thus dependent on its bounty; for those provided with wings, which would easily enable them to escape, are quite as passive under these circumstances as the rest.

The cultivation of the sugar-cane in the West Indian islands, has often been severely checked by the ravages of ants; but the injury they occasion arises altogether from their undermining the roots, in order to establish their nests where they can be protected from heavy rains, and secured against agitation from violent winds; advantages which the sugar-cane affords them in a very great degree. No part of the plant constitutes their food: and the same is true of those trees among the roots of which they burrow, and of which they speedily occasion the destruction, by preventing the access of moisture.

Ripe fruits are often attacked by ants, probably on account of the sugar they contain; and, for the same reason, the buds of trees are infested with these insects, and often injured by their depredations. There is no evidence, that they, at any time, feed upon corn, or other vegetable seed. This point has been well established by Mr Gould: and Bonnet, who kept a colony of ants prisoners in his study, observed, that, however long they had been kept without food, still they never touched the corn that he put before them. Honey and sweetmeats have strong attractions for ants, who, if they once discover their way to a magazine of these dainties, will immediately communicate the tidings to the rest of the society, and, leading them to the spot, a regular path will soon be established, which will continue to be crowded with a train of depredators, so long as any thing remains to be pilfered. It is, however, certain, notwithstanding the assertion of Bomare, who compares them to the miser, whose chief pleasure consists in contemplating the riches he has amassed in his coffers, that ants are not in the habit of hoarding provisions for future consumption. They grow torpid when the cold exceeds 27° of Fahrenheit, and in that state require no food, and the aphis affords them sufficient nourishment at other periods of the winter.

Their Nests.

In building their nests, each species of ant follows its own peculiar mode of construction, and employs different materials for this purpose. Many form them of clay, and particularly the smaller species; one set building up a regular series of apartments in successive stories, often forty in number, with materials which are furnished to them by another set of workers, who are excavating the ground below. The ceilings are supported throughout by small pillars in some parts, and by vertical walls in others; while broad arches are in other places raised, in order to protect larger spaces, and to admit of lengthened passages of communication throughout a long extent of apartments. These ants can proceed in the building only at such times as the earth has been softened by rain or dew, and the atmosphere is at the same time sufficiently moist to allow of the materials cohering firmly before they dry. Such are probably the ants, which Pliny mentions as working by moonlight. On one occasion, when the ants, under the inspection of Mr Huber, had discontinued their labours on account of too great dryness in the atmosphere, he succeeded in getting them to renew their operations by sprinkling water upon them with a wet brush, in imitation of a natural shower. They care-

fully close the doors of their habitations every night, in order to prevent the intrusion of other insects; and a few remain on the outside during the night, as centinels, to give the alarm in case of danger. Some species of ants collect fragments of leaves, of bark, or of straw, with which they construct more permanent and artificially constructed nests than the former. Others employ nothing but the fine powder which they collect from decayed wood. Some establish themselves for greater security under a large stone, or in the crevices of decayed buildings. Several tribes, on the other hand, penetrate into the solid substance of wood, which they scoop out into numerous cells, leaving only intermediate partitions of extreme tenuity, just of the strength sufficient to enable the whole fabric to support itself; while it crumbles into powder when pressed between the fingers.

Fœcundation, and Growth of their Young.

We shall now take a brief review of the principal circumstances relating to the fœcundation of the ant, and the evolution and growth of the young. The former is effected very generally during the flight of the females, in which they are accompanied by the males; both appearing to be provided with wings chiefly for this object. A certain number of the females that are impregnated, are also, by the assistance of their wings, enabled to reach distant situations, where they become respectively the founders of new colonies. The males, on the other hand, having fulfilled the office for which nature had destined them, are left to perish on the spot where they descend, being removed from those who formerly administered to them food, and being destitute of the means of procuring subsistence for themselves. Immense swarms of ants are occasionally met with; and some have been recorded of such prodigious density and magnitude as to darken the air like a thick cloud, and to cover the ground to a considerable extent where they settled. Mr Gleditsh describes, in the *History of the Berlin Academy*, for 1749, shoals of a small black ant, which appeared in Germany, and formed high columns in the air, rising to a vast height, and agitated with a curious intestine motion, somewhat resembling the Aurora Borealis. A similar flight of ants is spoken of by Mr Acolutte, a clergyman of Breslaw, which resembled columns of smoke, and which fell on the churches and the tops of the houses, where the ants could be gathered by handfuls. In the German *Ephemerides*, Dr Charles Rayger gives an account of a large swarm, which passed over the town of Posen, and was directing its course towards the Danube. The whole town was strewed with ants, so that it was impossible to walk without trampling on thirty or forty at every step. And more recently, Mr Dorthes, in the *Journal de Physique*, for 1790, relates the appearance of a similar phenomenon at Montpellier. The shoals moved about in different directions, having a singular intestine motion in each column, and also a general motion of rotation. About sunset they all fell to the ground; and, on examining the ants, they were found to belong to the *Formica nigra* of Linnæus.

The swarming of ants does not appear to be at all analogous to that of bees: its object seems to be confined to the propagation of the species, and is not the result of any co-operation of numbers, who associate together in search of a new habitation, in which an already populous assemblage may establish themselves. It would appear that the infant colonies consist of very small numbers, and are perhaps wholly the offspring of a common parent, who has migrated alone, or with but a few companions. The greater number of impregnated females alighting in the neighbourhood of the nest, are laid hold of by the labouring ants, who immediately deprive them of their wings, and drag them to the nest, where they keep them prisoners, till they are ready to deposit their eggs. Each female is, at this period, attended by a numerous retinue of labourers, who treat her with the greatest deference, and are solicitous to anticipate all her wants. Contrary to what happens among bees, many females inhabit the same nest, and live together in the utmost harmony. The eggs, when first deposited, are very small, but become considerably larger before the larva is excluded; being apparently nourished by absorption; for the ants, to whose care they are confided, are perpetually licking them with their tongues;—a fact, which, however curious, is by no means a solitary one in the history of insects. The larva comes forth at the end of a fortnight, and appears in the form of a transparent maggot, with a head and wings, but without any external organs of motion. They are in this state fed by their nurses, with a fluid disgorged from their stomachs; and in the course of their transformation to the state of nympha, and of perfect insect, are still dependent upon their assistance. These affectionate guardians help them to extricate themselves from the web of the cocoon, to unfold the duplicatures of their wings, and supply them with food, till they are capable of procuring it for themselves. The young ant is an exceedingly tender and delicate animal, easily destroyed by any considerable variation of temperature, or by excessive humidity; and great care and attention appear to be required to bring it to maturity: it appears to be the constant business of the ants which remain at home to convey them to different parts of the nest, where the temperature is suited to them; and, whenever danger threatens, they show the utmost solicitude to remove them to situations of security.

Their Sagacity.

Very different degrees of sagacity belong to different tribes of ants. Many traits in the history of the larger kinds, as related by Huber, are of so singular a character, as to be scarcely credible, if we had received them from a less reputable authority; and, if we were not already prepared to admit them, from our knowledge of many equally curious circumstances in the economy of bees, which have been established by the concurrent testimony of the most scrupulous observers. Some tribes of ants, according to this naturalist, who are peculiarly fond of the honey which exudes from the aphis, convey many of these insects into their own nests, lodging them near the vegetables on which they feed, but keeping them prisoners within their habitations, and assigning to them distinct apartments in the subterranean recesses of their dwellings. As if conscious of the future advantages they may derive from these insects, they

Ant.

collect their eggs, and superintend their hatching with the same care which they bestow on the eggs of their own species. The aphis lives in perfect harmony with its keepers, who, so far from molesting it, defends it with courage against ants belonging to other nests, who frequently attempt to get possession of them. Occasionally, they are lodged by the ants in fortified buildings, which they construct at a distance from the nest, in situations where they are most secure from invasion. The aphis is not the only genus of insect which furnishes this kind of provision to the ant; the kermes and gall-insect are employed occasionally for the same purpose; and are found domesticated in the nests of ants, at the same time that they contain several species of aphis, and from all of which they collect nutriment.

Their Wars.

This picture of domestic harmony is strongly contrasted with the scenes of ferocious contention, which are occasionally exhibited between the inhabitants of neighbouring nests; nature appearing to have instilled, together with the love of social order, the same passions of rivalry, of ambition, and of revenge, of which we deplore the operation among beings of a higher order. War, the scourge of the human species, exerts its desolating power among the tribes of gregarious insects, and tends to check their otherwise excessive increase of number. The battles which take place between rival colonies of ants, are often on a scale of prodigious magnitude: millions of combatants engage on either side, with a fury and pertinacity that is truly astonishing. Their weapons of offence are the jaws, which are capable of inflicting a deep bite, and of instilling into the wound a highly acrid liquor; and also, in many species, a sting resembling in situation and structure that of the bee, and likewise containing a venomous juice. This liquor is well known to possess acid properties, and, though long supposed by chemists to contain a peculiar acid, which was denominated the Formic, has been satisfactorily shown by Fourcroy and Vauquelin, to consist of the acetic and malic acids, combined with a portion of acid animal matter, to which it owes its peculiar taste and smell. It is extremely volatile and pungent, and is capable of being thrown out by the ant, when irritated, in considerable quantities. Roux, in the *Journal de Médecine* for 1762, reports a number of experiments which were made by exposing animals to its influence. Frogs were killed by the vapour from an ant's nest in less than five minutes: and persons breathing it, when of a certain intensity, were nearly suffocated, or were seized with fever, followed by an extensive cutaneous eruption, which terminated in desquamation of the cuticle.

Some of the most daring and courageous species, such as that which M. Huber calls the *Amazon-ant*, make it the business of their lives to attack the nests of the weaker species, and succeed, after a desperate conflict, in plundering them of their eggs and larvæ, which they convey to their own nests. These are hatched and reared by ants of the same species as themselves, who may be considered as auxiliaries to the Amazons, and who had themselves, at some former period, been kidnapped from their parent nest by the Amazons. Thus, a society is formed among different species of insects, to which no parallel exists but in the human race. The Amazons live without labour: they are attended, fed, and cherished by the ants which they have procured by this kind or slave trade, and who take as much care of their offspring, as they do of those of their own species. Perfect order is preserved, and the natural instinct of hostility, which in another condition of the society exists between the two tribes, seems in the auxiliaries completely extinguished, by their being educated with the race of their original oppressors.

Ants have numerous enemies among quadrupeds and birds; and some, as the ant-eater, dasypus, and manis, or pangolin, together with the tribe of woodpeckers, devour a very large proportion. The *Formica leonis*, or myrmelion, feeds almost wholly on these insects. The bees at the Cape, according to Mr Campbell, frequently drive out the ants from their nests, of which they take possession themselves. Ants are also infested by lice, which, as may well be imagined, are so minute as to be invisible without the assistance of a very high magnifying power. They are stated by Redi, who discovered them, to resemble in shape those of the fowl and the dove.

Mode of destroying Ants.

The most effectual mode of destroying ants is to pour boiling water into their nests, which destroys at once both the perfect insects, and their eggs and larvæ; so that those who, being from home, had escaped the general catastrophe, finding it impossible to repair the loss, abandon the spot, and disperse. The addition of urine, or of soot, or still better of tobacco, which may be infused in the water, will render it much more efficacious. A decoction of walnut-leaves, or lime-water, will also generally answer. The night is the best time for applying these remedies, as the ants are then all collected in the nest. Arsenic is exceedingly destructive to ants, and affords another ready mode of getting rid of those that intrude into cupboards or pantries; it may, for this purpose, be mixed with sugar, or kneaded with any kind of provision, and placed in the paths they are observed to frequent. Corrosive sublimate is also highly poisonous to them, and myriads of the sugar-ants at Grenada were destroyed by means of it; and it is stated to have had the effect of rendering the ants so outrageous that they destroyed each other, as could be seen by a magnifying-glass, and even, though less distinctly, by the naked eye. It appears also that this effect was produced even when they only came in contact with the poison. The whole island, however, was so overrun with these ants, that the numbers that could be destroyed by these means bore no sensible proportion to the whole; and recourse was had to fire as more applicable to destruction on a larger scale. It was observed that when wood, burnt to the state of charcoal, without flame, and immediately taken from the fire, was laid in their way, they crowded to it in such amazing numbers as soon to extinguish it, though thousands perished by so doing. Holes were therefore dug at proper distances in a cane-piece, and fire made in each of them. Prodigious quantities perished in this way; for those fires, when extinguished, appeared in the shape of mole-hills, from the numbers of dead that were heaped upon them. But as none of the females, or young brood, were destroyed by this ex-

Antrim.

pedient, the ants soon reappeared in as great numbers as before; and the island would probably have continued subject to this scourge, had it not been for the occurrence of the great hurricane of 1780, which at once cleared all the islands of this dreadful pest, by which the sugar-cane plantations had been threatened with total ruin. (w.)

Situation and Boundaries.

ANTRIM, a maritime County of Ireland, in the province of Ulster, situate in the northern extremity of the Island. It presents a considerable line of coast to the Northern Ocean, and to the Irish Channel. By the former it is bounded to the north, and by the latter to the east. Carrickfergus Bay, and the river Lagan, on the south-east, divide it from the County of Down as far to the south as Spencer's Bridge. To the south-west it has the same County, which, running to a point, meets Lough Neagh at Shanport. The winding shores of Lough Neagh and Lough Beg form its boundaries on the west, as far as the point where it meets the river Bann; whence this river, taking a northern course, inclining to the west, separates Antrim from Londonderry.

Extent and Divisions.

This County lies between 54° 26′, and 55° 12′ 16″ north latitude. Its greatest length from Bangorehead north, to Spencer's Bridge south, is about 56 English miles; and its greatest breadth, from the Gobbins east, to Island Reagh Toome west, about 30 miles. Its area comprises 972 square miles, or 622,059 English acres. It contains eight Baronies,—Dunbra, Carey, Killconeray, Glenarm, Toome, Antrim, Belfast, Massarene. All of these, except Killconeray and Carey, are subdivided into half Baronies, called upper and lower. There are also smaller divisions into Constablewicks and Town-lands. As nearly all the names of the Townlands are Irish, and expressive of the qualities of the land, or of some other local circumstance, it is probable that this subdivision is of very ancient date. Ploughlands were instituted in the reign of Philip and Mary, but this division is now quite laid aside. The number of parishes is seventy-seven. The chief towns in this County are Antrim, Belfast, Carrickfergus, Lisburn, Ballimena, and Ballimoney. It returns five members to Parliament, *viz.* two for the Shire, and one for each of the three principal towns, Belfast, Carrickfergus, and Lisburn. The assizes, elections, &c. are held at Carrickfergus, and the quarter-sessions at Antrim. The Bishopric of Connor comprehends the whole County, except the parish of Aghalee or Soldierstown, in the Barony of Massarene, which is in the Diocese of Dromore, and the parish or grange of Ballicullen, which belongs to the Diocese of Derry.

Face of the Country.

The interior of the County, on the eastern side, is mountainous, destitute of plantations, and abounding in bogs. This character also, in a great degree, applies to the northern side. The Baronies of Belfast and Massarene are the most level and fruitful. That remarkable range of basaltic pillars, called the Giant's Causeway, on the northern coast of Antrim, is described in the original work, under the head GIANT'S CAUSEWAY.

Mountains.

The principal mountains are Devis, near Belfast; Slenish, towards the middle; and Knocklayd, in the northern part of the County.

Minerals.

Besides basalt, limestone, gypsum, coals, fossil-wood, or woodcoal, sandstone, &c. are found. The fossil-wood, or woodcoal, in most places, is covered with columns of basalt, and is curious, as explanatory of the origin of coal. Notwithstanding the compressed state in which it is found, the bark and knots are quite distinct, and the rings, denoting the annual growth of the wood, may be counted. In some instances, the roots of the trees may be traced. Of the only two coal-mines which are wrought in the province of Ulster, there is one in Antrim, at Ballycastle. The coals are bituminous, and of a bad quality; a great part of them are exported.

Rivers.

The rivers of this County are very numerous, but in general small. The most considerable are the lower Bann, which discharges the waters of Lough Neagh into the sea; and the Lagan, which falls into the ocean near Belfast. Lough Neagh, belonging more properly to the County of Armagh, will be described under that article. It may be proper, however, to notice in this place, that of the two Islands in this expanse of water, Ram Island, from its contiguity to Antrim, is considered as belonging to that County.

Rathlin Island.

Rathlin Island lies off the northern coast of this County, opposite to Ballycastle. It is about five miles in length, and about three quarters of a mile in breadth. The number of its inhabitants is about 12,000. It is celebrated as having afforded a place of refuge to Robert Bruce.

Climate.

No regular and accurate accounts of the climate of Antrim have been kept, except at Belfast; and from these it appears, that less rain falls here than is generally supposed; the annual fall of rain, on an average of six complete years, being only 24.700 inches. The prevalent wind is the south-west. The greatest height of the barometer between the years 1796 and 1809, was 31 inches; the lowest 28 inches. The greatest height of the thermometer, during that period, was 78°.80; the lowest 25. The mean temperature of the northern coast of Antrim, near the town of Ballycastle, in latitude 55.12, as observed in the year 1788, by means of copious springs flowing from limestone soil, was 48°.

State of landed Property.

The estates in Antrim are in general freehold, being either immediate grants from the Crown, or held under those grants. The exceptions are the properties under the See of Connor. Some of the estates are very large. The Marquis of Hertford, and the Antrim family, possess the fee of the major part of the County. The former has 64,000 *green acres*, that is, land capable of tillage, independently of bog and mountain. Most of the Antrim estate is let on perpetuity, in farms worth L. 2000 or L. 3000 per annum. The other great proprietors are the Marquis of Donegal, Lord Templeton, and Lord O'Neil. The estate of Lord Templeton, however, is only leasehold under the Marquis of Donegal, who lets his land for 61 years and a life, but renews at the end of a few years for a fine. By a return to the House of Commons, 7th of February 1816, the number of persons who have registered freeholds in this county, between the 20th February 1807 and the 21st of February 1815, of the value of forty shillings, was 8074; of the value of L. 20, 152; and of the value of L. 50, 227.

Agriculture.

The farms in Antrim are in general very small;

Antrim.

the average of the rent of the *green land* is estimated at between 30s. and 25s. the Irish acre. The principal feature in the tillage system of a great part of Antrim, is the potatoe fallow. The small size of the farms, and, in some places, the rockiness of the soil, precludes the use of the ordinary means of culture, and therefore a part of the land is dug with the spade. The quantity of potatoe-land is regulated by the quantity of manure that can be collected. After potatoes, flax is sown, and the quantity of flax ground is regulated by the ability to purchase the seed. A crop of oats finishes the regular rotation. When the ground is exhausted, it is turned to rest, that is, it is suffered to lie till it is covered with natural grass. Such is the most general plan of husbandry pursued in Antrim. In those parts where the farms are too large for the spade culture, the land is ploughed by three or four neighbours uniting their strength; one supplying the plough, and the others bringing a horse, bullock, or even a milch cow. Wheat is a plant of very modern introduction in Antrim, and very little of it is sown. The quantity of seed sown to the Irish acre, varies from 224 to 171 lbs. avoirdupois; and the produce from 2272 to 2135. Bear or bigg is grown only in the colder and higher parts of the County; the seed used is 203 lbs.; the produce 3500. The quantity of barley used as seed varies from 203 to 209; and the produce from 2982 to 2646. Of oats, the seed varies from 333 to 291, and the produce from 3636 to 3227. Of potatoes, the seed varies from 2392 to 1383, and the produce from 22,248 to 15,183.

Flax.

The most important crop in Antrim is flax. The total number of acres supposed to be sown with flax in the year 1809, was 11,000; and the total number of bushels of flax-seed, supposed to have been saved out of the crops, was 3100. The annual average of flax-seed imported into Belfast is 5000 hogsheads, of about seven bushels each. The quantity of seed generally used for an acre is 30 gallons; the produce of seed averages 785 gallons: the average produce of flax is 30 stone per acre.

Live Stock.

The cattle in Antrim consist chiefly of milch cows belonging to small occupiers, of a small stunted breed. Sheep are very little attended to; and the few that are kept are of a very inferior kind. Goats are numerous in the mountainous parts of the County. Pigs also are kept in great numbers. During the salting season of 1811, not fewer than 70,000 pigs, weighing at least 200 lb. each, were brought to Belfast for exportation.

Trees.

This County by no means abounds with wood: nor are fruit-trees cultivated in great abundance, or with very much success. Of the apple, however, several new, and valuable varieties have lately been introduced, and advantageously cultivated.

Manufactures.

Antrim has long been distinguished for its linen manufacture; but latterly, the manufacture of cotton has, in some measure, supplanted it, especially in the vicinity of Belfast. In the year 1800, about 23 years after the introduction of the cotton manufacture, 13,500 people were *directly* employed in it; and including all manner of persons occupied in it in various ways, the number was 27,000, within a circuit of 10 miles; comprehending, however, the towns of Belfast, and Lisburn. The cotton yarn is chiefly brought from Scotland.

Linen Manufacture.

The linen manufacture, notwithstanding, is still the staple manufacture of Antrim. It is a peculiarity of this manufacture, as it is established in Ireland, that it does not remove the peasant from the comforts and healthiness of rural life. In Antrim, the weaver and the labourer of the soil are united in the same person. Many weavers have small farms, and only employ themselves in weaving during the intervals of their farming occupations; and almost all who pursue this trade, possess gardens, and ground for potatoes. Many of the houses have three looms, which cost from four to five guineas each: Children are hired to attend a loom at from 13s. to 17s. the half year, with diet, washing, and lodging: they bring a weaver eight guineas per annum. A good weaver will gain 10s. per web, and if he worked every day, he could weave a web in a week. A loom will employ four spinners, who are all females, and will spin five hanks in a week, the price of which is 2s. 8½d.

Food of the Peasantry.

The consumption of food per week, by a manufacturing family, consisting of six persons, in this County, is 3½ bushels of potatoes; 14 herrings; 9 quarts of butter milk; and one pound of salt: the cost of which may be estimated at five shillings. The expence of a family, consisting of the same number of persons, the head of which works at agricultural labours, will be 7s. 6d. per week, as he occasionally uses meat, milk, and pork.

Salmon-Fishing.

There is a considerable salmon-fishing on the coast of Antrim, at a place called Carrick-a-rede. This place is separated from the mainland by a chasm 60 feet in width, over which, every year, at the commencement of the fishery, a bridge formed of two strong cables, and a number of boards, is thrown.

Antiquities.

The antiquities of this County consist of cairns, cromlechs, mounts, forts, ecclesiastical and military remains, round towers, &c. There are three round towers, viz. one near the town of Antrim; one at Ardmoy; and one in Ram Island, in Lough Neagh. A few years ago, a double patera of gold, weighing 19 ounces, 10 dwts. was found in this County.

Population.

The number of houses in the County of Antrim, in the year 1777, was 22,184; of which 20,519 paid for one hearth; 3667 for two or more; 1066 were newly inhabited; and 3002 belonged to paupers. In the year 1788 the number of houses was 28,254, and the population was estimated at 160,000. At this rate there were about 13 acres to a house, and about 48 persons on the square mile. In the year 1791, the number of houses was 30,314, of which 22,353 paid for one hearth, and 3746 were inhabited by paupers. The number of men returned, in the year 1810, between the ages of 16 and 45, fit to serve in the militia, was 24,425. Mr Dubourdieu, in his *Statistical Survey of Antrim*, estimates the present population at 240,000.

Antrim is supposed to contain a greater proportion of Protestants than any other County in Ireland; and of the Protestants a very great majority is Presbyterian; being connected with the General Synod of Ulster, or with the Burghers and Antiburghers of the Church of Scotland. This arises from the Scotch

extraction of the greater part of the inhabitants of this County. The Catholics principally occupy the mountainous districts. No person of this persuasion possesses landed property.—See Beaufort's *Memoir of a Map of Ireland;* Wakefield's *Account of Ireland, Statistical and Political;* Newenham *on the Population, &c. of Ireland;* and *Statistical Survey of the County of Antrim,* drawn up by the direction of the Dublin Society, by the Reverend John Dubourdieu. (c.)

ANVIL, in Smithery, and other manufactures of the malleable metals, is an instrument on which substances are laid for the purpose of being hammered.

For some purposes, anvils are made of cast-iron; but, when the face of the anvil is required to possess great hardness, or a bright surface, it is made of wrought-iron, and faced with steel. The core or body of wrought-iron anvils is prepared at the forge, where malleable iron is first formed into bars, or into masses for any particular purpose. The body of the anvil is formed by welding a number of smaller masses together under the forge-hammer. These are rude blocks of different sizes, according to the size of the anvil. Smaller masses are also furnished in this way, which the anvil-maker occasionally welds to the large blocks, for giving to the anvil any particular form.

The fire-place or hearth of the anvil-maker's forge is similar to the common smith's forge. His bellows are not double, like the latter. His fuel is cork, which produces a great heat, without much flame. Adjacent to the hearth is a crane, which, turning upon a pivot, brings the heated masses of iron from the fire to the anvil. The latter is a large mass of cast metal, about eighteen inches square on the face, and about a foot from the ground. When the core of the anvil to be formed is heated, the first thing is to make three square holes, one in the bottom, and one at each end of the anvil. These holes are about 1¼ inch long, 1 inch broad, and about 2 inches deep. They are for the purpose of receiving a bar of iron, which is connected with the crane by which the anvil is held in the fire, and by which it is turned and guided while forming with the hammers.

The common smith's anvil is generally made of seven pieces, namely, the core or body; the four corners, for the purpose of enlarging its base; the projecting end, which contains a square hole, for the reception of a set, or chisel, to cut off pieces of iron; and the seventh piece is the beak, or conical end, used for turning pieces of iron into a circular form, welding hoops, &c. These pieces are each separately welded to the core, and hammered so as to form a regular surface with the whole. When large pieces are required to be welded to the core, one fire is not sufficient to heat both at the same time. In this case two hearths are employed. The core and the piece are both raised to a welding heat. The piece being put into its place, is hammered by a quick succession of blows, till it adheres. The whole is again heated and hammered till the due form is obtained. The hammering is performed by a number of men at the same time, each using a large swing-hammer. The blows follow each other in regular succession; great experience and care being required to prevent the hammers from coming in contact with each other.

When the anvil has received its due form, it now requires to be faced with steel. This is performed by first preparing the steel face to the size of the anvil. The anvil is then heated to a strong welding heat in one fire, while the steel facing is heated in another, but not so hot as the iron. The anvil is now brought out, and placed in a proper position, and the facing is brought to it. The surfaces, which are to be brought together, are brushed, and the facing is then laid on, and hammered as rapidly as possible, till it is closely united. The whole is finished by repeated heating and hammering.

The next process is that of hardening the anvil. This consists in heating the face, in particular, to a full red heat, and quenching it in cold water. When a stream of water can be employed it is better. Where this cannot be had, the mass of water should be great, and the anvil moved about as quick as possible. The facing should be laid on as thin as it can be firmly welded. When it is too thick it is apt to crack in the hardening.

After hardening, the face is ground till it is perfectly even, and the edges made sharp, or round, as may be required. When the anvil is required for planishing metals, it is polished with emery, and afterwards with crocus.

The smith's anvil is generally placed loose upon a wooden block, the root-end of an oak tree being preferred. The anvils used in cutlery, and for files, are fastened into a large block of stone, which is doubtless better than having the anvil loose upon a small block. The more firmly the anvil is connected with the earth, and the substance it stands upon, the greater will be the effect of the blow of the hammer. (T.)

ANVILLE (JEAN BAPTISTE BOURGUIGNON D'), a French Geographer of the highest eminence, and perhaps the most celebrated in modern times. He was born at Paris, on the 11th July 1697. His passion for geographical research displayed itself from his earliest years. At the age of 12, while reading the Latin authors at College, he amused himself with drawing maps of the countries which they described. While he was thus busily employing himself one day in the class, his master observed, and was about to punish him; but, upon casting his eye upon the performance, he immediately judged him to be rather deserving of encouragement. D'Anville from this time devoted himself entirely to geography, particularly that of the ancient world; and, at the age of 22, he began to delineate maps, which attracted the attention of the most eminent Geographers.

There are two modes by which problems in geography may be solved; one mathematically, by astronomical observation, or geometrical measurement; the other historically, by the distances of places inferred from the narrative of historians and travellers. The former is certainly the most satisfactory, and would supersede every other, could it be extended over the whole surface of the Globe. But, notwithstanding the splendid progress made since the era of D'Anville, it is still far from such a degree of per-

fection. In all countries, the bulk of the positions must be filled up, and, in some, the whole must be constructed, from mere historical materials. Perhaps there is no department of science, which requires greater extent of knowledge, and accuracy of judgment. The variety of sources, out of which the materials must be drawn, is almost infinite; and their application is equally nice and difficult. It must be regulated by a complete acquaintance with all the modes of measurement used by all nations; by a careful notice of those errors and contradictions which naturally arise from a partial and limited observation; and by the marking of certain delicate processes in the human mind, by which space and distance are sometimes diminished, and more frequently exaggerated. In the skilful Geographer, sound natural judgment, enlightened by experience, creates, as it were, a new sense, which enables him to see consistency amid a labyrinth of contradictions, and to elicit truth from a multitude of statements that are all erroneous. This art may be said to have originated with D'Anville, and to have been brought by him to its highest perfection.

The course of study on which D'Anville entered was truly immense. Works professedly geographical formed the least part of it; those of all the ancient and modern historians, travellers, narrators of every description, were assiduously examined. He studied, but only for the sake of the occasional geographical lights which they afforded, the philosophers, orators, and poets; for it was remarked, that, in perusing these masterpieces of human genius, he was totally indifferent to every thing which did not tend to fix a geographical position. The object of this immense labour was to effect a complete reform in the science of geography; to banish the system of copying blindly from preceding maps, and never to fix a single position without a careful examination of all the authorities upon which it rested. By this process, he detected many and great errors in the works of his most celebrated predecessors; while his own accuracy was soon attested on all sides, by the travellers and mariners, who had taken his works as their guide. His principles led him also to another innovation, which was, that of omitting every name, for which there existed no sufficient authority. The public was at first amazed at seeing vast spaces, which had before been covered with Countries and Cities, suddenly reduced to a perfect blank; but they soon recognised, that this was the only accurate course, and that the defect lay in the science, not in the geographer.

D'Anville was at first employed in the humbler task of illustrating by maps the works of different travellers, such as Marchais, Charlevoix, Labat, and Duhalde. The question respecting the figure of the Earth coming to be much agitated, he published in 1735, and 1736, two treatises, with a view to illustrate it. But this attempt to solve a geometrical problem by historical materials, was eminently unsuccessful. Maupertuis having gone to measure a degree within the polar circle, the result was found directly opposite to our Geographer's prediction. This, however, was considered by the intelligent public, rather as fixing limits to his mode of investigation, than as implying any want of diligence and ability in its employment.

Any loss of reputation which this failure might occasion, was completely retrieved by his map of Italy, published in 1743. It was marked by a species of investigation, often employed by D'Anville with peculiar success. This consisted in the application of ancient materials to correct the existing geography. By the diligent study of the Latin authors, he was enabled to trace numerous errors which had crept into the delineation of this interesting country. A trigonometrical survey which Pope Benedict XIV. almost immediately after caused to be made in the Ecclesiastical States, confirmed, in a surprising degree, all these alterations. On this occasion, he first set the example, which cannot be too much applauded, of accompanying the map with a memoir, exhibiting a view of the data on which it had been constructed.

He now applied himself to ancient geography, always his favourite department, and the aspect of which, under his hands, was soon completely changed. He illustrated successively, by maps, all the countries known to the ancients, among which Egypt attracted his peculiar attention. To render these labours more extensively useful, he published in 1768, an *Abridgment of Ancient Geography.* His attention was finally turned to the middle ages, which were illustrated by his *States formed in Europe after the fall of the Western empire;* and by some other works equally learned. Entirely devoted to geographical inquiries, the appearance of his successive publications formed the only events by which his life was diversified. From causes which are not explained, he was late of being admitted into the Literary Societies. In 1754, at the age of sixty, he became a member of the Academy of Inscriptions and Belles Lettres, whose Transactions he enriched with many papers. In 1775, he received the only place in the Academy of Sciences which is allotted to geography; and in the same year he was appointed, without solicitation, first Geographer to the King. But these honours came too late to illustrate a life, which was now drawing to its utmost verge. His last employment consisted in arranging his collection of maps, plans, and geographical materials. It was the most extensive in Europe, and had been purchased by the King, who, however, left him the use of it during his life. This task performed, he sunk into a total imbecility, both of mind and body, which continued for two years, and ended only with his death in January 1782, when he had reached the great age of 85.

D'Anville, with the qualities which form the great Geographer, united all the essentials of an honourable and worthy character. The advancement of the science to which he had devoted himself, formed almost the sole passion of his life; and mingling little with society, he contracted peculiarities, which solitary study is but too apt to engender. He talked with little interest on any subject except geography. This topic necessarily led to that of his own discoveries, on which he was never weary of expatiating. He boasted without any reserve of the services which he had rendered to that science, using, not unfrequently, the expression of Augustus, "I found it of brick, and left it of gold." He, however, did full justice to the

D'Anville. merit of those who excelled in other branches of knowledge; and to such as furnished him with materials for his researches, his gratitude was unbounded.

We shall subjoin a list of the numerous memoirs and dissertations composed by D'Anville, of which some were published separately, and others in the Transactions of the Academies. The following were published separately:

1. Mémoire pour faire la carte du diocèse de Lizieux.
2. Mémoire pour la révision de cette carte.
3. Mémoire instructif pour dresser des cartes particulières, avec une carte *in-folio*.
4. Observations sur la carte du Paraguay, avec une carte d'une demi-feuille.
5. Proposition d'une mesure de la terre, avec une carte d'une demi-feuille.
6. Mesure conjecturale de la terre sur l'équateur, avec une carte d'une demi-feuille.
7. Réponse de M. d'Anville au mémoire contre cette mesure.
8. Lettre au P. Castel, sur le Kamtchatka, avec une carte d'un quart de feuille.
9. Article de la géographie, tiré de l'Histoire ancienne de Rollin.
10. Nomenclature alphabétique de l'Italie, tirée de l'Histoire Romaine de Rollin.
11. E'claircissemens sur l'ancienne Gaule, avec deux cartes de deux demi-feuilles.
12. Lettre à M. de la Roque, sur un lieu nommé anciennement *Chora*.
13. Mémoire pour dresser des cartes d'un canton renfermant dix ou douze paroisses.
14. Analyse de l'Italie, avec trois cartes de 4 feuilles *in-folio*.
15. Mémoire pour dresser une carte de la généralité de Soissons.
16. Dissertations sur l'ancienne Jérusalem, avec une carte de demi-feuille.
17. Lettres sur la carte de l'Amérique méridionale, avec une carte de 3 feuilles *in-folio*.
18. Eclaircissemens sur la carte de l'Inde, avec deux cartes de 5 feuilles *in-folio*.
19. Mémoire sur la carte du Canada, etc., avec une carte de 4 feuilles *in-folio*.
20. L'article Vents Etésiens, tiré de l' Encyclopédie.
21. Analyse de la carte des côtes de la Grèce, avec une carte *in-folio*.
22. Notice de l'ancienne Gaule, avec une carte *in-folio*.
23. Mémoires sur l'Egypte ancienne et moderne, avec 5 cartes, dont 2 *in-folio*.
24. Géographie ancienne abrégée, avec 9 cartes *in-folio*.

Apiary. Memoire pour corriger la latitude de la Mesopotamie, avec une carte.

We find from a *Notice* in the second volume of that useful Geographical Miscellany—the *Annals du Voyages*, &c. by Malte Brun,—that a complete edition of the works of D'Anville, containing all the memoirs and tracts above enumerated, had been announced for publication at Paris in 1808. The first volume was to be published in that year, and the work was to consist of 6 volumes 4to, with a Folio Atlas. (B.)

APIARY. Under the article BEE, in the *Encyclopædia*, directions have been given at considerable length as to the management of an apiary; and various methods are there detailed of procuring honey and wax from the hive, without destroying the bees themselves. The most economic mode of attaining these ends, deserves more attention as a national object, than it has in general received in this country. It appears, from the returns of the Custom-House, that England pays annually to the North of Germany from L.40,000 to L.50,000 Sterling, for the wax and honey which are imported from thence, and which might very easily be raised by a more extended and judicious cultivation of bees at home. Greater attention to this useful appendage to the Cottage, would not only be productive of commercial advantage, but would tend to improve the condition of the lower order of Peasantry. It is not generally known, indeed, what profitable returns may be obtained, at a trifling expence of time and labour, by very simple processes. Mr Huish, who has lately published a valuable practical treatise on the management of bees, has made a calculation, from which he infers, that even supposing the first cost of a swarm to be one guinea, which is the price in the places where they are sold the dearest, the Cottager is almost certain, by proper care and management, of clearing, in five years, a net produce of nearly L.60; and of having besides, at the end of that period, ten good stocks of bees in his garden.

The principal objects to be attained in the construction and management of an apiary, are to secure the prosperity and multiplication of the colonies;—to increase the amount of their productive labour;—and to obtain their products with facility, and with the least possible detriment to the stock. The apiary should afford to the bees the best shelter against moisture and the extremes of heat and of cold, and especially against sudden vicissitudes of temperature; it should protect them against their numerous enemies; it should afford them every facility of constructing their combs, and of rearing their young; it should allow of every part of the combs being occasionally inspected, and being capable of removal when requisite; and, while due attention is paid to economy, it should be made of materials that will ensure its durability. Much ingenuity has been displayed by different Apiarians in the construction of hives, which should unite in the greatest possible degree all these advantages. Although it be in vain to hope that every one of these objects can at once be perfectly attained; yet there is still great room for improvement on the hives that are at present in common use; and we shall point out, in this Supplementary article, such modes of construction as have been recommended since the publication of the article BEE, above referred to.

Apiary.

While some Cultivators of bees have been chiefly anxious to promote their multiplication, and to prevent the escape of the swarms in the natural way, by procuring what they have termed *artificial swarms*,—which they effected by separating a populous hive, previous to its swarming, into two parts, and allowing to each greater room for the extension of their works; others have contemplated only the abundance of the products which they yielded, and the facility of extracting them from the hive, without showing any particular solicitude as to the preservation of the bees themselves. Another class of Apiarians have, on the other hand, had it more particularly in view to facilitate the prosecution of researches in the natural history and economy of bees. The hive invented by Mr Huber is peculiarly calculated for the last of these objects, and its construction is founded on an accurate knowledge of the habits of these insects. He has given it the name of *Ruche en livre ou en feuillets*, from its opening and shutting somewhat in the manner of the leaves of a book. This *book* or *leaf hive* is composed of from eight to twelve square wooden frames, placed vertically, and joined together sideways like the hoops of a cask. Each frame consists of two uprights, one inch in thickness, a foot in height, and an inch and a third in width, connected by an upper and lower cross bar, ten inches long, and of the same breadth and thickness as the former; so that all the frames may be joined together, without leaving any interval. The two external frames are closed each by a pane of glass, which is covered by a shutter on the outside: and the whole is properly secured in its place, and further protected by an external cover. An aperture must of course be left in the lower part of one of the frames to serve as a door. In order to determine the bees to construct their combs in the plane of each leaf, a small piece of honey-comb is fixed, by means of pegs, to the top of each in the proper position; as it is well known, that bees always complete their work in the direction in which they find it begun, unless they meet with some insurmountable obstacle. A proper distance is thus preserved between the lateral surfaces of the perpendicular combs; and the external ones, being only three or four lines distant from the glass panes, may be easily inspected by opening the shutters: and also, by opening in succession the different divisions of the hive, both surfaces of every comb may at pleasure be fully brought into view. No difficulty is experienced in introducing swarms into hives of this construction; and after the lapse of a few days, when the colony is fully established, the bees will very patiently submit to be daily inspected.

Mr Huber's Hive.

Mr Huber's hive is exceedingly well calculated for producing artificial swarms on the principle of Sebirach's discovery, of which a full account will be given in the Article BEE in this Supplement. It allows us to judge by inspection, whether the population is sufficient to admit of division,—if the brood is of the proper age,—and if males exist, or are ready to be produced, for impregnating the young queen; all

Apiary.

which circumstances are of material consequence to the success of the operation. It is essential, that some of the larvæ should not have been hatched above three days before this attempt is made. The frames must then be gently separated at the middle of the hive, and two empty frames be introduced in the interval between the former; each of these new frames having a partition which closes them completely, so as to enable the two portions to be entirely separated without leaving any opening. The door of that portion, in which the queen happens to be at this time, may remain open; but the one belonging to the other part must be closed, so as to retain the bees that have no queen, prisoners for four-and-twenty hours, allowing still, however, sufficient circulation of air. After this interval of time, they appear to have forgotten their queen; at least they are no longer anxious to seek for her, but bestow all their solicitude in the education of the larvæ, so as to convert a certain number of them into queens to supply the loss they have sustained. This they accomplish in ten days or a fortnight after the operation. The two colonies are now perfectly distinct, and are never found afterwards to intermix.

Another advantage attending a hive of this construction consists in its enabling us to force the bees to produce a much greater quantity of wax than they would naturally do. The interval which separates the combs, when the bees have not been disturbed in their operations, is constantly the same, namely, about four times. Were they too distant, it is evident that the bees would be much dispersed, and unable to communicate their heat reciprocally, and the brood would not be preserved in a sufficient degree of warmth. Were the combs too close, on the contrary, the bees could not freely traverse the intervals, and the work of the hive would suffer. It is evident that we may avail ourselves of this instinct, and by separating farther asunder the combs that are already built, induce the bees either to extend the breadth of those they had begun, or to build others in the interval, if sufficient space be allowed them for this purpose. Thus, by interposing three empty frames, one between every alternate interval of the combs in a hive containing six combs, three additional combs, if the proper season be chosen, will be obtained at the end of a week; and if the weather continue favourable, the operation may be repeated, and the same number of additional combs procured the week after.

The principal obstacles to the general employment of M. Huber's hives are the expence of constructing them, and the greater degree of attention which they perhaps require from the Cultivator. It has also been objected that the flatness of the roof was prejudicial, by allowing the moisture which exhales from the bees to collect at the top, and to fall in drops at different parts, to the great injury of the subjacent contents of the hive. Féburier proposes therefore the employment of frames in the form of a trapezium, so that the roof shall be considerably inclined to the horizon. He borrows this shape from Bosc, whose hive consists, however, only of two boxes joined together sideways, and separable in order to form artificial swarms. This was an improvement upon Gelieu's hive, which was formed of two square boxes united laterally. Delator had recommended a still more simple form than that of Bosc, though less convenient, namely, that of a triangle resting on its base. Mr Ravenel's hive consists of three square boxes instead of two; Mr Scrain's is also made up of three boxes; but they are low and of great length, and are joined endwise: a communication being established between them by apertures made in the divisions which separate the boxes. It is now, however, well established, that partitions of any kind are detrimental to the prosperity of the colony. The same objection applies, though perhaps in an inferior degree, to the system of storied hives, or those which are divided into stories one above another. A great variety of the latter description, however, have been recommended by different Cultivators. In France they are known by the name of *ruches en hausses*. Mr Thorley's improved hive, of which there is an account in the article Bee, is of this class, and Mr Lombard's *ruche villageoise* may also be referred to the same head, although it be of much simpler construction than any other compound hive. Mr Lombard's hive is composed of two parts, a body, and a cover, forming together an elevation of from seventeen to twenty inches, on a uniform diameter of one foot; excepting the upper part, which ought to be convex. The body is formed of bands of straw, similar to that of the cottages in this country. At the top and bottom of the body is placed an exterior band, which forms a projecting border, on each end; the lower one giving the hive a firm station on its pedestal; the upper one contributing to secure the attachment of the cover, or allowing of another similar body being placed above the first, if such an addition should be deemed necessary. At the top of the body, and even with the upper band, is placed a flooring board, made of a light plank, ten inches in breadth in all directions; and the four corners of which are sawed off in such a manner that the breadth along the diagonal measures one foot. This board is fixed by nails inserted in the upper double band, and entering a little into the front. The four openings that are left on the sides are necessary for the passage of the bees, and for the escape of the vapours which are exhaled from them in winter. A flat rod traverses the hive immediately under the board; and projecting from the two sides about an inch and a half, affords handles for lifting the hive, and facilitates the fastening of the cover, which has also a projecting rod, corresponding with that of the hive. At the bottom is an opening, two inches broad, and nine lines in height, for the ingress and egress of the bees. The cover is formed in the shape of a dome, with a vertical handle at the top, and a cross bar at the lower part, by the projecting ends of which it may be tied to the ends of the bar in the body; and which serves also as a support to the combs that are constructed in the cover. For the latter purpose, also, two other bars are placed crosswise, one above the other. All the hives, and all the bases of the covers, are to be made of one uniform diameter, in order that

Hives of other Apiarians.

the hives may, if occasion require it, be placed upon each other, and the covers be adapted to any of the hives that may happen to be at the top.

The *pyramidal hive* of M. Ducouédie, which the inventor extols in his book, entitled, *La Ruche Pyramidale, avec l'art d'établir et d'utiliser les ruches,* &c. as leaving nothing more to be wished for as to the cultivation of bees, differs but little from that of Mr Thorley. A common straw hive is taken, containing a swarm, which is allowed to remain till the spring of the following year; it is then placed on the top of a square box, with which it is made to communicate by a round aperture at the top of the box. In this state, it is termed by the French *la ruche Ecossaise*, or, *ruche de M. de la Bourdonnaye*. On the following spring, a second box is placed under the first, and the whole now assumes the name of *la ruche pyramidale*. The bees are still allowed no other ingress or egress, but by a single hole made in the lowest story. The upper stories may then be removed in succession, while further room is allowed below by the addition of fresh boxes. It is stated by M. Ducouédie, that the bees in his pyramidal hive never perish by hunger or by cold; for they always abound in provisions, and are too numerous to be affected by the most rigorous winter. When the bees are in groupes, they maintain the necessary warmth in the hive, and the brood, on the return of spring, is hatched one month sooner than in any other hive. Mr Huish has, however, made it clearly appear, that these pretended advantages are much exaggerated, while its inconveniences are passed over in silence. It is difficult, if not impossible, to proportion the hives in all cases to the magnitude of the swarms, or to the energy with which they labour. The honey being taken from the oldest cells, is deteriorated by an admixture of pollen, communicating to it a degree of bitterness, of which it is difficult to deprive it; and is less abundant in consequence of the diminished capacity of the cells, in which the coccoons of successive bees in their state of nympha have accumulated. From their being divided into different stories, the bees are obliged to live, as it were, in different families; while their own preservation, and that of the brood, requires them to live in the strictest union. The heat is also lessened by the division of the bees into different groupes. The upper part of these hives, being all necessarily flat (except the first or straw hive), occasions a serious inconvenience, by allowing moisture to collect and drop down into the middle of the hive, instead of trickling down the sides. The injury which this does to the combs, and to the bees themselves, who are constantly exposed to its influence, is, according to Mr Huish, the most common cause of the loss of the hives during the winter. The bees, he observes, always begin their work in the most elevated point of the hive, and seek for that purpose the central part of the roof. If the top be flat, and especially if it be as spacious as in the hives called pyramidal, the bees will not find this centre; they will work one year in one part, and the following year in another. This is, without doubt, one of the causes which obliges a proprietor to wait three or four years before any honey can be gathered from these hives.

The hive recommended by Mr Huish, as affording sufficient facility for examining any of the combs, and performing on them any operation at pleasure, is very similar in form to that described in the *Encyclopædia* (See Bee) as being used in Greece; and of which a figure has been given. The body of the hive is a straw basket in the shape of a flower-pot, that is, of a broader diameter above than below. Eight pieces of well seasoned wood, about eight inches broad, and half an inch thick, are laid parallel to one another, at equal distances, over the top of the basket, and fastened to an outer projecting band: they are then covered with net-work, over which is placed a circular board, or what is better, a convex cover of straw extending over the whole of the top of the hive. This net-work obliges the bees to fasten their combs to the transverse boards; by means of which, each comb can easily be lifted up, without interfering with any other part of the hive, or occasioning the loss of a single bee; and the whole of the interior of the hive is thus open to inspection, and we are enabled to trace the devastations of the moth, or to ascertain the presence of any other enemy.—See the article Bee in this Supplement. (w.)

APPRENTICE. The nature and object of the engagement contracted between the apprentice and his master, has been sufficiently explained in the body of this work. As, however, numerous laws have been passed, particularly in England, for the purpose, not only of guaranteeing the performance of this contract, but of regulating also the terms upon which it should be entered into by the respective parties, and of defining the relative duties of each, it will be necessary shortly to state the most important of these regulations.

In that country, the 5th Eliz. continued for a long period to be the leading statute on this subject; but its regulations were at length found to be fraught with such numerous inconveniences, and to be so ill adapted to the present improved state of the mechanical trades, that, by the 54th Geo. III. several of its most material provisions were repealed. By the 5th Eliz. it was required, in order to give validity to the contract of apprenticeship, that the apprentice should be bound by a regular deed; and, by the custom of some places, it was necessary that the deed or indenture should be enrolled. In London the custom is, that all indentures be enrolled, within a year, before the Chamberlain; and, if this form shall have been neglected, it is enacted that a writ of *scire facias* shall issue upon the petition of the Mayor and Aldermen, to show cause why it was not enrolled. If it shall be found that this omission proceeded from the fault of the master, the apprentice may sue out his indentures, and be discharged; and, if otherwise, the contract ceases to be binding on the master. The 5th Eliz. c. 4, § 25, also provided, that no apprenticeship could be constituted except by indenture; and it was found, that, under a different instrument, a master could not maintain an action against a person for enticing away and detaining his apprentice. The same act provided, that no agreement to execute indentures of apprenticeship should constitute a suffi-

Apprentice. cient binding, although a service of seven years might have been duly performed under it. To give validity to the indenture, it was not only necessary to comply strictly with the provisions of the 5th Eliz.; but every person who engaged apprentices against the terms of that act, was made liable to a penalty of L. 10.

By the common law, every person is left at liberty to follow whatever trade or employment may be agreeable to him. But, as it was supposed that great injury would result to the public if unqualified persons were to exercise the various crafts and mysteries connected with the mechanical trades, it was specially provided, by the 5th Eliz., that no person should exercise any art or craft, unless he had previously qualified himself for it by a regular apprenticeship, under a penalty of L. 400 for every month. Considerable doubts were always entertained as to the trades to which this statute applied; and, as the Courts of law do not seem generally to have favoured the principle of the statute, their decisions tended rather to confine than to extend the restriction. It was at length agreed that the law was only applicable to such trades as existed at the time of passing the act, and to such, also, as implied some mystery or craft. The operations of the statute was also held to be limited to market-towns; it being supposed necessary for the convenience of the inhabitants of country villages, that the same person should exercise different trades, even though he had not been regularly bred by a seven years' apprenticeship to each. These various limitations of the statute gave rise to many very absurd distinctions, which plainly shewed how very unsuitable this antiquated law was to the present advanced state of the mechanical trades. It was found, for example, that a coachmaker could neither himself make, nor employ journeymen to make his coach-wheels, but that he behoved to buy them of a master wheelwright, this last trade having been exercised in England before the 5th Eliz. But a wheelwright, though he has never served an apprenticeship to a coachmaker, might either himself make, or employ journeymen, to make coaches, the trade of a coachmaker not having been prohibited by the statute, as not being exercised in England at the time it was passed. All the great manufactures which, in modern times, have arisen throughout England, in Manchester, Birmingham, Sheffield, Wolverhampton, were, on this account, exempted from the restrictive operation of this law, and the perfection to which they have arrived, seems a practical proof of its inutility for the encouragement of trade.

The effects of those restrictions imposed by the 5th Eliz. were at length felt to be so injurious, that, in the year 1813, petitions were presented to Parliament, from various manufacturing towns, for a repeal of certain parts of this exceptionable statute; and the 54th Geo. III. was accordingly passed, by which all the penalties and prohibitions imposed by the 5th Eliz. on those who should exercise any trade or mystery, unless qualified by six or seven years' apprenticeship, were repealed. That part of the statute was also repealed, which enacted that no person should become an apprentice except in strict conformity to the provisions of the 5th Eliz., and which rendered all indentures contrary to this act null and void. In opposition to this, it was provided, that all indentures, or covenants, which would otherwise be valid, should now be valid, anything in the 5th Eliz. to the contrary notwithstanding.

Apprentice.

In the incorporated trades, bye-laws have generally been enacted, for the purpose of restraining each master to a certain number of apprentices, and those bye-laws have, in many cases, been confirmed by the public laws of the kingdom. In Sheffield, it is a standing rule in the corporation of cutlers, that no master cutler can have more than one apprentice at a time. In Norfolk and Norwich, no master weaver can have more than two apprentices, under a penalty of paying L. 5 per month to the King. The 5th Eliz. c. 4, § 33, enumerates various trades in which the master is obliged, under a penalty of L.10, to keep one journeyman for every three apprentices. No master hatter can have more than two apprentices anywhere in England, or in the English plantations, under a penalty of L. 5 per month. Most of these statutes, however, are now so ill adapted to the state of trade and manufactures, that in practice they are very generally evaded.

The engagement contracted between the master and apprentice is entirely of a personal nature, arising from the confidence they mutually place in each other; the master engaging to instruct the apprentice in his business, and to take care of his health and morals, while the latter engages, in like manner, for a return of faithful and diligent service. The transaction thus rests on the personal qualities of the two parties, and indentures are, therefore, not transferable to third persons. By the death of the master the contract is annulled, and a new engagement, with another master, can only be entered into by the consent of the apprentice. A different custom, however, prevails in London, where one freeman can transfer his apprentices to another freeman, without any injury to the original engagement. Where the maintenance of an apprentice forms one of the conditions of his service, the death of the master does not dissolve this obligation, his executors being bound to discharge it in so far as it can be done out of the effects left by the deceased. By the 32d Geo. III. (c. 57, § 5,) parish apprentices may, with the consent of two justices, be assigned over, by indorsement of their indentures, to third parties; and the person declaring his acceptance of the assignment, shall be bound to perform all the duties of a master to the apprentice, for the residue of his term. Where the master of a parish apprentice dies, upon whose binding no larger a sum than L. 5 has been paid, it is provided, that the covenant for maintenance of the apprentice shall not remain longer in force than three months.

A master is entitled by law to use moderate chastisement in the event of any misbehaviour on the part of the apprentice. But he has no right to treat him with any unnecessary harshness; and in that case, by the 20th Geo. II. c. 19, § 3, he may, on the complaint of any parish apprentice, or of any other apprentice, on whose binding there is no larger a sum than L. 5, be summoned before any two justices, and,

Apprentice. on proof of the alleged facts, the apprentice may be discharged by a certificate under the hands of the justices. In like manner, by § 4, on the complaint of the master on oath, of misbehaviour on the part of the apprentice, he may be summoned before the two justices, who may commit him to the house of correction to hard labour for any time, not exceeding a kalendar month, or they may, as in the former case, sign a certificate for his discharge. By § 5, either party has the privilege of an appeal to the next Quarter Sessions. If an apprentice, with whom a premium under L. 10 has been paid, shall absent himself from his master's service, it is provided, by the 6th Geo. III. c. 25, that he shall either serve for so long a time beyond the period of his service, or make any other suitable satisfaction to his master for the loss of his labour. In case of his refusal, he may be apprehended, and brought before a justice, who may determine the satisfaction that shall be made; and, on his refusal to comply with this determination, he may be committed to the house of correction for three months. The master may make application for compensation within seven years after the expiration of the term of apprenticeship. Either party may appeal against the decision of the justices to the Quarter Sessions.

By the common law, minors may bind themselves out as apprentices, and if they serve out their regular term, they are entitled to all the privileges of apprentices. But no minor can contract such an obligation as will entitle the master to maintain an action against him, provided he either departs from his service, or commits any other breach of his engagement. He may indeed correct him in his service, or complain to a Justice of the Peace to have him pursued according to the 5th Eliz. But no remedy lies against a minor for breach of any such covenant. The children of paupers may, however, be apprenticed out by the overseers, with consent of two Justices, and in this case (5th Eliz. c. 4; 43d Eliz. c. 2. Cro. Car. 179.), the indenture is obligatory, though the apprentice be under age. In consequence of the incapacity of the minor to enter into any regular contract of apprenticeship, the usual practice is to procure some of his friends to become surety for his due performance of the engagement into which he enters. According to the custom of London, a minor above the age of fourteen, may bind himself apprentice to a freeman in London by indenture, with proper covenants, and these covenants are in law equally binding as if he were of full age.

Indentures were formerly subject to a variety of duties which were imposed by successive acts, and these duties necessarily gave rise to a series of intricate enactments, which frequently occasioned much perplexity and inconvenience. By the 44th Geo. III. c. 98, § 8, all those numerous duties were consolidated into one simple duty on the stamp, which varies from 14 shillings to 19 guineas, according to the premium which is paid with the apprentice. By the 43d Geo. III. c. 161, an annual duty is imposed of L. 1, 1s. on every apprentice who pays a premium above L. 20.—See Jacob's *Law Dictionary*.—Smith's *Wealth of Nations*, with Notes, and an additional volume of Dissertations, by David Buchanan. (O.)

Apprenticeship. APPRENTICESHIP. The *Encyclopædia* contains an account of the rules by which apprenticeships are regulated in different countries, together with a view of the objections urged by Dr Smith, against the utility of the engagement concluded between the apprentice and his master.

Dr Smith considers the institution of apprenticeships as a device, by which trading corporations endeavour to confine to as few hands as possible the mystery of their craft, and by which, keeping the market always understocked with their particular sort of labour, they expect to regulate according to their discretion the price of such manufactures as they bring to market. He accordingly condemns all those laws which limit the number of apprentices, to be taken by each master in particular trades, or which prescribe to apprentices a certain term of service before they are permitted to work as journeymen. The tendency of such laws, he observes, is to restrain the competition to a much smaller number than might otherwise be disposed to enter into the trade; the limitations of the number of apprentices restraining it *directly*, and a long apprenticeship restraining it *indirectly*, but as effectually, by increasing the expence of education. Long apprenticeships, or indeed any apprenticeship, for however short a term, Dr Smith considers quite unnecessary, as the nicest mechanical arts, such as the making of clocks and watches, contain, according to his theory, no such mystery as to require a long course of instruction. A few weeks, he calculates, or even a few days, would be sufficient to enable a mechanic to set to work in any of those trades; and if he were paid the full price for his work, he paying of course for such materials as he might spoil through awkwardness and inexperience, he imagines that he would learn his business more effectually, and be more apt to acquire habits of attention and industry, than when he works under a master who has a right to share in the produce of his labour.

It may be generally remarked, however, that, in his reasonings on these subjects, Dr Smith seems uniformly disposed to overrate the practical effect of those expedients by which corporations have been always endeavouring to secure special advantages for particular trades; and that his theory respecting apprenticeships is only a part of that more general theory, by which he endeavours to show that the policy of Europe has always been to encourage the industry of the towns at the expence of that of the country; and that the effect of this policy has been to enable the merchants and manufacturers of the town, in bartering their produce for that of the country, to levy, for several centuries, an unjust and oppressive tax on the agricultural classes of the community. We know, however, that, according to the nature of human society, as it is so admirably explained in Dr Smith's work, monopoly can never succeed on so great a scale; and, on the same principle, we may rationally question if the contract between the apprentice and his master were merely the device of corporations, whether it ever could have come into such universal use throughout Europe. The engagement by which the apprentice is bound to his master, is his own voluntary act. He agrees to bind himself to work to his master at an inferior rate, on condition

Apprenticeship.

of receiving from his master the necessary instruction in his business. This instruction, Dr Smith asserts, may be given him in the course of a few days or weeks. It is well known, however, to every practical tradesman, or to any one acquainted with the nature of mechanical employments, that the instruction of three days or weeks would scarcely teach an apprentice the name of his tools, and that almost all the mechanical trades require, throughout their various operations, such nicety and exactness, that the necessary habits are not formed by the training of years, in place of weeks or days. It is for the troublesome superintendence of the apprentice during this period that the master exacts compensation, without which he would employ none but finished workmen. But he puts up with the awkwardness of his apprentice, because he expects to be benefited by his labour after he shall be better instructed in his business; on the same principle that the farmer lays out his capital on the improvement of his land, in expectation of a future increase of produce. The contract of apprenticeship is thus a voluntary agreement between two parties for their mutual benefit, the result neither of law nor of the usages of petty corporations, but of circumstances. The law, indeed, takes cognizance of the contract, and enforces its fulfilment; and it may also have encumbered it with absurd regulations. But the contract itself stands independent both of law and usage, having its origin in the plainest principles of reciprocal expediency. There seems no reason therefore to class it with those artificial expedients which originate in the exclusive spirit of trading corporations.

Dr Smith appears also to have greatly overrated the effects of those laws, the object of which is to limit the number of apprentices which shall be reared to particular trades. No law of any corporation will ever be found in practice to impose any limitation on the number of apprentices which will be trained to a business. It will depend on the state of the business, whether it is advancing, stationary, or declining, what number of apprentices will be bred to it; and if, while a flourishing trade called for a continual supply of new hands, any corporation were to enact a law, limiting the masters to such a number of apprentices as would barely keep up their present stock, a scarcity of hands would soon be felt, wages would rise, and the masters would soon be induced, by regard to their own interest, to rescind the law which imposed so great an inconvenience on themselves. But if the law is thus modified and accommodated to the state of the trade, it is a mere form. It imposes in reality no restraint, since it is always in the power of the masters to alter it whenever they feel that it interferes with their arrangements.

But though the law were even rigidly persisted in, it is evident that it would not permanently diminish the number of apprentices, which would be bred to a business, since the consequence would be, that the workmen would turn masters, and each taking the full allowance of apprentices which the law permits, would soon train up an ample supply of hands. All those petty contrivances of corporations, therefore, though they may originate in the lowest mercantile jealousy, and though they may be exceedingly absurd, cannot materially disturb the general progress of things; and, though they may harass individuals, their effect on the industry of a great country hardly deserves notice; their bad effects being corrected by those general causes on which society depends for completing its arrangements, in spite of the obstacles arising from the mistaken policy of legislators.—See Smith's *Wealth of Nations*, with Notes, and an additional volume of Dissertations, by David Buchanan. (o.)

Aqua Tofana.

AQUA TOFANA, called also *Aqua della Toffanina*, or *Aqua della Tofa*, from its supposed inventress,—*Aqua del petesino*,*—*Aquetta di Napoli*, or simply *Aquetta*,—a poisonous liquor which was used to a very great extent at Naples and Rome during the latter half of the seventeenth century. Gmelin † says, that more people were destroyed by it than by the plague, which had prevailed a short time before it came into use; and Garelli, chief physician to the Emperor, wrote to Hoffmann that Tofania confessed she had used it to poison more than six hundred persons. This he learnt from the Emperor himself, to whom the whole criminal process instituted against her was transmitted.‡

It is to be regretted, that Garelli, who had such an authentic source of information, has not given us some details of the infamous Tofana or Tofania; as the little that we know of her rests upon the authority of travellers, and is evidently exaggerated, and sometimes irreconcilable with established facts. She was a Sicilian by birth, and resided first at Palermo, and then at Naples. When she began to exercise her horrible profession, is nowhere stated; but it will presently appear, that it must have been at a very early age, and before 1659. She was extremely liberal of her preparation, chiefly it is said, to ladies tired of their husbands; and the better to conceal the nature of her gift, it was put up in small flat phials, inscribed *Manna of St Nicholas of Bari*, ornamented on one side with an image of the Saint, that it might pass for a liquid said to drop from his tomb at Bari, which was in great request on account of the medicinal virtues ascribed to it. Nor is it ascertained how long she carried on her murderous practices with impunity and undiscovered. Labat § says, that when he was at Civita Vecchia in 1709, the Viceroy of Naples, then Count Daun, made the discovery. It was long before she was secured, as she was extremely cautious, and often changed her abode or retired into Convents. At last she was betrayed, and, although in a Convent, was seized and carried to the *Castel del Uovo*, where she was examined. Cardinal Pignatelli, then Archbishop of Naples, indignant at the violation of a religious sanctuary, threatened to excommunicate

Aqua Tofana.

the whole city, if she was not delivered up to him, and the people were ready to rise. But the sagacious Viceroy caused a report to be spread, that she and her accomplices had determined upon the same day, to poison all the springs in the city, the fruits brought to market, and the public granaries. The manœuvre succeeded. The credulous people were now clamorous for her punishment, and saw with satisfaction the persons whom she accused of having purchased her *Aquetta*, taken from the Churches and Monasteries. Some of inferior birth were executed publicly; those of higher rank secretly in prison; and the whole city resounded with the praises of the Viceroy, whose energy had saved it from general destruction. A kind of compromise was entered into with the Cardinal; in consequence of which, after being strangled, her body was thrown at night into the court of the Convent, by way of testifying some respect for the rights of the Church. But the reverend traveller must have either been misinformed as to the actual execution of this Medea, or she must have been resuscitated; for Garelli expressly says that she was alive in prison at Naples, when he wrote to Hoffmann, not long before 1718; and Keysler, who visited Naples in 1730, * likewise asserts, that she was then living in prison, and that few strangers left the city without going to see her. He describes her as a little and very old woman.

The Roman ladies very quickly availed themselves of Tofania's dicovery; for it was remarked in 1659, that many husbands died when they became disagreeable to their wives; and several of the clergy also gave information, that, for some time past, various persons had confessed themselves guilty of poisoning. This led to the detection of a society of young married women (who had, for their president, an old woman of the name of *Hieronyma Spara*, a pretended fortune-teller), as the perpetrators of these murders. On being put to the torture they all confessed except Spara, who seemed to rely upon the protection of powerful individuals whom she had formerly served. But she was left to her fate, and was hanged along with her assistant, one *Gratiosa*. Others were afterwards hanged, or whipt and banished. Spara, who was a Sicilian, had acquired her knowledge from Tofania at Palermo. †

Pope Alexander VII., immediately on the discovery and punishment of those who dealt in poison in his capital, published an edict forbidding the distillation of aquafortis, or the purchase of any of its ingredients, without the permission of the Government; which Gmelin considers as an artifice to mislead the people as to the real composition of the poison, or as originating in the absurd nomenclature of the Chemists of former times, who called arsenic, concrete aquafortis. But the prudence of the Pope was rendered fruitless; for we are informed by Gayot di Pitaval (*Causes Celèbres*, Vol. I. Amsterd. 1764, p. 317.), on what authority he does not state, that Tofania's fatal secret was disclosed by the indiscretion of the judges at Naples, to whom she had made confession of her crime. The whole city soon knew that she employed in its composition a very common herb, and that its preparation was otherwise easy; and in this way the art of poisoning became very common in Naples, where, Keysler says, it was still secretly practised when he visited Italy; and Archenholz, ‡ who was there in 1780, states, that Aqua Tofana was then in use, although its composition was only known to a few; but Joseph Frank, who was long Professor in Pavia, and has written a work on toxicology (*Handbuch der Toxicologie*, Wien, 1803, p. 168.), regards this as an unfounded calumny, and asserts that it no longer exists or is heard of.

Aqua Tofana is described as being as limpid as rock water, and without taste, and hence it could be administered without exciting suspicion. The Abbé Gagliani adds, ‖ that there was not a lady in Naples, who had not some of it lying openly on her toilet among her perfumes, in a phial known only to herself.

It was generally believed, that the effect of this poison was certain death; and that it could be so tempered or managed, as to prove fatal in any determinate time, from a few days to a year or upwards. Four or six drops were reckoned a sufficient dose, and they were said to produce no violent symptoms, no vomiting, or but very seldom, no pains, convulsions, inflammation, or fever; § but only a feeling of indisposition, without any very definite symptoms, except sometimes inextinguishable thirst; the victim, however, sunk into a languid state, and his weakness increased daily. Disgust at all kinds of food, and weariness of life, succeeded; the nobler organs were then attacked, the lungs were wasted by suppuration, and death closed the miserable scene. This termination was the more certain, that the true cause of these symptoms was not at first suspected, and the remedies commonly prescribed rather aggravated the evil. Indeed, even when known, no treatment was of any avail, although a Dr Branchaletti, according to Keysler, wrote a book on its remedies, until it was discovered by accident that lemon-juice, when very early administered in large doses, sometimes proved effectual (Bertholinus), after which, Keysler tells us, that the poison fell into some disrepute.

Various accounts of the composition of this detestable liquor have been given. Abbé Gagliani, and more lately Archenholz, state it to be a prepara-

tion of cantharides and opium; but this is perfectly inconsistent both with its appearance and effects. By no preparation can the smell and taste of opium, if the quantity be sufficient to produce any effect, be concealed, and the acrimony of cantharides is equally connected with its activity. The one of these drugs is highly stimulant, the other a sedative, and neither of them capable of remaining latent in the system, or injuring the constitution. Erndtel,* but without any probability, has conjectured that the chief ingredient was lead: Halle (*Die deutchen Giftpflanzen*, Berlin, 1783) believes, that it was prepared from the frothy saliva gathered round the mouth of a person tortured to death. Garelli, on the contrary, positively asserts it to have been nothing but a solution of crystallized arsenic in a large quantity of water, with the addition, for some unknown reason, of a very innocent herb, the *Antirrhinum cymbalaria*. The same account is given by Bertholinus, Lobel (*Der freymüthige Heilkunstler*, Berlin, 1786), Plenk (*Toxicologia*, p. 335), Haller,† Molitor (*Commerc. Lit. Noric.* 1737, p. 182), and Möhsen,‡ and is received by the most judicious systematic writers, as Gmelin and Hahnemann. (*Ueber die Arsenikvergiftung*, 8vo, Leipzig, 1786, p. 35.) Wildberg,‖ however, considers its composition to be unknown.

From Italy this poison seems to have found its way to Paris. In 1672 Godin de Sainte Croix, an adventurer, who lived in a scandalous intimacy with the Marchioness Brinvilliers, was suddenly killed by suffocation, as it is said, in consequence of the falling off of a mask of glass, which he wore to protect him from the fumes of certain chemical operations about which he was employed. As he had no known relations, his effects were examined by a public officer, and among them was found a casket, containing many packets of poisonous articles, sealed up in a mysterious manner, together with a kind of last will, directing the whole to be delivered to the Marchioness, and, in case of her having predeceased him, to be burnt unopened. This led to the discovery of his having been instructed in the art of preparing poison, by an Italian, called Exili, with whom he had become acquainted, when confined in the Bastille; and of his having furnished the Marchioness with the means of poisoning her father and her two brothers, besides others on whom she tried the effect of her preparations. One of these afterwards was called from her by the name *Eau de Brinvilliers*. She is also said to have employed a powder called *Poudre de Succession*.§ La Chaussée, who had been valet to Sainte Croix, was convicted of being accessory to these murders, and was broken alive on the wheel. The Marchioness herself, who had escaped to Liege, was also seized, and her execution, which took place on the 17th of July 1676, is described with revolting levity by Mad. de Sevigné in a letter to her daughter of that date.

The practice of poisoning, however, did not seem to terminate with the death of this infamous woman; and a particular court called *Chambre des Poisons*, or *Chambre Ardente*, was established in 1679, to endeavour to put an end to it. In consequence of the investigations which took place in it, many persons, some of the highest rank, especially the Duc de Luxembourg, were implicated. More than forty persons were at one time confined in the Bastille; but it was ascertained, that almost all of them had been guilty of no crime, but were merely the dupes of a few impostors, who pretended to raise spirits, foretell future events, and to possess many secrets of a similar nature. Two women, La Vigoureux and La Voisin, with the brother of the former, and a priest called Le Sage, ¶ pretended fortune-tellers, were convicted of being dealers in poison, and burnt alive, on the 22d Feb. 1680; some others were hanged, and others acquitted. This closed the proceedings of this inquisitorial court, which has been accused of being a political engine, contrived to serve the purposes of Louvois and the Marchioness de Montespan. Voltaire, however, admits that the crime of poisoning infected Paris from 1670 to 1680.

Concerning the effects of the *Eau de Brinvilliers*, Pitaval tells us (p. 271.) that the Marchioness's father experienced violent effects from the poison,—extraordinary vomiting, insupportable pain at stomach, and great heat in the bowels. He died soon after his return from his country-seat to Paris. The brothers, and five other persons, were all taken ill, and affected with vomiting, after partaking of a tart at dinner. On their return from the country to Paris, the brothers had the appearance of persons who had been long ill; and after suffering, the one for two, and the other for three months, from nausea and vomiting, they died extremely emaciated, and as it were dried up, without fever, though experiencing a burning sensation in the stomach. On opening the bodies, the stomach and duodenum were black and tender, and the liver gangrenous and burnt. Mad. Sevigné relates, that the Marchioness often poisoned her husband, that she might marry Sainte Croix, but that the gallant, having no desire for a wife of her disposition, as often gave the poor husband an antidote. She is also said to have attempted to poison her sister; but did not succeed; and that she was in the habit of trying the effects of her poisons on the

poor, and even on the patients in the Hotel Dieu, under pretence of charitably supplying them with biscuits. But Voltaire positively denies this horrible imputation, and says, that she never attempted the life of her husband, who overlooked a connection, of which he was the cause.

The information concerning the nature of the *Eau de Brinvilliers*, derived from the examination of Sainte Croix's famous casket, is not satisfactory. It contained poisons enough to have killed a whole community; besides opium, lunar caustic, antimony and vitriol, more than 75 lbs. of corrosive sublimate, and two bottles of a liquid, like water, with a sediment in one. The clear liquid was probably his real poison; as none of the other substances could have been given so as to produce death, without instantly being detected, by their abominable taste; but what this liquid was, we can now only conjecture, for its examination, as reported by Pitaval, shows that the physicians, at that time, had not the slightest notion of the mode of detecting arsenic even in substance, much less in solution; and accordingly, although both the liquor and powder killed the animals to which they were given, it is candidly admitted, that the poison of Sainte Croix surpassed the art and capacity of the physicians, and that it baffled all their experiments to discover its composition. We have, however, no doubt, that arsenic was the only active ingredient of all these pretended secret poisons; as it is the only substance capable of explaining all the credible circumstances related of them. From the mode of administering them in small, but repeated and perhaps increased doses, there was some foundation for the belief that they could be given so as to kill in any determinate time, while their failing in any instance to produce death, was easily accounted for by supposing antidotes to have been administered. But although the progress of knowledge has proved, that there is no such thing as such antidotes, it has on the other hand, by rendering the detection of poison easy and certain, put a stop for ever to the trade of *poisoner;* and what is perhaps of equal importance, to the general alarm and cruel punishment of individuals which have often resulted from natural deaths being ascribed to poison. It is not because we know less, but because we know a great deal more than our forefathers, that the art of secret poisoning seems to be lost.—See Forensic Medicine in this Supplement. (x.)

ARACHNIDES. A class of animals of the type Annulosa. See *Index* to Annulosa.

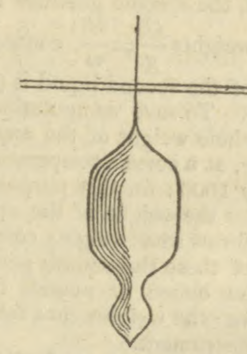
History.

ARÆOMETER (composed of ἀραιος, *levis, tenuis,* and μετρον *mensura*), a measure of the comparative density and rarity of bodies. The name does not occur in ancient authors; hydroscopium and baryllium being the ancient names of the instrument. This instrument was known in the civilized part of the Roman empire, about the year 400, as appears from the fifteenth epistle of Synesius, addressed to Hypatia, daughter of Theon; and to Hypatia some modern writers have erroneously ascribed its invention. The instrument is also described in some verses annexed to Priscian; and the principles on which its operation is founded, are to be seen in the treatise of Archimedes on floating bodies *(De Humido Insidentibus)*. The term, as used by writers on natural philosophy, is chiefly applied to instruments which are made to float, so as to indicate the specific gravity of the liquids in which they are placed: the *pêse liqueur*, and hydrometer, in common use for measuring the specific gravity of vinous spirits, are instruments of this kind.

Theory.

A floating body displaces a portion of the liquid, the weight of which is equal to its own weight, the liquid acting upwards with a force equal to this weight, and the weight of the body acting downwards with the same force, equilibrium takes place. If the body be afterwards placed in a liquid of less density, the part of the body immersed, will be greater than when the body was in the more dense liquid, because it requires a greater volume of this less dense liquid to equal the weight of the floating body. The absolute weights of two bodies being the same, their specific gravities are in the inverse ratio of their volumes $\frac{G}{g} = \frac{v}{V}$, when $G$ is put for the specific gravity of the first body, $g$ for that of the second; $V$ for the volume of the first, and $v$ for the volume of the second. On this principle the common hydrometer is constructed; the instrument described by Synesius, is also of this kind. In order that a small difference in the volume immersed may be sensible, the part which is intersected by the surface of the fluid is in the form of a very slender cylinder, the great bulk of the instrument being always immersed in the liquid. At the inferior part is a small ball, containing mercury or small lead shot, which serves as ballast, bringing the centre of gravity low, so that the instrument may float erect, and without much lateral oscillation. The common hydrometers are made of glass, and sometimes of brass, or tin or pewter, and some have been made of amber as objects of curiosity: when made of glass, a scale, inscribed upon paper, is inserted in the cylindrical stalk; the division of the scale at which the surface of any liquid intersects the stalk, denotes the specific gravity of that liquid.

Aræometer with Scale.



Mode of forming the Scale.

The divisions of the scale should be formed by immersing the instrument in liquids of known specific gravity, and marking a number corresponding to that specific gravity opposite to each division. The specific gravities of water and alcohol mixed in various proportions, have been accurately ascertained by Mr Gilpin (see his Tables, and Dr Blagden's paper in the *Philosophical Transactions*); on immersing the instrument in a mixture of known proportions of these two liquids, the point at which the surface intersects the stalk, is to be marked with the number expressing the specific gravity of the mixture taken from the table. Some hydrometers, such as that constructed by the French chemist Beaumè, and which is much used in France under the name of *Aréometre de Beaumè*, have the

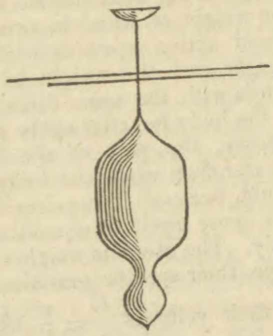
A R Æ

Aræometer.

scale divided into equal parts, so that the divisions do not correspond as they ought to do with the numbers which express specific gravities.

Fahrenheit's.

In the aræometer of Fahrenheit, the uncertainty arising from the erroneous division of the scale is obviated, no division being required. The form of the instrument is the same as that just described, only at the top there is a small cup, into which weights are put, so as to bring the surface of the denser liquid to a fixed mark on the stalk; when the instrument is placed in a liquid of less density, some of the weights are taken out till the mark again comes to the surface.



Manner of using it.

Suppose the weight of the instrument and of the weights in the cup together equal to 1000, when sunk to the mark in distilled water at a certain temperature; the instrument is now taken out of the water and immersed in a liquid, where 10 must be taken out of the cup in order to bring the mark to the surface; the immersion in water indicates that a volume of water weighs 1000; the immersion in the second liquid, shows that an equal volume of this liquid weighs 990; when the volumes of bodies are equal, the specific gravities are directly as the absolute weights $\frac{G}{g} = \frac{W}{w}$, consequently the specific gravity of the second liquid is 990, that of water being 1000.

Construction of the Weights.

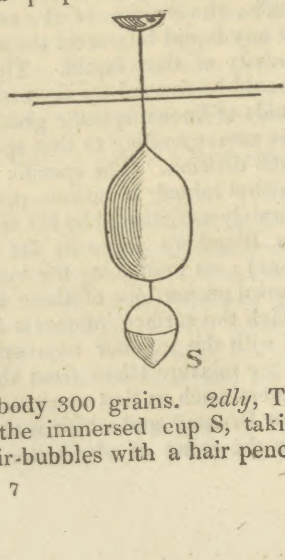
To save computation, it is convenient that the whole weight of the apparatus, when in distilled water, at a certain temperature, should be represented by 1000; for this purpose, the instrument-maker divides the weight of the apparatus into 1000 parts, and forms small weights consisting of one, two, three, &c. of these thousandth parts, the relation of which to the ounce or pound, does not require to be known; the weights thus formed are to be used with the instrument.

Nicholson's.

The aræometer of Nicholson is like that of Fahrenheit, with the addition of an immersed cup, whereby it is rendered proper for ascertaining the specific gravity of solids.

Mode of using it.

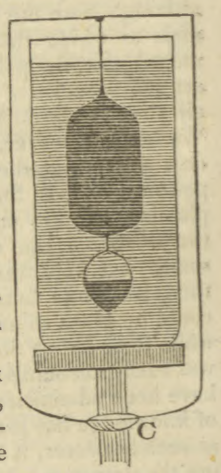
Suppose that it requires 400 grains in the exterior cup to sink the instrument to the mark in distilled water, at 60 degrees of Fahrenheit's thermometer; 1*st*, The body under examination is put into the exterior cup, and weights (say 300 grains) are taken out till the mark again stands at the surface; this gives the absolute weight of the body 300 grains. 2*dly*, The body is then put into the immersed cup S, taking care to brush off any air-bubbles with a hair pencil,



Aræometer.

and in order to bring the mark to the surface, a weight (say 100 grains) must be put into the exterior cup, that is, the weight of a volume of water equal to the body, is 100 grains. The first part of the process gave the absolute weight of the body 300 grains, and the volumes being equal, the specific gravities are as the absolute weights, consequently the specific gravity of the body is 300, that of water being 100. This aræometer may be used to find the specific gravity of liquids; the process, in that case, is the same as that described above in speaking of the aræometer of Fahrenheit. The aræometer of Nicholson is useful to the mineralogist for ascertaining the specific gravity of minerals; the specific gravity being a convenient character for distinguishing one kind of mineral from another. It is sometimes made of tinned iron, but where more accuracy is required, copper is the material employed. When put together, it does not exceed a foot in length, and therefore is suited to form a part of the travelling mineralogist's apparatus.

Some aræometers have been constructed with the exterior cup C placed underneath, and supported by a stirrup, whose upper part is fixed to the stalk of the aræometer, as represented on the margin; this is done in order to place the centre of gravity low, that the aræometer may thereby float more steadily. The aræometer floats in a cylindrical vessel fitted to the size of the stirrup, and this vessel is supported on a stand so formed as not to interfere with the free motion of the stirrup.



Deparcieux's.

The aræometer of Deparcieux is like the common hydrometer, only the ball is much more voluminous; this renders it capable of indicating the small difference which exists in the specific gravity of the water of different springs, for which purpose Deparcieux proposed it. The dilatation of the large glass bulb by heat, has a considerable effect on the operation of this instrument, and this dilatation being different in different instruments, renders the results inaccurate. The different aræometers above-mentioned, have the advantages of being easily made and easily carried about; but where the specific gravity of a body is required with the greatest accuracy, recourse must be had to the hydrostatic balance, which ought to be constructed with the utmost care by the most skilful artist.

Formula.

The following algebraic expressions may serve to elucidate some of the properties of the aræometers hitherto spoken of:

$g$ is the specific gravity of water, which is 1000 ounces when the ounce and foot are taken as unities, 1000 ounces avoirdupois being the weight of a cubic foot of water.

$z$ is the diameter of the wire-stalk of the aræometer.

$\pi$ is 3.1415, &c. the number expressing the periphery of a circle whose diameter is 1.

Aræometer.

$\frac{1}{4}\pi z^2$ is the surface of a transverse section of the wire-stalk.

$v$ is the volume of the bulb or body of the aræometer.

$w$ is the whole weight of the aræometer.

$x$ is the length of the stalk that is plunged in the water.

$\frac{1}{4}x\pi z^2$ is the volume of the immersed portion of the stalk.

When the aræometer floats in equilibrio, it displaces a volume of water equal to its own weight, therefore, $w = g\ (v + \frac{1}{4}x\pi z^2)$, and, $g = \frac{w}{v + \frac{1}{4}x\pi z^2}$, $x = \frac{4(w - gv)}{2g\pi z^2}$; $w - gv$ is the difference between the quantity of water displaced by the whole aræometer, and the quantity displaced by the bulb alone, $w - gv$, therefore, is the volume of water displaced by the immersed portion of the stalk, as the diameter of the stalk $z$ is very small, the cylinder of water $w - gv$, which has $z$ for its diameter, is likewise very small, and does not exceed a few grains in weight; therefore, a small variation in $w$ (the weight of the aræometer), or in $g$ (the density of the liquid), occasions a great variation in $x$ (the length of the immersed part of the stalk). The value of $x$ changes rapidly, when $z$ (the diameter of the stalk) is changed, because the value of $x$ is divided by $z^2$, which is the square of a very small quantity.

Sensibility to the sp. gr. of Liquid.

When the aræometer is immersed in a liquid of another specific gravity $g^1$, then the equation is $x^1 = \frac{2(w - g^1 v)}{g^1 \pi z^2}$; subtract the value of $x^1$ from that of $x$, and there results $x - x^1 = \frac{2w(g - g^1)}{gg^1\pi z^2}$; this is the diminution in the length of the immersed part of the stalk, which takes place when the aræometer is transferred to a liquid of a greater density. By this formula, it is seen, that the sensibility of the aræometer, that is, the length of the portion of the stalk which emerges upon transferring the aræometer to a denser liquid, is augmented, in the first place, by increasing $w$ (the weight of water displaced by the aræometer), that is, by increasing the volume of the body of the aræometer; secondly, by diminishing $z$ (the diameter of the stalk), which is in the denominator of the value of $x - x^1$. Consequently, the faculty of the aræometer to show the different densities of liquids is, in general, expressed by the fraction $\frac{w}{z^2}$.

Expression of the Sensibility to additional Weight.

With regard to the vertical mobility of the aræometer, when put in motion by placing a small weight ($s$) in its exterior cup, substitute $w + s$ for $w$, then, $x^1 = \frac{4(w + s - gv)}{2g\pi z^2}$, take the difference between this and $x = \frac{4(w - gv)}{2g\pi z^2}$; this difference is $x^1 - x = \frac{4s}{g\pi z^2}$. Which shows that the length of the portion of the stalk that a small weight causes to immerge, is proportional to $\frac{s}{z^2}$, or in the direct ratio of the small weight, and in the inverse ratio of the square of the diameter of the stalk.

Expression of the Diameter of the Stalk.

When the small weight, the density of the liquid, and the length of that part of the stalk which is submerged on adding the small weight, are known, then this equation will give the diameter of the stalk in known quantities $z = 2\sqrt{\frac{s}{g\pi(x^1 - x)}}$.

Density of a liq. expr. in terms of $w$.

When the weight of the whole aræometer is known in ounces, &c., and the specific gravity of one of two liquids (water for instance) is known, the difference of specific gravity between that liquid and another liquid may be had in known quantities.

$g$ is the specific gravity of water.

$g^1$ is the specific gravity of the second liquid, which is here supposed more dense.

$w$ is the weight of the volume of water displaced by the aræometer.

$s$ is a small additional weight placed on the exterior cup to keep the aræometer, when placed in the denser liquid, at the same point of immersion as when it floated in water.

$w + s$ is the whole weight of the apparatus when floating in the denser liquid.

The equation $g^1 = \frac{w + s}{v + \frac{1}{4}x\pi z^2}$ is obtained by substituting $g^1$ for $g$, and $w + s$ for $w$ in the equation, $g = \frac{w}{v + \frac{1}{4}x\pi z^2}$, which was given above. Divide by $g = \frac{w}{v + \frac{1}{4}x\pi z^2}$, and there results $\frac{g^1}{g} = \frac{w + s}{w}$, which gives the proportion of the density of the second liquid to the density of water. By subtraction there results $\frac{g^1 - g}{g} = \frac{s}{w}$ and $g^1 - g = \frac{sg}{w}$, that is, the difference between the density of the second liquid, and the density of water is found by multiplying the small weight by 1000 ounces, and dividing this product by the number of ounces, &c., which denote the weight of the aræometer uncharged.

Bead Aræometer.

Small bodies, whose specific gravities are known, serve to indicate the specific gravity of a liquid in which they just remain suspended. In this way, beads of glass, three or four tenths of an inch in diameter, are employed, each of which remains suspended in spirit of a certain specific gravity. The density of each of these beads, or rather bubbles, is regulated by the proportion between the quantity of glass and the cavity which the glass incloses. A piece of bees-wax, whose specific gravity, by the addition of lead, is such, that the body is just suspended in brine of a known density, is used as an aræometer in some salt works. The fresh egg of a common fowl is just sustained by brine of a certain specific gravity, and is employed as an aræometer.

Homberg's.

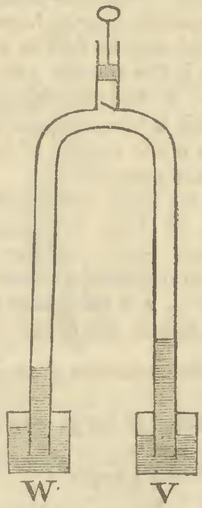
The aræometer of Homberg, consists of a phial, with a slender neck and glass-stopper, so made, that it may be filled with the same volume of different liquids. It is employed in finding the specific gravity of liquids in the following way: 1*st*, The phial is filled with distilled water, and then weighed in a balance; 2*dly*, The phial is emptied, and again filled with the liquid, whose specific gravity is sought, and weighed in a balance, the proportion of the weight of the contents of the phial in the second process to the weight of its contents in the first, is the specific gra-

Aræometer || Araucania.

vity required. The inconveniences which have prevented this method from being generally used, are; the difficulty of completely cleaning the phial from the liquid which it previously contained; the difficulty of filling the phial exactly with the same volume of each liquid; and the variation of the volume of the phial from changes of temperature.

Pump Aræometer.

The pressure of the atmosphere supports columns of different fluids, whose height is inversely as the densities of the fluids. An aræometer has been constructed on this principle. It is a curved tube, one leg of which has its extremity immersed in water, and the other in the spirit whose density is to be tried. On rarifying the air in the tube, by means of a pump fixed at the upper part of the tube, the water ascends in one leg, and the spirit in the other; the height of the column of each liquid being measured by a scale of equal parts applied to each branch of the tube. This instrument has never come into use, probably on account of the difficulty of ascertaining, with precision, the points at which the surfaces of the columns are terminated. See *Encyclopædia*, Art. Hydrodynamics, Part I. ch. 2. sect. 2. for some farther notice of Aræometers. (Y.)



ARAUCANIA, a territory on the western coast of South America, extending 186 miles in length, between the rivers Biobio and Valdivia, and penetrating 420 miles inland to the foot of the Andes. The lower parts of these mountains are included within its limits, and the whole superficies which is bounded by 36° 44′ of south latitude on the north, and 39° 50′ on the south, occupies about 78,120 square miles. Originally, Araucania was of smaller dimensions, not reaching above 300 miles from the sea-shore; but it received a great accession by the union of another territory belonging to the tribe Puelches, in the course of the seventeenth century.

This is a pleasant and fertile country, partly consisting of wide and extensive plains, partly mountainous, with spacious valleys interposed. It contains two considerable lakes, Laquen, called Villarica by the Spaniards, 72 miles in circuit, with a conical islet in the centre; and Nahuelguapi, 80 miles in circuit, which also has an islet towards one side covered with trees. The latter is the source of a river of the same name, which, after a long course, falls into the ocean, near the Straits of Magellan; and the Talton, which discharges itself farther north into the sea, rises from the latter. A great volcanic mountain, fourteen miles in circumference at the base, and visible at the distance of 150, stands near the lake Villarica. Its eruptions are not violent, though it is always in an active state. The summit is covered with snow, but lower down, perpetual verdure is intermixed with woods, and besides mineral springs, several streams flow from it. Sulphur and Salt are plentiful on the eastern confines; and quantities of Ambergrease are thrown up on the coast. Mines of Gold, formerly yielding immense revenues, are said to exist in the southern parts, but ever since the natives expelled their Spanish invaders, they have prohibited resorting to them under pain of death. Possibly all remembrance of their site is lost, and the Araucanians are sufficiently prudent to avoid awakening the cupidity of neighbouring nations by discovering it. This precious metal is not rare beyond their confines. We are acquainted with the vegetable productions of this territory, only in common with those of the surrounding country; they are numerous, useful, and afford a copious supply for the sustenance of mankind. The beauty and utility of a tree called the Pehuen, probably a kind of bread-fruit, or of some analogous species, is particularly celebrated, as uniting the properties of the Pine, Chesnut and Frankincense. It is of spontaneous growth, requiring no culture, and rises 80 feet in height, by about 8 in circumference; the whole tree at full size being of a pyramidal figure. The flowers are conical, and its fruit, which is as large as the human head, is divided into cells, containing kernels resembling chesnuts. These are ate in the same way, or sometimes reduced to flour, and preserved by boiling. A yellowish odoriferous gum exudes through the bark. The sea abounds in fishes, and various phocæ frequent the shores. Of these the sea Elephant is the largest, often being 22 feet in length, and 15 around the breast; it produces more oil than the rest; and is so fat, that undulations under the skin are perceptible during its motion. Furious combats ensue among the males for possession of the females, which latter always retire until their issue; and that for the most part is in the death of one or other of them. Their skins are generally covered with scars; yet notwithstanding the great size of the animal, and its warfare among its own species, a smart blow near the nose is invariably fatal. A species of Hippopotamus is said to inhabit some of the lakes and rivers of Araucania, different from that of Africa, but its existence is not sufficiently authenticated. However, it is only of late years that Naturalists have become acquainted with the real Hippopotamus, whose figure and habits were long considered to be fabulous. One of the most useful animals in this country is the Chilihueque, a species of diminutive camel, greatly resembling the sheep, about 4 feet high, of various colours, grey, brown or black, and bearing very soft wool, which is employed solely in manufacturing the finest cloths. Formerly, it was used as a beast of burden; now it is highly prized by the inhabitants, by whom it is never killed except at festivals, or on occasion of solemn sacrifices.

Inhabitants.

The natives of the country now described, are called Araucans or Araucanians from the province of Arauco, which forms a small portion of it. They denominate themselves *Auca*, which signifies free, or unsubdued, though some European authors have affirmed, that both Auca and Araucanian originated with the Spaniards, as a name of reproach, signifying rebel or savage banditti; and others, such as Falkner, says, that they denominate themselves generally *moluches* or warriors. Whatever may be the truth, they are a

Araucania.

warlike and independent race, and have shed the blood of their invaders in torrents.

The Araucanians do not differ from the ordinary stature of mankind; their persons are handsome; they are of a strong muscular form and martial appearance; their complexion is of a reddish brown, clearer than that of the other Americans; they have round faces, small expressive eyes, and small flat feet. Deformity among them is very rare. The women are of a fine delicate figure, and many, especially of one of their tribes called Boroanes, are beautiful. The Araucanians possess uncommon vigour of constitution, which is probably augmented by their free and uncontrolled mode of life. Inhabiting a delightful country, and unaccustomed to that variableness of climate which generates lasting distempers, they rarely become grey before attaining sixty or seventy years of age; many are to be seen who have reached an hundred; and to the latest period, their personal and mental faculties remain equally entire.

Their Character.

These people are said to rank high in moral character; they are intrepid and patient of labour, enthusiastic admirers of liberty, which has gained them the name of invincible from their enemies; courteous, and hospitable. But these good qualities are sullied, if not altogether obscured, by numerous vices. They are prone to all kinds of drunkenness and debauchery: they are haughty and presumptuous, entertaining a profound contempt for other nations, and considering war the only genuine source of glory; sentiments which powerfully conspire to keep barbarians barbarous. Not content with exercising their prowess against their neighbours, they practise invasions of each others property, and carry off quantities of spoil. But notwithstanding their natural violence, these private dissensions are generally confined to pillage, without bloodshed, for deadly weapons are seldom resorted to. Their animosity towards the Spaniards being originally roused by just provocation, has remained for centuries unabated; and, in their incursions into their settlements, they have sometimes put all the men to the sword, while the women were spared, and carried into captivity. They have been called faithless and treacherous by that nation; but most probably more from resisting oppression, than from truly meriting such reproaches.

The Araucanians being a military people, have adopted a suitable costume, consisting in clothes fitted close to the body, and a mantle or cloth, called *poncho*, with an opening in the middle, to admit the head. Some of these are of so fine and elegant a texture, as to sell for an hundred, or an hundred and fifty dollars. The head is begirt by a wreath of embroidered wool, and ornamented with beautiful plumes, during warfare. Modesty and simplicity equally distinguish the dress of the women, which is entirely of woollen stuff, and consists of a piece descending to the feet, a girdle, and a cloak, called *ichella*; the hair floats gracefully in tresses over their shoulders, and their heads are decorated with a kind of false emerald, that is held in great estimation. Necklaces and bracelets are also wore for ornament, and rings on every finger. The national colour for all the apparel of both sexes, especially among the lower classes, is greenish blue.

The Araucanians never inhabit towns: their love of independence has deterred them from living in places surrounded by walls, which they consider a mark of servitude: hence they dwell in cottages or hamlets scattered on the banks of rivers, or on plains: and, as their local attachments are strong, each family prefers occupying the same bounds which have served for the subsistence of its forefathers. The houses are simple, kept remarkably clean and neat, and proportioned to the size of the family. They are surrounded by trees, under which they partake of their meals, in the open air during summer; and the wealthy are then fond of displaying their plate. These people are much less carnivorous than most uncivilized tribes, neither do they esteem fish grateful food, and they live chiefly on what is prepared from different kinds of grain. At their feasts, however, or marriages, funerals, and such public occasions, remarkable profusion prevails: three hundred individuals are then sometimes present; the feast lasts two or three days, and as much provision is consumed as would maintain an ordinary family during two years. Fermented liquors form a principal ingredient of the entertainment, and the guests testify great dissatisfaction, should they be at all sparingly supplied with it, whatever may be the quantity of provisions. Every man of property being anxious to entertain his friends, Bacchanalian revels succeed each other, almost without interruption; and they are the chief occupation of the Araucanians, when free of warfare.

Marriage.

Celibacy is thought reproachful here. Both sexes in that state are exposed to contemptuous expressions, and polygamy is practised to an unbounded extent. A man marries as many wives as he can afford to purchase, for the father of each female receives a price on her being transferred to a husband. Marriage is attended with apparent violence. The husband, in concert with the father of his bride, accompanied by some friends, lies in wait near a certain place, where he knows she is to pass. Notwithstanding her shrieks, and affected resistance, she is placed behind him on horseback, and is conducted with much clamour to his house, where her relations receive the covenanted presents, after having partaken of a feast. The expence on such occasions is so considerable, that none except the rich can afford to marry many wives; and the poor are generally content with one or two. The first, however, is alone respected as the real or legitimate spouse; all the others are held in a secondary view; and she has the whole arrangement and regulation of the internal domestic concerns. But it is no easy matter for the husband to repress the jealousy and rivalship excited by the jarring inclinations of his different wives. Each must daily present him with a dish of some food prepared by herself, in her own kitchen or fireplace; for which reason, the Araucanians have a number of fires in their houses equal to that of the women inhabiting them, and the most polite way of inquiring of any one how many wives he has, is asking "how many fires he keeps?" Each wife must, besides, supply her husband with a *poncho* or cloak yearly. They entertain great respect for their husbands; and in addition to their domestic duties,

they have to perform all the most laborious operations. Both sexes practise several daily ablutions, in the course of which they become expert swimmers and divers, and they are able to cross the largest rivers with great facility.

Estimation of Eloquence.

Reading and writing are no part of the accomplishments of the Araucanians, nor can they be induced to acquire either; but they hold oratory in high estimation. Children are accustomed from an early period to speak in public, and are carried by their parents to the national assemblies, where the best Orators of the country display their eloquence; therefore much attention is paid to speaking correctly, and preserving their language pure. So great is their precaution to avoid the introduction of any foreign expressions, that if a stranger settle in their territory, he is compelled to abandon his own name, and assume one in the Araucanian language. The Missionaries who preach in the national language with the design of making converts, are frequently interrupted by the audience when an error escapes them. The speeches of the Araucanian Orators are said to be highly figurative, allegorical, and elevated; they contain all the essential parts of rhetoric, and are constructed by its rules. Their style is impressive, and seems capable of being directed to the passions. They are fond of poetry, which is expressed in blank verse, not in rhyme, and, like that of all barbarous nations, is employed on warlike exploits. Its images are bold, lively, and animated; for it has been truly observed, that unrestrained enthusiasm is the chief characteristic of the poetry of the uncivilized.

Learning.

Their learning, however, is very limited, and certainly the cultivation of poetry will not readily lead to its improvement. In physic, the Araucanians deal in simples, or the practice of ceremonies; and their leading theory ascribes the origin of all diseases to insects or witchcraft. Ordinary remedies are resorted to for destroying the former; but for the latter, a different course is followed. The physician having lighted up the patient's room, desires the women to sing a doleful tune, to the accompaniment of drums, while he fumigates the patient, and a sheep, about to be sacrificed, with tobacco smoke. Having killed the animal, and sucked some blood from its heart, he approaches the patient, pretending to inspect his belly for poison which has been administered by some sorcerer, and then falls into a pretended swoon, accompanied by frightful contorsions. While the sick person's relations question him concerning the cause of the evil, he answers in a manner the most suitable to the occasion, or fixes an accusation on some individual, which frequently leads to the murder of the innocent in revenge of the supposed injury. Their physicians, however, are capable of reducing dislocated joints, and setting fractured bones; they can even perform wonderful cures of wounds, and have a slight skill in dissection.

The Araucanians divide the year into twelve months, the names of which are characterized by their properties, as *Avun-cujen*, the month of fruits; *Cogi-cujen*, the month of harvest; *Huin-cujen*, the unpleasant month; *Hucul-cujen*, the first month of winds; thus somewhat resembling the *Prairial*, *Floreal*, *Nivose*, in the revolutionary language of the French. They divide the day into twelve parts, each equal to two hours with us in duration. The stars are classed in constellations; they are acquainted with the planets; and some among them even entertain speculations of their being other inhabited worlds. Comets are supposed to originate in terrestrial exhalations united in the higher regions; and they call eclipses the death of the sun or moon. Few generations can avail themselves of the knowledge of their ancestors, or preserve their own to posterity, where writing is not practised.

They have little acquaintance with the arts, and are ignorant of the principles of commerce: chiefly employed in warfare, they are accustomed to constant privations, and thence abstain from those luxuries which are the offspring of a state of peace and the arts. Their principal manufacture consists of *ponchos* or Indian cloaks, which some years ago they were wont to dispose of to the extent of 4000 annually, either to the neighbouring tribes or to the Spaniards: their other articles of traffic are cattle, horses, feathers, and baskets of curious workmanship. They have the character of strict integrity in commercial transactions, which are conducted entirely by barter. They have no money, and for their own commodities receive wine, iron, and hardware.

Government.

The government of the Araucanians bears some analogy to the feudal system, but it does not appear, that, as in Europe, their lands are held by military tenure. The whole territory is divided into four parallel districts called *Uthal-mapus*, being the maritime country, the plains, the country at the foot of the Andes, and that which is occupied by part of these mountains. Each district is subdivided into five provinces, and each province contains nine counties; therefore their total possessions are partitioned into an hundred and eighty parts. Each *Uthal-mapu* is governed by a chief, styled *Toqui* or commander, subordinate to whom are the *Apo-Ulmenes*, and on these, in so far as respects military affairs, are dependent, the *Ulmenes*, under whose immediate jurisdiction the counties are placed. All these orders have badges of distinction; the *Toqui* a stone hatchet, the *Apo-Ulmen* a silver-headed baton, encircled by a ring on the middle, the *Ulmen* a baton simply with a silver head, and their dignities are hereditary. The whole combine in a great national council usually held in a plain, where the pleasures of the table usually divide their attention with state affairs. This grand council is vested with the power of declaring war; and the election of a military commander in chief, immediatly follows a resolution to that effect. Should none of the *Toquis* be themselves qualified for so important a station, any other person whatever may be chosen, even one of low rank: and on his appointment he assumes the title of *Toqui*, bears the stone hatchet, which is laid aside by the rest, who now take an oath of fealty to him. He regulates the number of soldiers to be furnished by each portion of the state, and nominates the higher officers, who have the choice of their own subalterns.

Warfare.

Meantime expresses are secretly dispatched to all the allies of the nation, announcing the approach of hostilities: which are intimated by investing the envoy with a bundle of

Araucania.

arrows tied together with a red string; but if they have actually commenced, the finger of a slain enemy is added to the arrows. The armies consist of five or six thousand men, cavalry and infantry, though some authors who have written on this subject, deny that the whole country can produce such a force: the infantry is divided into regiments, of 1000 each, containing ten companies of 100 men: the cavalry is divided in the same manner, but the numbers are not always alike: their arms are swords and lances; those of the infantry, pikes or clubs pointed with iron. The onset of these troops is terrible; they bear every thing before them, and always try to cope hand to hand with their foes. Each soldier, as was the custom of Europe in feudal times, carries his own provisions, which consist only of a small bag of parched meal; and this diluted with a little water, generally proves sufficient subsistence until reaching an enemy's country, where he can live at free quarters. Their conflicts are conducted with great desperation, though, at the same time, wonderful regularity and subordination are preserved: but as all pant after military glory, and as valour is the only path to fame, the post of honour is eagerly courted, where rank after rank is successively destroyed before defeat or victory can be declared. The battle over, and the spoils of war divided by equal portions, according to numbers, not in proportion to rank, the next ceremony is a horrible sacrifice of one of the unfortunate captives to the manes of those who have fallen, called *Proluncon*, or the dance of the dead. Many barbarous nations, nay some emerging from the darkness of their savage state, have been accustomed to offer up human sacrifices; and all mankind have believed, at one period or other in their progress to civilization, that blood was grateful to their Deities, or that it was necessary for the repose of their deceased relatives. Some, less cruel and sanguinary, have been content with the destruction of the lower animals; but others, more atrocious, have shed the blood of their own species. This deliberate murder has been of three distinct descriptions: first, to propitiate Divinities, or to avert their wrath; secondly, that the victims might be useful to deceased persons passing to a future state; and thirdly, that the manes of those who had fallen in war might be appeased. The *Proluncon*, nevertheless, is seldom resorted to; but, when determined on, it is conducted with great formality. The miserable prisoner is seated on a horse, deprived of its ears and tail, with his face turned towards his own country, and ignominiously conducted amidst a circle of the Araucanians and their chiefs. There he is obliged to dig a hole in the ground, wherein a number of rods are cast in succession; and while he repeats the names of the warriors of his nation, the surrounding soldiers accompany his words with contempt and execrations. He is next ordered to cover the hole, as if to bury the reputation and value of his fellow warriors, whom he has just named. Then the *Toqui*, or one of his bravest companions, ambitious of the honour, dashes out the brains of the unfortunate victim with a club. But the solemnity is not yet completed; for, with cannibal-like ferocity, his heart is instantly torn out, and presented to the Chief, who, sucking a little of the blood, transmits it to his officers, to follow his example. Should the skull of the prisoner not have been fractured by the violence of the blow, a cup is made of it, which, as is told of the ancient Scythians, is used at the succeeding banquets. Meanwhile the soldiers strip the flesh from off the bones, in order to procure them for flutes; and, having cut off the head, carry it on a pike around their circle, stamping a measured march, and vociferating the war song of Savages. In the next place, the head of a sheep is applied to the mangled corpse, and the whole ceremony closes with a scene of riot and intoxication. Should a truce follow victory or defeat, and both, or either side be weary of the contest, the parties meet in congress, and an Araucanian Orator makes a speech on the evils of war, the advantages of peace, and the most eligible means of mutually preserving it. A branch of the cinnamon-tree is here a pacific emblem, as that of the olive is elsewhere. If the enemies are Spaniards, their President or leader makes an answer adapted to the circumstances of the case; and articles of treaty having been agreed upon, several *chilihueques* are sacrificed for its permanence. The Chiefs of each party then participate of a meal together, and presents are distributed to those of the Araucanians. It is affirmed, that, as the latter suffer least from warfare, and conduct it without much difficulty, they never sue for peace, and thence that the first overtures always proceed from the Spaniards, with whom they have incessantly been engaged in bloody and destructive contests. But it is rather to be inferred, from the best authorities, that they have not invariably felt equal confidence; and that their numbers, at the end of a war, have been so greatly diminished, as to make them as desirous as their foes of pacification. A congress must frequently be repeated, as without it, the Araucanians, a haughty race, would consider themselves neglected and despised, and go to war for no other reason.

Laws.

The civil code of these people is very limited, and, as well as their criminal laws, rest entirely on consuetudinary principles, none being written. The latter chiefly respect the punishment of murder, robbery, witchcraft, adultery, and treachery, which are all capital offences. The murderer, however, can escape by a pecuniary composition with the relatives of the deceased; and husbands and fathers are not subject to any punishment for putting their wives or children to death, because they are judged to be the natural masters of their lives. Persons accused of sorcery are first tortured by fire, on purpose to obtain a discovery of their accomplices, and then stabbed with daggers. Execution immediately follows the sentence, and justice is sometimes administered in a very irregular and tumultuous manner. Impatient of delay, the Araucanians often resort to the law of retaliation in lesser offences, which leads to the subversion of all public order, and is the source of many enormities in their turn becoming the objects of this kind of retributive justice.

Religion.

The religion of the Araucanians is a compound of absurdity invented by the designing or superstitious, and imposed on the blind and credulous whom they found ready to receive it; but, amidst that absurdity, containing some principles which have generally

Araucania. been admitted by the more reflecting part of mankind. They are said to believe in a Supreme Being, who has subordinate Deities, like their own subaltern officers. One of these is the god of war, another a benevolent, and a third a malevolent divinity, who is called *Guecubu*. This last is the most active agent of all others, and the source of every misfortune. If a horse dies, it is because the *Guecubu* has rode him; if the earth trembles, it is because the *Guecubu* has given it a shock; nor does a person ever die, who is not suffocated by the *Guecubu*. Such is the language of the Missionaries, from whom alone our principal knowledge of the Araucanians is derived. However, these Divinities receive no adoration; they have no temples, and only on occasion of some severe calamity, or the conclusion of a peace, are sacrifices offered to them. Then the Araucanians immolate animals, and burn tobacco, which is esteemed the most grateful incense. The Supreme Being, and the benevolent Deity, are invoked on urgent occasions,—those which most naturally induce mankind to seek the protection of superior powers. Christianity has never made any progress among this nation; and although the Missionaries are well treated, respected, and allowed ample liberty to preach their doctrines, they are utterly unsuccessful in making converts. The Araucanians are extremely superstitious; they have implicit confidence in omens and divination, particularly such as may be gathered from dreams, or the flight of birds; and he who has confronted death with intrepidity in battle, will tremble at the sight of an owl. They entertain uncommon apprehensions of pretended sorcerers, who they imagine keep under control a kind of beings partaking of the nature of men and animals, concealed in caverns by day, but let loose to transform themselves into nocturnal birds, that shoot invisible arrows at their enemies as they traverse the air. On all occasions they consult Soothsayers, who boast of their own powers, and give firm credit to their predictions. The immortality of the soul is a principle admitted by the Araucanians; they maintain that the human frame is compounded of two substances essentially different, one destructible on death, the other incorruptible and incorporeal, which exists for ever. They have also wavering ideas about a place of future reward and punishment, situated to the west beyond the sea; but regarding the actual state of the virtuous or the vicious, they are not agreed. Their funerals are ceremoniously conducted. The body of the deceased, clothed in his best attire, is laid on a high bier or scaffold, where it remains during the night, and the interval is passed by the relatives in weeping, or in eating with those who come to offer consolation. This meeting is called *caricahuin*, or the black entertainment. On approaching the place of interment, a woman walks behind strewing ashes on the way, to prevent the soul, it is supposed, from returning to its late abode; and the body being laid on the ground, is surrounded with arms and other instruments, and covered with a pyramid of earth or stones. Sometimes a horse is killed and inclosed among them. But no sooner do the relatives retire, than, according to their ideas, an old woman comes in the shape of a whale, to transport the deceased to the Elysian fields, though before his arrival, a toll is exacted by another old woman guarding a very narrow passage, who malevolently deprives the passenger of an eye, in event of refusal. In this Elysium the same functions are exercised by the souls of the deceased as on earth; husbands have the same wives, but the latter have no children, because that region cannot be inhabited by any but the spirits of the departed. They may revisit their own country, still possessing the same properties as when united to the body; and the Araucanians conceive that the tempests of wind, or thunder and lightning which they witness, originate from their furious combats in the air. A storm never happens among the Andes, or on the ocean, which they do not ascribe to a battle between the souls of their deceased countrymen, and those of the Spaniards; the roaring of the wind is the trampling of their horses; thunder the rolling of drums; and lightning the flashes of their artillery. If the course of the storm travels towards the Spanish frontier, they believe that the spirits of their countrymen are victorious; if it approaches their own territory, they are overwhelmed with consternation, and encourage them to be firm and resist their enemies.

Though the Araucanians wander about their own country, they are rarely seen out of it, unless while waging war; sometimes they cross to the eastern parts of South America, and, meeting with another tribe called Pampas, repair to Buenos-Ayres, there passing for the people of that nation.

History. Our knowledge of their history is limited nearly to the period when the American Continent was visited by Europeans in the fifteenth century; and as they are themselves destitute of written records, it must be sought among the Spanish Chronologers. About the year 1450, an Inca of Peru attempted the conquest of the extensive region of Chili, and consequently, of Araucania along with it; but his army retired on being defeated in a sanguinary engagement. A century later the Spaniards having gained a firm establishment in America, resolved to extend their conquests, but were obstinately opposed by the Araucanians with a body of 4000 men, led beyond their own confines; and their conduct on this occasion, though they did not prove victorious, impressed their enemies with apprehensions which have never abated. The Spaniards were at length enabled to form settlements within their boundaries; and sometime after, Pedro de Valdivia, a celebrated officer, was defeated in a pitched battle, taken prisoner, and dispatched with the blow of a club, about the close of the year 1553. A period of bloody warfare followed, which cost the Araucanians the life of their favourite commander Lautaro, whose talents were held in the highest esteem. Though sufficiently exasperated before, their resentment was inflamed still farther against the Spaniards for their barbarous mutilation of those unfortunate prisoners who fell into their hands. One of their bravest commanders Caupolican, being treacherously betrayed after a gallant resistance, was condemned to be impaled alive, and shot with arrows; but when brought to the place of punishment, and beholding the ignominy that awaited him, he hurled the executioner from the scaffold, exclaiming, "Is there no sword,

Araucania. and some less cowardly hand to be found to put to death a man like myself? This has nothing of justice in it,—it is base revenge." But the merciless Spaniards were deaf to his appeal. Various successes and discomfitures ensued, when, about the termination of the sixteenth century, the Araucanians besieged the enemy in the fortress of Puren. Unable to reduce the place so speedily as he desired, their chief presented himself before it, mounted on a fine horse recently taken from the governor, and challenged the Commander, Don Garcia Ramon, to single combat at the end of three days. The defiance being accepted, the Chieftains met, each accompanied by a small body of men who stood at a distance. Putting spurs to their horses, they advanced impetuously, but at the first encounter the Araucanian *Toqui* was pierced through the body by his adversary's lance. Refusing to acknowledge himself vanquished, he endeavoured to remount his horse, but in doing so expired. These events were followed by the siege of Villarica, a rich and populous city belonging to the Spaniards, which, after a resistance of two years and eleven months, fell into the hands of the Araucanians. A similar fate awaited Imperial and Osorno, other cities of equal importance, and their inhabitants were led into captivity. Incessant wars, with very short intervals of repose, occupied almost the whole of the seventeenth century, and thousands after thousands fell in their prosecution. But the Araucanians received an important accession to their strength, in the union of a warlike tribe called Puelches, which was thenceforth incorporated under the same government. The eighteenth century did not open more auspiciously; for although a cessation of hostilities had prevailed some time, the Araucanians became sensible that it afforded opportunities for the Spaniards to form new and permanent establishments within their territories: the arrogance of those who resided among them, under pretence of protecting the missionaries, had also excited their indignation. Villumilla, a man of low origin but distinguished abilities, was appointed military *Toqui*, or commander in chief, and formed a plan for expelling the Spaniards from the whole coast. But his attempt to raise his own and the neighbouring countries, in the year 1723, proved abortive, and the war was marked by nothing except some inconsiderable skirmishes. Peace having been restored, the Spanish governor conceived a scheme for the civilization of the Araucanians (regarded as chimerical by those best acquainted with their disposition), which was persuading them to live in cities. They agreed, however, to build a city, and were supplied with materials by the Spaniards, who also had assistants and superintendents on the spot, but suddenly seizing their arms, they killed their overseers, about the year 1753. Peace was once more interrupted by repeated encounters, and at length a bloody battle ensued in the year 1773. The Spaniards found themselves unable to retain any settlements within the Araucanians' territories, and the natives, in opposition to all the skill and force employed against them, have ever since been able to keep possession of their country. See the excellent work of Molina, on the *Natural and Civil History of Chili*, and Alcedo's *Geographical and Historical Dictionary*, Art. Chili. (s.)

Arcon. ARCON (J. C. E. Le Michaud D'), a French engineer and military writer of eminence, and memorable as the inventor of the *Floating Batteries* employed against Gibraltar, was born at Pontarlier in the year 1733. He was originally destined for the church; but, instead of employing himself in the studies suited to that profession, he became wholly engrossed with plans of fortifications, and was at length admitted, with the consent of his parents, into the Corps of Engineers. He distinguished himself at several sieges during the seven years' war; and had acquired so much reputation by his professional services and by his writings, that he was specially employed to assist in the last grand effort made by France and Spain for the reduction of Gibraltar, in 1782. It was about this period that he projected the famous floating batteries; an invention which inspired the combined armies with the greatest hopes of success, and which at first occasioned no small degree of alarm in the British garrison. "The battering ships," says Drinkwater, in his interesting account of this memorable siege, "were found to be no less formidable than they had been represented. Our heaviest shells often rebounded from their tops, whilst the 32 pound shot seemed incapable of making any visible impression upon their hulls. Frequently we flattered ourselves they were on fire; but no sooner did the smoke appear, than, with the most persevering intrepidity, men were observed applying water, from their engines within, to those places whence the smoke issued." Of the ultimate fate of these expensive and formidable engines of attack, all British readers must be sufficiently informed. Not one of the whole ten escaped destruction from the bombs and red-hot balls poured upon them from the garrison. M. D'Arcon, however, published a memoir to show, that his batteries were wilfully exposed to destruction through the envy and jealousy which the contrivance had excited among the Spaniards; and this statement seems to have obtained the general concurrence of his countrymen. But projectors do not readily admit any inadequacy in their schemes; nor will a vain-glorious people, who have been foiled in war, ever ascribe their disgrace to the superior skill or constancy of their enemy.

M. D'Arcon appears in the capacity of a General in the first years of the Revolution; and, in particular, was employed in the invasion of Holland, where, in 1793, he besieged and took several fortified places. He soon afterwards withdrew, or was driven from public life; and remained in retirement till 1799, when he was made a member of the Conservative Senate by Bonaparte. He died the following year, aged sixty-seven. He was a member of the Institute, and author of the following works:—1. *Reflexions d'un Ingenieur, en reponse à un Tactitien*, 1773, in 12mo. 2. *Correspondance sur l'Art de la Guerre, entre un Colonel de Dragons et un Capitaine d'Infantrie*, 1774, in 8vo. 3. *Defense d'un Systême de Guerre Naturale*, &c. 1779, in 8vo. 4. *Mémoires pour servir à l'Histoire du Siege de Gibraltar*, 1783, in 8vo. 5. *Considerations sur l'Influence du Genie de Vauban dans la Balance des Forces de l'Etat*, 1786, in 8vo. 6. *Examen detaillé de l'Importante Question de l'Utilité des*

Arcy ‖ Argyleshire.

*Places Fortes, et Retranchements*, 1789, in 8vo. 7. *De la Force Militaire Considerée dans ces Rapports Conservateurs*, 1790, in 8vo. 8. *Considerations Militaires et Politiques sur les Fortifications*, 1795, in 8vo. This work was published at the expence of the Government, and contains a sort of digest of all his observations and opinions on military subjects. —See *Biographie Moderne*, Tom. I. and *Biographie Universelle*, Tom. II.

ARCY (Patrick D'), Member of the Academy of Sciences of Paris, a general officer in the French army, Chevalier of the order of St Louis, &c. was born in Ireland in 1725. His parents, in consequence of their attachment to the House of Stuart, left Ireland, and settled in France. He studied Mathematics with distinguished success under Clairaut the elder, and had for his fellow-student the celebrated Clairaut the son. He obtained a commission in the French army; and, in 1746, was embarked in the expedition which was intended to make a descent in Scotland. He was made prisoner, and was treated like other prisoners of war, no notice being taken of his having been born a British subject. He continued attached to the House of Stuart during the whole of his life.

In 1760, he published his *Essay on Artillery*. To estimate the force of the explosion of gun-powder, he employed a cannon suspended, so that the arc of vibration described by it on its being fired, was a measure of the force of explosion. To measure the initial velocity of a projectile, he used Robins's machine. Robins showed, that when the velocity of a projectile is great, the resistance opposed by the air is not in proportion to the square of the velocity, as is the case when the velocity is small. D'Arcy made experiments with a view of ascertaining this law, but without success. His work contains an account of experiments made by him to determine the most advantageous length of cannon. He published a paper on hydraulic machines in 1754, where he treats of the maximum of effect of water-wheels. He also published a paper concerning the duration of the impression of light on the retina. He found that the revolution of a luminous point must be rapid, so as to be performed in $\frac{8}{60}$ of a second at the least, in order to produce the appearance of a continued luminous circle.

He was of a handsome figure, and passed much of his time in the gay world. A short time before his death he married a young lady his niece, and took the title of Count. Although attached to the House of Stuart, and therefore inimical to the English Government, yet he admired the national character of the English, and was attentive to English travellers. He died in 1779, and was succeeded at the Academy by the Abbé Bossut. (Y.)

Mainland.

ARGYLESHIRE, or Argyllshire, an extensive County in the west of Scotland, is usually described under two great divisions,—the mainland, and such of the Western Islands as are politically attached to it. It is of the former only, that we propose to give some account at present, referring to the article Hebrides for the Islands noted below,* which form a part of this County.

Situation.

The mainland of Argyleshire, situate between 55° 21′ and 57° north latitude, and between 1° 22′ and 3° 25′ of longitude west from Edinburgh, is bounded by Inverness-shire on the north, by the Shires of Perth and Dumbarton on the east, by the Irish Sea on the south, and by the Atlantic Ocean on the west; the Firth of Clyde, which separates it from the Shire of Renfrew, forming its boundary on the south-east. Its greatest length, from the Mull of Kintyre on the south, to the point of Ardnamurchan on the north, is 115 miles; its breadth above 68; and from the windings of the numerous bays and creeks with which the land is everywhere indented, it is supposed to have more than 600 miles of sea-coast. Of 27 parishes into which the mainland of Argyleshire is divided, two of which belong in part to Inverness-shire, only one is altogether inland. The extent of this part of the County, of which the land comprehends 2200 square miles, and the lakes 60, is equal to about one-thirteenth part of the whole of Scotland.—Having pointed out the principal divisions, and given a general view of the surface in the article in the body of the work, we shall here confine our notices to the industry and condition of its inhabitants.

Extent.

Agriculture.

The only crops cultivated to any extent on the mainland of Argyleshire, are bear or bigg, oats, and potatoes. A little wheat is raised near Campbelltown, and in other parts of Kintyre; and a few patches of turnips are occasionally seen, but chiefly on the farms of proprietors. Clovers also, though more frequent, have not yet come into extensive culture, notwithstanding these, and other green crops, are better adapted, both to the climate and the leading branches of the husbandry of the country, than grain. The principal object in the culture of bigg is the supply of the distilleries. The great body of the inhabitants live almost exclusively on oatmeal and potatoes; of the former of which they have been in the practice of importing about 20,000 bolls (of 140 lbs.) annually. Considerable progress, indeed, has been made of late in the improvement of agriculture, but this is necessarily limited by the small proportion of land fit for profitable cultivation; there being only 125,000 acres arable out of 1,408,000 which this part of Argyleshire contains; as well as by the mode in which, till very lately, farms were held—without leases—and for performance of many vexatious services. Even, at this time, we can recognise in Argyleshire the prominent features of the feudal ages,—a few great proprietors, and a numerous tenantry, indolent and poor. Of the valued rent, taken in 1751, of the mainland, with four small Islands, amounting to L.9924, 8s. 1d., almost a fourth belongs to two pro-

Valued Rent.

* Those of the first rate are Islay, Mull, and Jura; of the second,—Gigha, and Cara, Colonsay, Lismore, Tyree, Coll, Ulva and Gometra, Kerreray, Luing, Seil or Saoil; and of the third,—Scarba, Lunga, Shuna, Icolmkill or Iona, Eisdale, Inch Kenneth, Staffa, Monk, Rum, and Cannay.

Argyleshire. proprietors. This valuation was considered to be equal to the half of the real rent at that period, after deducting all public burdens; but in 1798, when the agricultural survey of the County was published, the gross rental had risen to L. 89,000, collected from upwards of 2700 tenants; and in 1811 the rent of the whole County, of which the Islands might produce about a fifth, amounted to L.192,073, 14s. 2d. for the lands, and for the houses to L.5208, 18s. 10d. The frequent transference of landed property, which has taken place in this County within the last fifty years, and the example and encouragement of the Duke of Argyle, the greatest landholder in it, cannot fail to extend a more beneficial system of rural economy.

Real Rent.

Cattle.

Cattle were long the principal source of the revenue of the landholders and tenantry of Argyleshire; and the native breed, which has been improved of late by more careful treatment, is well known to be equal, if not superior, to any other race of cattle in the kingdom. Their number in 1798 was computed at upwards of 50,000, and they are understood to have increased since; for though they are now excluded from the more elevated tracts, which are more profitably occupied by sheep, the improved management of the lower grounds has, upon the whole, enlarged the means of their subsistence. These cattle are sent from the country in a store condition, commonly when about three years old, and fatted on the pastures of the south, the greater number for the consumption of England. The dairy begins to be an object of attention in the peninsula of Kintyre, where there is a large proportion of arable land, but cannot be extended to the inland and more mountainous districts of the county.

Sheep.

Until the middle of last century, the only sheep in Argyleshire (and their number was inconsiderable), were of the small native race, the same that are still to be found in the Hebrides, and in most parts of the Highlands of Scotland and of Wales. About that period coarse woolled heath sheep were introduced into the higher and more barren districts; and as it was soon discovered that the scanty herbage of these gloomy mountains, could be converted into a much greater quantity of mutton than of beef, besides yielding a valuable article of manufacture,—these hardy animals soon spread over extensive regions, upon which cattle could barely subsist in the summer months: and the income of the landed proprietors, and of the public, was accordingly augmented in proportion. Notwithstanding the outcry of ignorance, and the more mischievous speculations of mistaken philanthropy, the introduction of this species of live stock, now increased to about 300,000, has not, as we shall see immediately, had the effect of diminishing the population of Argyleshire.

Woods and Plantations.

In this division of the County, there is a considerable extent of natural coppice woods; probably near 40,000 acres, which are cut periodically, commonly every 19 or 20 years, and are understood to return about 20s. per acre annually. Very extensive plantations have been formed by the Duke of Argyle and other proprietors. About 20 years ago, those of his Grace were reckoned to contain 2,000,000 of trees, then worth 4s. each, amounting to the enormous sum of L. 400,000.

Fisheries.

Next in importance to its agriculture, are the fisheries, which, from the great extent of sea coast, and the form of the district, penetrated in almost every direction by arms of the sea, and traversed by extensive lakes, ought to furnish food and employment to the inhabitants, to an extent, perhaps, still greater than their barren territory and ungenial climate can supply. Some notion of their great importance may be formed, when we are told that the herrings caught in Lochfine alone, in the years 1794 and 1795, were computed to be worth more than L. 80,000 (Smith's *Survey*, 1798). But the regulations of the revenue laws in regard to salt are universally complained of, as an intolerable grievance; forming an insuperable obstruction to the industry of the lower classes, who have not the means, nor even the knowledge, which a strict compliance with these regulations requires. Whole cargoes of herrings have been thrown into the sea in a putrid state, and others used as manure, in consequence of the inability of the fishermen to find surety for the requisite supply of salt, according to law.

Mineralogy.

The mainland of Argyleshire is principally composed of primitive rocks, which, in some quarters, are skirted and intermixed with those of the transition class; while flœtz rocks occur very sparingly. No volcanic rocks have hitherto been met with in the mainland of Argyleshire, but those of an alluvial nature abound everywhere. The primitive and transition rocks are stratified, and the general direction of the strata is from NE. to SW. The primitive rocks are granite, gneiss, mica slate, clay slate, limestone, porphyry, sienite, trap, and quartz rock. The transition rocks are greywacke, greywacke slate, clay slate, trap, and quartz; and the flœtz rocks are red sandstone, conglomerate, and rocks of the coal formation. The Islands off the coast of Argyleshire afford highly interesting examples of rocks of the different classes; Isla and Jura of the primitive and transition rocks; Mull of flœtz and primitive rocks; Staffa, Rum, and Cannay, of flœtz rocks; and Coll, Tyree, and Iona, of primitive rocks.

Coal has been wrought for many years near Campbelltown in Kintyre, and lead at Strontian in Sunart; and besides the slate quarries of Eisdale, an Island belonging to this County, others have been opened at Ballachelish in Appin.

Manufactures.

Manufactures have made little progress in this district, and no attempts to establish them upon a large scale have yet been successful. Mr Dale endeavoured to extend to it some branches of the cotton manufacture, which failed, it is said, from want of water carriage; but a number of weavers in Campbelltown and its neighbourhood, have been employed for some time in working cottons from Glasgow. The late Duke of Argyle, almost 40 years ago, set on foot a woollen manufactory near Inverary, which, notwithstanding very uncommon encouragement given to it by his Grace and the other landed proprietors, has been long in rather a languishing state. There is a bleachfield in Kintyre; tanneries at Campbelltown and Oban; iron works in Upper Lorn and at Loch-

Argyleshire. fine, below Inverary, belonging to English companies, who bring the ore thither, chiefly for the sake of the charcoal which the woods afford; and near Campbelltown, the formation of salt from sea water has been lately carried on to some extent. The manufacture of kelp from sea weed, to the extent of 600 tons annually, is none of the least profitable branches of industry; and that of their scanty crops of grain into ardent spirits, certainly the most pernicious.

Commerce. The commerce of Argyleshire is also very limited, its exports consisting chiefly of raw produce; sheep and cattle, and fish, form at least two thirds of the whole: The imports are almost confined to the supply of necessaries, including only such articles of luxury, as habit has rendered scarcely less indispensable.

But, though such is the present state of this extensive territory, there is reason to anticipate a great increase of its wealth, of its industry, and of its population, as soon as a revisal of the revenue laws shall have removed the present obstacles to the prosecution of the fisheries. It is upon this species of industry, that the prosperity of the County must be founded; and it is only after wealth has flowed in from this source, that the inhabitants can be expected to succeed in manufactures or in commerce. To its natural advantages, a very important addition has been made by the Crinan Canal, cut across the peninsula of Kintyre, at an expence of L. 140,000; which shortens the voyage from the West Highland and Hebridian ports, to the river Clyde, about 200 miles. The Caledonian Canal, from the access it will give the County to the German Ocean, and still more, from the frequent intercourse of which it will be the channel, must contribute, in an eminent degree, to the prosperity of Argyleshire. Canals.

The population of the whole County, as taken under the Acts 1800 and 1811, will be seen from the following Tables: Population.

1800.

| DISTRICTS. | HOUSES. | | | OCCUPATIONS. | | | PERSONS. | | |
|---|---|---|---|---|---|---|---|---|---|
| | Inhabited. | By how many Families occupied. | Uninhabited. | *Persons* chiefly employed in Agriculture. | *Persons* chiefly employed in Trade, Manufactures, or Handicraft. | All other *Persons* not comprised in the two preceding classes. | Males. | Females. | Total of Persons. |

* No returns for Kilfinichen and Kilvicuen; population in 1791, 3002
Tyree, population in 1792, - - 2416
Rum, Cannay, and Muck, population in 1795, - 940

6358

The whole population in 1800 must therefore have amounted to 78,217. (A.)

# ARITHMETIC.

Introduction.

The *Encyclopædia* contains a short treatise of Arithmetic, constructed in the ordinary way. But a philosophical exposition of the principles of numerical calculation has long been a desideratum in our systems of elementary instruction. The operations of Arithmetic, from being so common, are apt to be reckoned vulgar, and hence abandoned to the blind and mechanical application of certain rules. Yet the study of numbers, if rightly directed, is admirably fitted for opening the mind, and training it to habits of accurate thought, which are of such vast importance to the pupil, whether he means afterwards to engage in the details of business, or aspires to the ulterior pursuits of science. But the theory of numeration acquires a higher interest, from its being closely interwoven with the texture of human society. The diligent inquirer may trace, in the obscure vestiges of ancient language and practice relative to numbers, the slow progress of the mind, from the first dawnings of reason to the full illumination of day. What a vast interval, in the range of intellectual achievement, from the knots or shells which the ferocious savage employs in reckoning his prisoners, to that magic play of figures by which the astronomer, instructed in all the refinements of calculation, and aided by the sublime invention of logarithms, penetrates through time and space, and determines with unerring certainty the changes of the heavens in future ages!

We purpose, therefore, in this article, to give a philosophical view of the Elements of Arithmetic. But our object is, only to sketch the great outlines of the science, without descending to all the subordinate or practical details. The exposition of those principles in a simple form may proceed with ease, and will derive additional interest from the variety and importance of the collateral discussions which it involves. We shall endeavour to elucidate the origin of numbers, to trace their early application, and to connect the progress of arithmetical computation with the history of civil society. But to succeed in the performance of this task, it would require much patient and laborious research in quarters which have hitherto remained almost unexplored. Where so many difficulties must be surmounted, the first attempt will need some portion of indulgence. We shall endeavour to maintain perspicuity, though at the risk of appearing tedious. But while intently pursuing the chief object, we may sometimes fail in observing the due proportions in the distribution of the subordinate parts of the discourse.

Arithmetic may be viewed under two very distinct forms, that would require separate appellations. 1. *Palpable Arithmetic*, in which numbers are exhibited by counters, or abbreviated representatives of the objects themselves; and, 2. *Figurate Arithmetic*, in which numbers are denoted by help of certain symbols, or artificial characters, disposed after a particular order. The progress of Arithmetic is analogous to that of writing, but it has followed the advances and transitions of this sublime art at a great distance. The numeration by counters, balls, or strokes, evidently resembles hieroglyphics or picture-writing; while the invention of the alphabet, so happily contrived for the rapid transmission of thought, probably led the way to the subsequent discovery of the science of *Figurate Arithmetic*, founded nearly on similar principles. These capital divisions of Arithmetic we shall consider in succession.

Introduction.

## PALPABLE ARITHMETIC.

The idea of number, though not the most easily acquired, remounts to the earliest epochs of society, and must be nearly coëval with the formation of language. The very savage, who draws from the exercise of fishing or hunting a precarious support for himself and family, is eager, on his return home, to count over the produce of his toilsome exertions. But the leader of a troop is obliged to carry farther his skill in numeration. The systematic practice of war and murder has ever distinguished our species from other animals of prey. The chieftain who prepares to attack a rival tribe, marshals his followers; and, after the bloody conflict has terminated, he reckons up the slain, and marks his unhappy and devoted captives. If those numbers were small, they could easily be represented by very portable emblems, by round pebbles, by dwarf-shells, by fine nuts, by hard grains, by small beans, or by knots tied on a string. But to express the larger numbers, it became necessary, for the sake of distinctness, to place those little objects or counters in regular rows, which the eye could comprehend at a single glance; as, in the telling of money, it would soon have become customary to dispose the rude counters, in two, three, four, or more ranks, as circumstances might suggest. The attention would then be less distracted, resting chiefly on the number of marks presented by each separate row.

Language insensibly moulds itself to our wants. But it was impossible to furnish a name for each particular number: No invention could supply such a multitude of words as would be necessary, and no memory could ever retain them. The only practical mode of proceeding was to have recourse, as on other occasions, to the powers of classification. By conceiving the individuals of a mass to be distributed into successive ranks and divisions, a few component terms might be made sufficient to express the whole. We may discern around us traces, accordingly, of the progress of numeration, through all its gradations.

The earliest and simplest mode of reckoning was by *pairs*, arising naturally from the circumstance of both hands being employed for the sake of expedition. It is now familiar among sportsmen, who use the names of *brace* and *couple*, words that signify *pairing* or *yoking*.—To count by *threes* was another step, though not practised to the same extent. It has been preserved, how-

ever, by the same class of men, under the term *leash*, meaning the strings by which *three* dogs and no more can be held at once in the hand.—The numbering by *fours* has had a more extensive application: It was evidently suggested by the custom, in rapid tale, of taking a pair in each hand. Our fishermen, who generally reckon in this way, call every *double pair* of herrings, for instance, a *throw* or *cast*; and the term *warp*, which, from its German origin, has exactly the same import, is employed to denote *four*, in various articles of trade.

Those simple arrangements would, at their first application, carry the reckoning but a very little way. To express larger numbers, it was necessary to repeat the process of classification. The ordinary steps, by which language ascends from particular to general objects, might point out the right path. A collection of *individuals* forms a *species*; a cluster of *species* makes a *genus*; a bundle of *genera* composes an *order*; and a group of *orders* perhaps constitutes a *class*. Such is the method indispensably required in framing the successive arrangement of the almost unbounded subjects of Natural History. A similar mode is pursued in the subdivision and distribution of the members of a vast army.

In following out the classification of numbers, it seemed easy and natural, after the first step had been made, to repeat the same procedure. If a heap of pebbles were disposed in certain rows, it would evidently facilitate their enumeration, to break each of those rows into similar parcels, and thus carry forward the successive subdivision till it stopped. The heap, so analysed by a series of partition, might then be expressed with a very few low numbers easily formed, and capable of being distinctly retained. The particular system adopted, would soon become clothed with terms borrowed from the vernacular idiom.

Let us endeavour to trace the steps by which a child or a savage, prompted by native curiosity, would proceed in classing, for instance, *thirty-nine* similar objects. He might be conceived first to arrange them by successive *pairs*. Selecting *thirty-nine* of the smallest shells or grains he could find, he would dispose these in *two* rows,

each containing *nineteen* counters, with *one* over. Having thus reduced the number to *nineteen*, he might subdivide this again, by representing only one of the rows with shells twice as large as before.

He would consequently obtain two rows of *nine* each, with an excess of *one*. Instead of these shells, were he to employ shells of a double size, it would be sufficient to denote one of the rows, or to dispose it into *two* rows. These rows contain only *four* counters with *one* over.

Again, by adopting counters of a double size, the last row might be represented by one pair,

each containing only *two* marks exactly. These again could be denoted by a *single pair* of counters, having twice the former dimensions.

As a final analysis, *one* counter, of double dimensions, will express the last row.—Hence the number *thirty-nine*, decomposed by repeated *pairing*, would be denoted by *one* counter of the *sixth* order, *one* of the *third*, *one* of the *second*, and another of the *first*.

Suppose a person should attempt to represent the same number, by *triple* rows of shells or counters. He would first have *thirteen* of the smallest shells in each row, and no more.

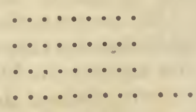
Then, expressing one of the rows by shells of *three* times the size or value, it would be again resolved into *three* rows, each containing *four* counters, with an excess of *one*.

Taking the *last* of these rows, therefore, and employing counters of triple size, it would be represented by *a column* of single counters, with *one* over.

Finally, this column would be marked by a single tripled counter.

—The number *thirty-nine* is thus expressed, on the system of *triplication*, by *a counter* of the fourth order, *one* of the third, and *another* of the second.

Lastly, conceive the number *thirty-nine* to be reckoned by *double pairs* or *quadruple* rows. Each row would then contain only *nine* counters, with an excess of *three*.



But a *single row* would express the same as all these *four*, if each counter in it were changed into another of quadruple size or value; and, consequently, this row might be again distributed into *four* ranks, each consisting of only *two* marks, with *one* left.

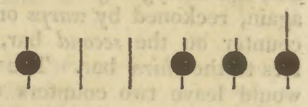
Retain one of these ranks, and substitute counters of *quadruple* effect, and *two* such will express the whole amount.

—Hence *thirty-nine*, analysed by the system of *double pairs* or *warps*, would be represented by two counters of the *third* order, one of the *second*, and three of the *first*.

In the ruder periods of society, a gradation of counters, accommodated to such a process of numerical analysis, was supplied by pebbles, grains, or shells of different sizes. This series, however, is very limited, and would soon confine the range of decomposition. To reach a greater extent, it was necessary to proceed by a swifter analysis; to distribute the counters, for instance, successively into ten or twenty rows, and to make pebbles, shells, or other marks, having their size only doubled perhaps or tripled, to represent values increased ten or twenty

fold. Beyond this stage in the progress of numeration, none of the various tribes dispersed over the vast American Continent seem ever to have passed. In the Old World, it is probable that a long pause of improvement had ensued among the nations which were advanced to the same point in the arts of life. But the necessity, in such arithmetical notation, of employing the natural objects to signify a great deal more than their relative size imports, would lead at last to a most important step in the ascent. Instead of distinguishing the different orders of counters by their *magnitude*, they might be made to derive an *artificial value* from their *rank* alone. It would be sufficient, for that purpose, to employ marks all of the same kind, but disposed on a graduating series of vertical bars or columns. The augmented value which these marks acquire in rising through the successive bars, would evidently be quite arbitrary, depending, in every case, on a key to be fixed by convention. This point in the chain of discovery was attained by the Greeks at a very early period, and communicated to the Romans, who continued, during their whole career of empire, to practise a sort of tangible arithmetic, which they transmitted to their successors in modern Europe. The Chinese also have, from the remotest antiquity, been accustomed to employ a similar mode of calculation, which they are said to manage with singular skill and address.

Resuming, therefore, the number *thirty-nine*; if it were distributed by successive *pairing*, it would be thus denoted on a series of six vertical bars.



The same number, decomposed by a repeated *trisection*, will assume a simpler appearance, being comprised in *four* bars.

But *thirty-nine*, when analysed by a succession of *double pairs*, would require for its expression six counters arranged on three bars.

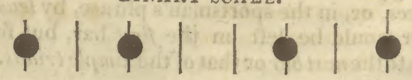
Suppose the objects to be reckoned were so numerous, that *one hundred and sixty-five* counters might be required to represent them. Placed in a single row, these counters would only give the very confused idea of multitude. But, if counted by *pairs*, or divided into two rows of *eighty-two* each, with an odd *one*, they would become a little more distinct. Were every counter now, in each row to denote a pair, a single row of them would have the power of both. Let this row be reckoned again by pairs, and it will change into two higher rows, each consisting of *forty-one* counters, without any excess. But one of these *third* rows would be sufficient alone, if each counter in it were esteemed equal to a *pair* in the *second* rows, or equal to a *duplicate pair*, or *four* in the *first* row. Again, tell one of the *third* rows over by pairs, and the *forty-one* counters will be converted into two *fourth* rows, containing *twenty* each, and *one* over. In like manner, each counter of a *fourth* row, being conceived equal to a pair in the *third* row, or a *triplicate pair*, that is, *eight* on the *first row*, a single row, including *twenty* of those higher counters, would have the same effect. Now, this *twenty* would be reduced to a pair of rows of *ten* counters each. Let each counter in the *fifth* row have the power of two in the *fourth* row, or of a *quadruplicate pair*, or *sixteen* in the *first row*; and *ten* such counters would be sufficient. But *ten* would give *five* pairs of *sixth* rows, one of which might denote the whole, if each counter in it were held equal to *two* in the preceding row, or to a *quintuplicate pair*, or *thirty-two* on the *first row*. Again, the last *five* counters would be divided into *two pairs* and *one* counter, and these two pairs into a *single pair* of a higher order.

This analysis appears tedious when so detailed, but it would proceed with great ease and rapidity in practice. The number *one hundred and sixty-five* would, therefore, on the system of successive *pairing*, be expressed by *one septuplicate pair*, *one quintuplicate pair*, *one duplicate pair*, and *one*. The language seems very uncouth, merely from its novelty and inaptness to our idiom; but its elements are extremely clear and simple. If a few cognate words had been devised to express the several combinations of pairs, or the ascending scale of the powers of two; it would have removed every objection.

Binary Scale.

This arrangement, whereby a number is analysed into certain elements by the operation of distributing it and its sections into successive *pairs* or *duads*, may be called the *Binary Scale*, of which *two* is the *root* or *index*. This scale, resting on so narrow a basis, expands slowly, and is therefore not very fit for expressing large numbers by words. But it is well adapted for the simplicity of emblematic exhibition. Suppose marks or counters were placed in perpendicular rows or parallel bars, proceeding from the right hand to the left, such that a counter on any bar should be equivalent to *two* laid on the bar immediately before it. Instead of putting the *hundred* and *sixty-five* counters on the *first* bar, it would be the same thing to leave *one* on that bar, and place *eighty-two* on the next. But instead of *eighty-two* counters on the *second bar*, the effect would be the same, to pass over it, and put *forty-one* on the *third bar*. Counting these *forty-one* also by pairs, we should leave *one* on the *third* bar, and carry *twenty* to the next. But twenty divided into successive pairs, would leave the *fourth* and *fifth* bars vacant, and throw *five* on the next. The *five* again would, after bisection, leave *one* on the *sixth* bar, and transfer *two* to the *seventh*; or, passing over this, they would carry *one* to the *eighth* bar. The decomposition thus effected would appear as below; where only *four* counters, and as many blanks, are sufficient to exhibit the number *one hundred* and *sixty-five*. By this elementary arrangement, a very distinct idea is conveyed: The eye can easily catch the picture, and the memory preserve it.

BINARY SCALE.



A similar effect would be produced, though much less clearly, by the combination of strokes, or of Runic sculpture, as thus represented.

Palpable Arithmetic.

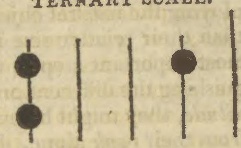
The advantages of the binary scale of notation were prodigiously extolled by the celebrated Leibnitz, who condescended even to write a discourse on its use and mode of adaptation. This very learned, original, and indefatigable philosopher, had the satisfaction to discover, from the researches of ingenious Missionaries, and particularly from the letters of Father Bouvet, some feeble traces of the *Binary Notation* in the early history of China. Fou-hi, the first Emperor and founder of that vast monarchy, is venerated in the East as a promoter of Geometry, and the inventor of a science, the knowledge of which has been since lost. The emblem of this occult science consists of eight separate clusters of three parallel lines or *trigrams*, drawn one above another, after the Chinese manner of writing, and represented either entire or broken in the middle. Those varied trigrams were called *Koua* or *suspended symbols*, from the circumstance of their being exposed in the public places. In the composition of such varied clusters, it was not difficult for the sagacity of Leibnitz to perceive the application of the *Binary Scale* carried only to three ranks, or as far as the number *eight*. The entire lines signify *one, two*, or *four*, according to their order, while the broken lines are void, and serve merely to indicate the rank of the others. Before this invention, the only mode of reckoning used in China was by knots tied on a single cord. In Plate XXVII. the Emperor is figured, pointing with a *stylus* at the two-fold progression; being copied exactly from the third volume of the *Mémoires sur les Chinois*, omitting only the grotesque portrait of the Sage. Those emblems were besides intended to convey a store of mystical or mythological knowledge. In the trigrams of Fou-hi, the pious and orthodox Missionaries could not fail to discover certain edifying traces of the mystery of the Trinity, at an epoch perhaps as remote as that of the Deluge.

The next Emperor, Chen-noung, devoted his attention chiefly to the improvement of agriculture. But he likewise extended the *Kona* or the dualic system of his predecessor, employing hexagrams instead of trigrams. These hexagrams were formed with six parallel lines, broken or entire, and placed one above the other. In short, they were the first six bars of the binary scale, of which the last term would represent thirty-two, and all the terms together would reach to *sixty-four*. *Chen-noung* contrived that the hexagrams should likewise exhibit sixty-four varieties of combination, by placing them in eight rays issuing from the same central space which was occupied by one of the eight trigrams. See *Mémoires sur les Chinois*, Tome II. p. 189, Planche viii.

Ternary Scale.

The *Ternary Scale* of numeration, which reckons by successive *threes* or *triads*, advances with more speed. Thus, suppose, as before, that *one hundred and sixty-five* were to be exhibited on it. Counted by *threes*, or, in the sportsman's phrase, by *leashes*, no counter would be left on the *first* bar, but fifty-five thrown to the *next bar* or that of the *simple triads*. These fifty-five counters, being again told by threes, would leave one on the *second* bar, and carry eighteen to the *third* bar, or that of *duplicate triads*. This eighteen, counted twice in succession, would pass over the *fourth* and *fifth* bars, and throw *two* marks to *sixth bar*, or that of *quintuple triads*. The original number so decomposed, might therefore be denominated *two quintuple triads*, and *one single triad*. It is denoted by three counters, as in the form here annexed.

TERNARY SCALE.



The number might likewise be readily expressed, though less perfectly, by combined strokes or points.

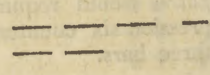
It is apparent that the *Ternary* Scale, though more powerful than the *Binary*, requires two sets of marks or counters. In the example now taken, each counter on the ascending bars represents *three, nine, twenty-seven*, or *eighty-one;* and the number itself is consequently split into two *eighty-ones* and *three*.

Quaternary Scale.

Let still the same number be arranged on the *Quaternary Scale* which proceeds by *Fours* or *Tetrads*. *One hundred and sixty-five*, told over by *double pairs* or *warps*, would leave *one* counter on the *first* bar, and carry *forty-one* to the next. This *forty-one* again, reckoned by *warps* or *throws*, would drop *one* counter on the *second* bar, and transfer *ten* counters to the *third* bar. The *ten* being now counted, would leave two counters on the *next* bar, and carry *two* to the *fourth* bar. The original number would therefore be described as containing *two triplicate tetrads, two duplicate tetrads, one tetrad and one;* and it would be designated in this manner:

QUATERNARY SCALE.

Or, if the less satisfactory mode of strokes were employed, *one hundred and sixty-five* would be thus exhibited.



This number is analysed into *twice sixty-four, twice sixteen, four*, and *one*. *Three* sets of counters would evidently be required to fit this scale for its application.

The *Quaternary Scale* may be considered as a reduplication of the *Binary*, each bar of the former comprizing two bars of the latter. This effect will appear more conspicuous by comparing the same number as it was exhibited on both scales. It is alleged that the Guaranis and Lulos, two of the very lowest races of savages which inhabit the boundless forests of South America, count only by fours; at least that they express five by four and one, six by four and two, and so forth. We may gather from Aristotle, that a certain tribe of Thracians were accustomed to use the quaternary scale of numeration; for he says that they proceeded no farther than *four*,*

* Μόνοι δὲ ἀριθμοῦσι τῶν Θρακῶν γένος τὶ ἐις ΤΕΤΤΑΡΑ. *Arist.* Problemat. xv. 3.

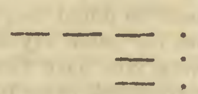
which they would doubtless continue to repeat. If such was the historical fact, those simple people must have never advanced beyond the early practice of reckoning successively by *casts* or *warps*. It seems probable that Pythagoras was acquainted with the quaternary system, which he brought from Egypt and India. Hence perhaps the mystical veneration which the followers of that philosopher professed to entertain for the *tetractys* or *quaternion*, the root of the scale, which contains besides, within itself, the number denoting the elementary musical proportions. Near the end of the seventeenth century, Weigelius seriously proposed, in Germany, the adoption of the *Tetractyc* or *Quaternary* numeration, which he explained, with copious detail, in a learned work entitled *Aretologistica.**

**Quinary Scale.**

To advance a step farther, let the same number be represented on the *Quinary Scale*, which reckons by the series of *fives* or *pentads*. Classed in this way, it would pass over the *first* bar, and throw *thirty-three* counters to the *second*. Told over again, it would leave *three* counters on the *second* bar, and carry *six* to the *third;* and the *six*, reckoned by *fives*, would drop *one* counter on the *third* bar, and advance one to the *next*. *One hundred and sixty-five* would therefore be denominated *one triplicate pentad, one duplicate pentad*, and *three single pentads;* and it would be thus denoted:

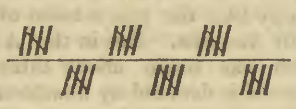
QUINARY SCALE.

This number might also be exhibited on the same scale by the combination of strokes with dots:



By this classification, the number *one hundred and sixty-five* is divided into *one hundred and twenty-five, twenty-five*, and *three fives*. The *root* or *index* of the scale being five, it would require *four* sets of counters to adapt it for practice.

The first bar of the *Quinary Scale* is actually used in this country among traders. In reckoning articles delivered, the person who takes charge of the *tale*, having traced a long horizontal line, continues to draw, alternately above and below it, a *warp* or four vertical strokes, each set of which he crosses by an oblique score, and generally, we believe, calls out *tally!* as often as the number *five* is completed.



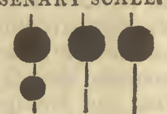
&c.

The *Quinary* system has its foundation in nature, being evidently derived from the practice of counting over the fingers of one hand. It appears accordingly, at a certain stage of society, to have been adopted among different nations. Thus, the Omaguas and the Zamucas of South America reckon generally by *fives*, which they call *hands*. The Toupinambos, a most ferocious and warlike race that inhabit the wilds of Brazil, would seem, according to the relation of Lery, to use the same kind of numeration. To denominate six, seven, and eight, those tribes only join to the word *hand*, the names for one, two, and three. The same mode, as we learn from Mungo Park, is practised by some African nations; particularly the Yolofs and Foulahs, who designate *ten* by *two hands, fifteen* by *three hands*, and so progressively. The *Quinary Numeration* seems likewise, at a former period, to have obtained in Persia, for the word *pentcha*, which denotes *five*, is obviously derived from the radical term *pendj*, signifying a *hand*.

**Senary Scale.**

When the index of the scale is larger, it often becomes inconvenient to place so many counters as are wanted on the same bar. But this notation may be abridged in the case where the index is even, by adopting a counter of greater dimensions, to signify the half of it. Suppose *one hundred* and *sixty-five* to be disposed in the *Senary Scale*, which proceeds by successive *sixes* or *hextads*. Parted into *six* rows, that number would leave *three* counters on the *first* bar, and cast *twenty-seven* to the next; this *twenty-seven*, being reckoned by sixes, would drop *three* counters on the *second* bar, and transfer *four* to the *third* bar. The original number would hence be described as *four duplicate hextads, three single hextads*, and *three*. But instead of placing *three* counters on the first and second bars, and *four* on the third bar, one large counter may supply the place of three; as in the form here annexed.

SENARY SCALE.



The *Senary* arrangement has few advantages to recommend it; yet it seems at one period to have been adopted in China, at the mandate of the Emperor CHE'-HOANG-TI. This capricious tyrant, who murdered the *literati* and burnt their books, having conceived an astrological fancy for the number *six*, commanded this to be used in all concerns of business or learning throughout his vast Empire. He directed a sort of arithmetic to be composed, with *six* for its basis; and he enjoined, that all weights and measures should be arranged on the same scale. He divided China into six times six, or thirty-six, provinces; and was so much enamoured of this favourite number, as to order his chariot to be just six feet long, and to be drawn by six horses, with only six attendants.

---

* This writer even goes so far as to invent names for the several orders of his *Tetractyc System*. They will appear to have a sufficiently German air, though not harsher than the terms we now use.

Weigelii, *Aretologistica vel Logistica Virtutum Genetrix.* Norimbergæ, 1687.

Palpable Arithmetic.

Octary Scale.

Let the *Octary Scale*, which proceeds by successive *eights* or *octads*, be treated in a similar way. The original number, being reckoned by *eights*, would leave *five* counters on the *first* bar, and throw *twenty* to the next; and this *twenty* being told over again by *eights*, would leave *four* counters on the *second* bar, and carry *two* to the *third*. If, therefore, the large counter signify half the index, or four, *one hundred and sixty-five* will be thus denoted:

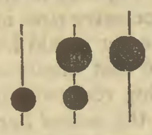
OCTARY SCALE.

The number is denominated *two duplicate octads*, *four single octads*, and *five*; and it has been decomposed into *two sixty-fours*, *four eights*, and *five*.

Denary Scale.

Suppose now that the *Denary Scale* of Notation were employed. The same number, reckoned by *tens* or *decads*, would leave *five* counters on the *first* bar, and cast *sixteen* to the *next* bar; which, being told again, would leave *six* counters on the *second* bar, and carry *one* to the *third*. This arrangement furnishes the denomination of *one duplicate decad*, *six single decads*, and *five*; which is simpler than any of the former appellations, and yet it sounds uncouth, owing merely to our want of familiarity with the terms. It would be marked in this way:

DENARY SCALE.



We are thus conducted by successive advances to that system of numeration which has prevailed among all civilized nations, and become incorporated with the very structure of language. This almost universal consent, clearly bespeaks the influence of some common principle. Nor is it difficult to perceive that the arrangement of numbers by tens would naturally flow from the practice so familiar in the earlier periods of society,—that of counting by the fingers on both hands. Aristotle in his Queries, points at this origin, but with a less decided tone than might have been expected from him.* The philosopher even hints at other concurring causes, some of which appear to be very fanciful. Such, for instance, is his conjecture, that the root of the denary scale might be derived from the summation of the numbers *one*, *two*, *three*, and *four*, included in the Pythagorean *tetractys*. If the original import and composition of the Greek terms, δεκα, ἑκατον, χιλια, and μυρια for ten, a *hundred*, a *thousand*, and *ten thousand*, could be safely traced, we might discern the influence of the denary system in the formation of those words. The Roman terms for numerals proceed not farther than *mille*, a *thousand*; but they are evidently of the same family, with some of the slighter modifications.

But the origin of the names imposed on the radical numbers, appears most conspicuously displayed in the nakedness of the savage dialects. The Muysca Indians, who formerly occupied the high plain of Bogota in the province of Grenada, were accustomed to reckon first as far as *ten*, which they called *quihicha* or a *foot*, meaning no doubt the number of toes on both feet, with which they commonly went bare and exposed; and, beyond this number, they used terms equivalent to *foot one*, *foot two*, &c. corresponding to *twelve*, *thirteen*, &c. Another tribe, who likewise inhabits South America, the Sabiconos, call *ten*, the root of the scale, *tunca*, and repeat only the same word, to signify an *hundred* and a *thousand*, the former being termed *tunca-tunca*, and the latter *tunca-tunca tunca*.

Etymology, guided by the spirit of philosophy, furnishes a sure instrument for disclosing the monuments of early conception, preserved though disguised, in the structure of language. Our own dialect as immediately derived from its Gothic stem, betrays a composition not less rude or expressive than the simple articulation of the Sabiconos. According to the authorities collected by a celebrated German philologist, the late very laborious and accurate Adelung, the word *eleven* was most anciently written *einlif* or *einlivin*, being compounded of *ein* or *one* and the verb *liban*, to *leave*, and therefore signified merely *one*, *leave*; that is, *retain one*, and *set aside* no doubt *ten*, the root of the scale. *Twelve* has the same etymon. The names *twenty*, *thirty*, *forty*, &c. have the terminating syllable *ty*, which corresponds to *zig* in German, and *zug* or *zuch* among the oldest writers of that parent tongue. This termination is derived from the verb *ziehen*, to *draw*, and hence *twenty* means simply *two drawings*, *thirty*, *three drawings*, &c. intimating evidently, that so many tens are separated from the heap. The term *hundred*, which also runs unvaried through all the filiations of the Gothic, is formed of *hund*, which anciently signified only *ten*, and *red* or *ret*, a participle from the verb *reitan* to *reckon* or *place in rows*: The compound would therefore intimate as much as *ten times told*, that is the reduplication of ten, or *ten added ten times*. In the Gothic Translation of the Gospels made by Ulphilas, in the fourth century, *one hundred* is expressed by *tachund tachund*, or the word for ten merely doubled; exactly like the *tunca tunca* of the Sabiconos of South America. But in the Anglo-Saxon version, which was made about three centuries later, *one hundred* is denoted by *hund teontig*, meaning *ten of ten drawings*. In the same curious monument of our early language, *hund seafontig*, or *ten of*

* "Διὰ τί πάντες ἄνθρωποι καὶ βάρβαροι καὶ ἕλληνες ἐς τὰ δέκα καταριθμοῦσι, καὶ οὐκ εἰς ἄλλον ἀριθμὸν, οἷον β. γ. δ. ε, (εἶτα πάλιν ἐπαναδιπλοῦσιν, ἓν πέντε, δύο πέντε,) ὥσπερ ἕνδεκα, δώδεκα οὐδ' αὖ ἐξωτέρω παυσάμενοι τῶν δέκα, εἶτα ἐκεῖθεν ἐπαναδιπλοῦσιν; ἔστι (μὲν) γὰρ ἕκαστος τῶν ἀριθμῶν, ὁ ἔμπροσθεν, καὶ ἓν ἢ δύο καὶ οὕτος ἄλλος τις. ἀριθμοῦσι δ' ὅμως ὁρίσαντες ἄχρι τῶν δέκα οὐ γὰρ δὴ ἀπὸ τύχης γε αὐτὸ ποιοῦντες φαίνονται, καὶ ἀεί. τὸ δὲ ἀεὶ καὶ ἐπὶ πάντων, οὐκ ἀπὸ τύχης, ἀλλὰ φυσικόν" And, after throwing out some loose conjectures, he subjoins: "ἢ ὅτι πάντες ὑπῆρξαν ἄνθρωποι, ΕΧΟΝΤΕΣ ΔΕΚΑ ΔΑΚΤΥΛΟΥΣ; οἷον οὖν ψήφους ἔχοντες τοῦ οἰκείου ἀριθμοῦ, τοῦτο τῷ πλήθει καὶ τἄλλα ἀριθμοῦσι." *Arist.* Problemat. xv. 3.

Palpable Arithmetic.

*seven drawings*, is employed to express *seventy*. It seems probable, that *hund* and *ten* or *teon* were only variations of the same word. The term a *thousand* is merely an abbreviation of *diuis-hund*, its earliest form. The prefix *diuis* is the same as the word *twice*, and *hund* was probably contracted for *one hundred:* The combined expression would, therefore, signify a *redoubled hundred*, or *one hundred repeated ten times*.

It is remarkable that the Peruvian language was actually richer in the names for numerals than the polished dialects of ancient Rome or Greece. The Romans, we have seen, went not farther than *mille*, a thousand; and the Greeks made no distinctive word beyond *μυρια*, or ten thousand. But, the inhabitants of Peru, under the Incas, following the *Denary System*, had the term *huc*, to denote *one; chunca, ten; pachac, one hundred; huaranca, a thousand;* and *hunu, a million*. These words are either original, or have been formed, like our numerical terms, by the abbreviation of certain compound expressions.

Philosophers, from Aristotle down to Locke, have too hastily given credit to the vague reports of travellers, concerning the very scanty knowledge which savages possess of the art of numeration. Even the cautious and discriminating historian Dr Robertson, thinks himself warranted to conclude, from authorities which he quotes, that certain tribes of native Americans could reckon no farther than ten, or perhaps twenty, while others advanced not beyond three. But, it is utterly repugnant to congruity, to suppose that any people should be found so destitute of mental faculties, as not to rise above those low numbers. It seems far more probable, that such numbers were merely the *roots* of the systems of classification adopted by the several tribes, and mistaken by unphilosophical travellers for the whole extent of their numeration. Every savage nation must surely be supposed capable of reckoning up the bands of warriors which they can bring into the field, amounting generally to hundreds, and often to thousands.

Roger Williams, one of the earliest settlers of New England, a man of sense and observation, though deeply tinctured with the enthusiasm of the age, published in 1643, a small Key to the language and manners of the Indian nations who then surrounded that infant colony, in which he gives an ample list of the numerals employed by the native tribes. It hence appears, that those people used the *Denary Scale* of arrangement, and had a set of distinct words to express the numbers as far as a *thousand*, and could even advance as high as *one hundred thousand*, by help of combined terms. Thus, *one* they named *nquit; ten, piùck; an hundred, pâwsuck;* and a *thousand, mittânug*. But these words are apparently compound, and would doubtless be found to throw much light on the subject of numeration, if we had any means of analysing them. The same author assures us, that the Indians, employing grains of corn for symbols, were very expert in their computations.

According to the testimony of Leems, a respectable Moravian missionary, the Laplanders, in their computations, join very significantly the cardinal to the ordinal numbers. Thus, to express *eleven* and *twelve*, they say *auft nubbe lokkai*, and *gouft nubbe lokkai;* that is, *one to the* SECOND *ten*, and *two to the* SECOND *ten*. In like manner, to signify *twenty-one* and *twenty-two*, those rude people use the expressions *auft gooalmad lokkai*, and *gouft gooalmad lokkai*, meaning *one added to the* THIRD *ten*, and *two added to the* THIRD *ten*. This procedure affords a curious and very happy illustration of the principle of numeral arrangement.

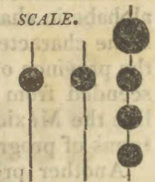
Duodenary Scale.

The *Duodenary System* of arrangement was introduced at a more advanced stage of society. It plainly drew its origin from the observation of the celestial phenomena, there being twelve months or lunations commonly reckoned in a solar year. The Romans adopted that index, to mark their subdivision of the unit of measure or of weight. They distinguished the *foot* into *three hand-breadths* or *palms*, and each *palm* into *four* lengths of the *thumb-joint* or *digit;* and, in like manner, they first bisected the pound, next bisected this again, and then divided the *quarter* into *three* final portions. The twelfth part of a foot and that of a pound were alike termed *uncia*, which has branched into the modern words *inch* and *ounce*, applied more discriminately with us to the subdivisions of *measure* and of *weight*.

The mode of reckoning by *twelves* or *dozens* has been very generally adopted in the wholesale trade. Nor is its application confined to the first term of the progression, but extends to the second or even the third. Twelve dozen, or *an hundred and forty-four*, makes the long or *great hundred* of the Northern Nations, or the *Gross* of traders. Twelve times this again, or *seventeen hundred and twenty-eight*, forms the *Double Gross*.

Let the same number, one hundred and sixty-five, as before, be reckoned on the *Duodenary Scale*. It contains *thirteen dozen* and *nine*, or *one gross one dozen and nine*, and consequently, will be represented as here annexed.

DUODENARY *SCALE.*



Next to the Denary Scale itself, the system of counting by progressive *scores* or *twenties*, derived from the same source, appears to have been the most prevalent. The savage who had reckoned the fingers on both hands, and then the toes on both feet, making *twenty* in all, might seem to have reached the utmost limit of natural calculation. The Guaranis, a very simple and inoffensive tribe, who live on the shores of the Marañon, are accordingly said to proceed no farther in their direct numeration. When these people want to signify *an hundred*, they only place in a row five heaps of maize, each composed of *twenty* grains. The Mexicans, however, being more advanced in society, were accustomed to employ the higher terms of the same progression, thus combining the *Denary* with the *Binary* scales. In the ancient hieroglyphic paintings of that unfortunate race, *units*, as far as a *score*, are exhibited by *small balls;* and *twenty* is denoted by a figure, which some authors, and particularly Clavigero, have mistaken for a *club*, but which was really a *small standard* or *flag*. In the same curious monuments, *twenty scores*, or *four hun-*

Palpable Arithmetic.

*dred*, is signified by *a spreading open feather;* probably, because the grains of gold, lodged in the hollow of a quill, represented, in some places, money or the medium of exchange. This symbol has, from the rudeness of the drawing, been taken at times for a pine-apple, an ear of maize, or even the head of a spear; but its application to intimate the *duplicate scores* is certain and invariable. A sack or bag, was also painted by those ingenious people, to represent *twenty times twenty scores*, or *eight thousand*. It was of the same form as a purse called *xiquipilli*, and supposed to hold *eight thousand* grains of cacao. To avoid the multiplication of the balls, and other symbols, the Mexicans sometimes divided the flag denoting a score by two cross lines, and coloured the one half of it to signify *ten*, or covered three quarters of it with colour to mark *fifteen*. This mode of abbreviating the signs was evidently capable of farther extension. Plate XXVII. exhibits the series of Mexican hieroglyphic numerals, copied from Humboldt's splendid work entitled *Vues des Cordilleres;* and to illustrate their application, we have represented the current *year* 1816, by help of them, having its circle prefixed as indicating a complete revolution of the four seasons.

Traces of numeration by *scores* or *twenties* still exist in the old continent. The expression *three score* and *ten*, in our own language, is more venerable than *seventy;* and the compound *quatre-vingts et dix*, is the ordinary mode in French for signifying *ninety*. The Arâbians, according to Sylvestre de Sacy, counted no farther than *four hundred* or *twenty scores*, before the sixth century of the Hejira, which corresponds to about the middle of the eleventh century of the Christian æra. To denote *nine hundred*, they had recourse to the clumsy expedient of redoubling the alphabetic character of *four hundred*, and joining to it the character of *one hundred*. The inhabitants of the province of Biscay, and of Armorica, people descended from the ancient Celts, are said to reckon like the Mexicans, by the powers of *twenty*, or the terms of progressive *scores*.

Another progression, still swifter in its operation than that by scores, and long familiar to Astronomers, was introduced into the Alexandrian school by the famous Ptolemy, who had the merit of digesting the results of celestial observations into a body of regular science. We allude to the *Sexagenary Scale*, which proceeds, as its name implies, by the successive powers of *Sixty*. This arrangement of numbers appears quite artificial, and was no doubt suggested by the division of the circle founded on astronomical phenomena. Since the year is composed of twelve months, containing each about thirty days, the round number, three hundred and sixty, was chosen as the most convenient for subdividing the ecliptic into degrees. But the radius of the circle, was naturally employed as a standard for the measuring of lines and arcs in general; and this being nearly the sixth part of the circumference, and comprising, therefore, about sixty degrees, the arcs themselves, or their multiples, when expressed by degrees, came to be reckoned by *Sixties*. The notation was effected by annexing a single dash for *Sixty*, two dashes for its duplicate, and three dashes for its triplicate.

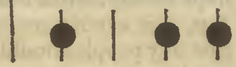
Palpable Arithmetic.

Since, in the notation by numeral scales, the import of a counter depends on the position of the bar on which it stands, any alteration of the place of units must produce a proportional change on the value of the whole amount of an expression. Thus, in the *binary* classification, the shifting of the bar of units one place lower, would, in effect, double all the preceding terms, and a second shift would double these again. In like manner, to carry the beginning of the scale a bar lower would, in the *denary* system, convert the units into tens, the tens into hundreds, and the hundreds into thousands; thus augmenting the whole tenfold. On the contrary, if the units were moved to a bar higher, the amount of any expression, would, in the *binary* scale, be reduced to one-half, and, in the *denary*, to the tenth part of its former value. Hence, to multiply or divide by the index of any scale or its powers, we have only to change the names of the bars, or to shift the place of the units.

Mode of representing Fractions.

The systems of progressive numeration are as well adapted to represent a descending as an ascending series; a property which greatly facilitates and simplifies the exhibition of fractions. Suppose, for example, it were sought to express *eleven-sixteenths* on the *Binary Scale*. Since a counter depressed by four bars will signify only the *sixteenth* of its original value, so *eleven*, reckoning upwards from the low bar, will express the value required.

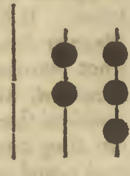
BINARY SCALE.



But the analysis of the fraction might be performed otherwise. It is evident, that *eleven-sixteenths* on the *first* bar, or the bar of units, are only equivalent to *twenty-two* such parts, that is, *one* counter and *six-sixteenths*, placed on the next descending bar. This excess again corresponds to *twelve* parts on the *second* bar, or *twenty-four* carried to the *third* bar, making *one* counter and *eight-sixteenths*. But these *eight-sixteenths* are equivalent to a whole counter on the *fourth* bar, where the exhibition stops. Hence the fraction proposed appears to consist of *one-half, one-eighth*, and *one-sixteenth*.

On the *Quaternary Scale*, this fraction would require only *two* bars, since *sixteen* is only the *second* power of the index *four*.

QUATERNARY SCALE.

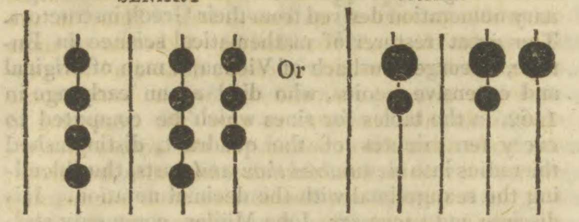


But the second mode of decomposition is, on the whole, simpler. The *eleven-sixteenths* of a counter on the bar of units, are equivalent to *forty-four*, or *two* counters, and *twelve* such parts on the next bar; and these *twelve-sixteenths* correspond to *forty-eight*, which compose *three* entire counters on the *third* bar. The original fraction is thus analysed into *two-fourths* and *three-sixteenths*.

To express the fraction on the *Senary Scale*, more bars are wanted. It is now equivalent, on the bar immediately after that of units, to *sixty-six-sixteenths*, or *four* counters and *two* parts. This small excess corresponds to *twelve* on the *third* bar, or *seventy-two* on the *fourth* bar, making *four* counters and *eight*

parts; which again correspond to *forty-eight*, or *three* entire counters on the fifth bar.

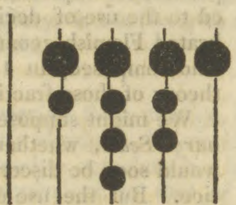
SENARY SCALE.



The fraction is thus resolved into *four-sixths*, *four-two-hundred and sixteenths*, and *three-twelve-hundred and ninety-sixths*.

Let the same fraction be represented on the *Denary Scale*. It might be found, that *sixteen*, multiplied by *six hundred and twenty-five*, produces *ten thousand*, or the *fourth* power of the index, ten. Wherefore *eleven* times *six hundred and twenty-five*, or *six thousand, eight hundred and seventy-five*, reckoned upwards from the fourth bar, below the rank of units, will denote the fraction proposed.

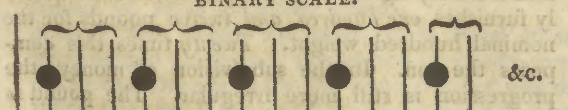
DENARY SCALE.



But the expression of this fraction on the descending scale is more easily and directly obtained, by the process of successive decomposition. *Ten* times *eleven sixteenths*, or *one hundred and ten* parts on the bar immediately below the units, make *six* counters and *fourteen* parts. These *fourteen* parts are equivalent to *one hundred and forty* parts, or *eight* counters and *twelve* parts on the *third* bar. This excess again gives *one hundred and twenty* parts, or *seven* counters and *eight* parts, for the *fourth* bar. And lastly, these remaining *eight* parts are represented by *five* counters placed on the *fifth* bar. The fraction *eleven sixteenths* is thus analysed into *sixteenths*, *eight-hundredths*, *seven-thousandths*, and *five-ten-thousandths*.

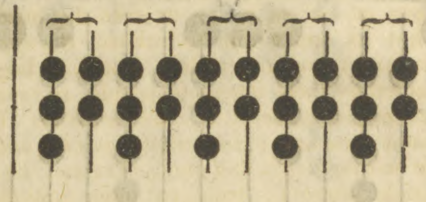
There is not the same facility, however, in decomposing all fractions, and reducing them to the terms of a descending scale. It often happens that the expressions for these will run through many bars, or even maintain a perpetual circulation, without ever drawing to a termination. Suppose, for example, that *four sevenths* were to be represented on the *Binary Scale:* It would correspond to *eight-sevenths*, or a counter and one part of the *second* bar; which excess would be equivalent to *two* parts on the *third* bar; *four* on the *fourth*, *eight*, or a *counter* and *one* part on the *fifth* bar. This bar would therefore leave out the same portion as the *second* bar; and consequently the notation would be continually repeated at the interval of three bars.

BINARY SCALE.



The same fraction would be thus expressed on the *Senary Scale*.

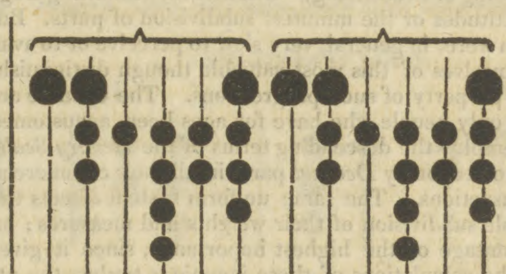
SENARY SCALE.



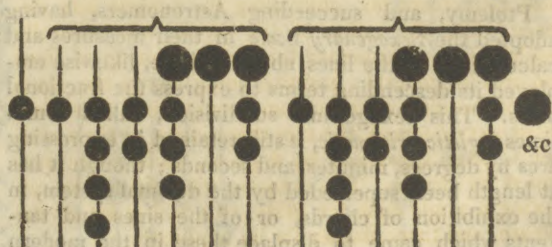
The *four sevenths* of a counter are here equivalent to *twenty-four* parts or *three* counters and *three* parts on the *second* bar: and these parts correspond to *eighteen* parts, or *two* counters and *four* parts on the *third* bar. The process of decomposition is hence incessantly renewed on the alternate bars.

If this fraction be reduced to the *Denary Scale*, the circulation will be still more complex. It will give for the *second* bar *forty* parts, or *five* counters and *five* parts; for the *third* bar, *fifty* counters, or *seven* counters and *one* part; for the *fourth* bar, *ten* parts, or *one* counter and *three* parts; for the *fifth* bar, *thirty* parts, or *four* counters and *two* parts; for the *sixth* bar, *twenty* parts or *two* counters, and *six;* and for the *seventh* bar *sixty* parts, or *eight* counters and *four* parts, which, being the same remainder as at first, will occasion the perpetual recurrence of the same series of counters.

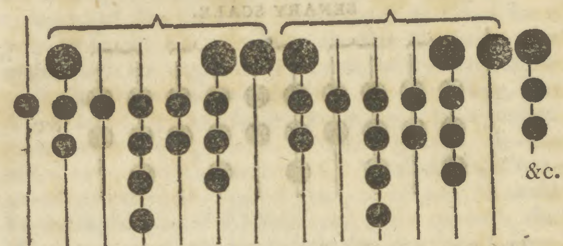
DENARY SCALE.



It is curious to remark with regard to the present example, that if the expression on the *Denary Scale* were multiplied by any number whatever, the same counters, and after the same order, would always appear to occupy the inferior bars: Thus, when doubled, it will assume this form, commencing like the *fourth* bar of the single expression.



If the expression for *four-sevenths* be *tripled*, it will show the same aspect, only beginning at the *third* bar:



&c.

A little reflection will discover the case to be an unexpected result. Since the perpetual succession of *six* bars, or only one less than the denominator, was necessary to represent the value of the given fraction; it follows, that every possible remainder arising from the repeated subdivision or decomposition by *seven*, must have some corresponding bar from which the same recurrence will take place. Thus, in the analysis of *four-sevenths*, the remainders on the successive bars were *five, one, three, two, four* and *six*; and consequently every fraction having *seven* for its denominator, would belong to one of these.

To reduce a fraction to any descending scale, may therefore prove a tedious, and often impossible task. But the converted expression approximates rapidly to its true value, and a very few terms will be sufficient for every practical use. The numerical scales are thus equally fitted by their constitution for ascending or descending,—whether for exhibiting huge multitudes or the minutest subdivision of parts. But men were, in general, very slow to perceive or to avail themselves of this most valuable though distinguishing property of such progressions. The Chinese are the only people who have for ages been accustomed to employ the descending terms of the *Denary Scale*, or to reckon by *Decimal* parts in all their commercial transactions. The same uniform system directs the whole subdivision of their weights and measures; an advantage of the highest importance, since it gives to the calculations of those ingenious traders the utmost degree of simplicity and readiness. The natives of India, who have so long been acquainted with the use of the *Denary Scale* of numeration, are yet ignorant of its application to denote fractions. Below the place of unity they change the rate of progression, and descend merely by a continued bisection, adopting successively the *half*, the *fourth*, the *eighth*, and the *sixteenth*; beyond which partition they seldom advance.

Ptolemy, and succeeding Astronomers, having adopted the *Sexagenary Scale* in their measures and calculations of the lines about a circle, likewise employed its descending terms to express the fractional parts. This sexagesimal subdivision, called sometimes *logistic arithmetic*, is still retained in expressing arcs by degrees, minutes, and seconds; though it has at length been superseded by the decimal system, in the exhibition of chords, or of the sines and tangents which came to displace these in the modern Trigonometry. Nor was the latter improvement embraced, or even contemplated at once. The Arabians, though well acquainted with the advantages of the *Denary Scale*, appeared satisfied with the sexagenary numeration derived from their Greek instructors. The great restorer of mathematical science in Europe, George Purbach of Vienna, a man of original and extensive genius, who died at an early age in 1462, in the tables for sines which he computed to every ten minutes of the quadrant, distinguished the radius into *six hundred thousand* parts, thus blending the sexagesimal with the decimal notation. His disciple and successor, John Müller, commonly styled Regiomontanus from Köningsberg, the name of his place of birth, after some hesitation laid aside this subdivision of the radius in 1464, and enlarged it to a *million* of parts, having recalculated the sines, and likewise joined to them tables of tangents. But his work lay many years after his decease in manuscript, and was not printed until 1533. A very long period still elapsed before mathematicians were trained to the use of decimals. Simon Stevinus, a celebrated Flemish geometer and engineer, was the first who composed, in 1582, a distinct treatise on the theory of those fractions.

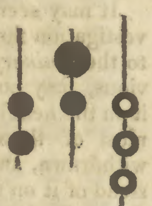
We might suppose that the properties of the *Denary Scale*, whether in ascending or descending, would soon be discerned and reduced to actual practice. But the use of fractions is associated with a more advanced state of society. Men very seldom take large and connected views of things; they generally grope their way step by step, as actual wants and circumstances chance to direct them. In the subdivision of the unit, they have often proceeded by *bisection*, sometimes by *trisection*, and frequently by joining together these modes, or combining them with *decimation*. This irregular and unsteady procedure is apparent in our own dissection of weights and measures. The simplest division is that of *halving*, which seems very naturally to spring from the competition between seller and buyer.—Our dry measure is, accordingly, broken down by a series of *bisections*. Thus, the chaldron is divided by a redoubled bisection into *four* quarters, each of these by a triple bisection into *eight* bushels, each of these again by a redoubled bisection into *four* pecks, each peck bisected into *two* gallons, each gallon by a redoubled bisection divided into *four* quarts, and each of these bisected into *two* pints. The avoirdupois weight, which is the sort generally used in business, appears both to ascend and descend, from a common point. The pound is divided by a quadruple bisection into *sixteen* ounces, and each of these again into *sixteen* drams. But were it desired that a hundred pounds should constitute the quintal, this would be reduced, by a successive quartering, to *six and a fraction*. Wherefore the nearest round number, *seven*, was taken, which being doubled gives *fourteen* pounds for a stone of horseman's weight, and this doubled again makes *twenty-eight* for the quarter, which consequently furnishes *one hundred and twelve* pounds for the nominal hundred weight. *Twenty* times this composes the ton. In the subdivision of money, the progression is still more irregular. The pound is

first divided into *twenty* shillings, next each of these into *twelve* pence, and then each *penny* into *four* farthings.

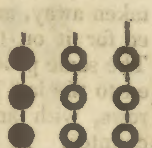
All the calculations in theoretical mathematics are now conducted invariably on the decimal scale. The same kind of subdivision has, to a certain extent, been introduced, for the sake of its great convenience, into the practice of gauging and land-surveying. But we may despair of ever seeing the decimal progression adopted in the general intercourse of society. The French have, indeed, set an example to the rest of Europe, in this case, at least, perfectly harmless, and highly worthy of imitation,—by framing a consistent and universal system of measures, weights, and coins, drawn from nature itself, and disposed with admirable simplicity and elegance. Yet, even in France, that seductive plan has, amidst the collision of opposite views and interests, experienced only a partial success. National prejudice, inflamed by ignorance, is too often opposed to every species of improvement; and the influence of a country, now shorn of her glory, is not likely to extend beyond her own frontiers.

When the index of a *Numerical Scale* is large, the notation may be conveniently abridged, by marking only what counters are wanted to complete any bar, or render its expression equivalent to that of an additional counter placed on the bar immediately before it. Thus, instead of *eight* counters on a particular bar, it would be sufficient to join *one* to the preceding bar, and put *two* defective or open counters in the *Denary Scale*, or *four* such counters on the *Duodenary Scale*. The same mode of contraction is alike applicable to the expression of integers, or of fractions. For the sake of illustration, let some of the former examples be resumed. The number *one hundred* and *sixty-five* was thus represented on the *Octary Scale*; there being *one* counter, and the substitute for *four* on the first bar, the same substitute on the second bar, and two counters on the first bar. Now add a counter to the second bar, and lay *three* open counters on the third bar, and this will be changed into the form annexed.

OCTARY *SCALE.*



This expression again is, by a similar process, converted into another, consisting of *three* open counters on the first and on the second bar, with *three* full counters on the third bar. Hence the number proposed, must consist of *three* duplicate octads, abating *three* octads and *three*, or is equal to *one hundred* and *ninety-two*, diminished by *twenty-seven*.



On the *Denary Scale*, the same number was denoted as under I. and will be successively changed into two other forms.

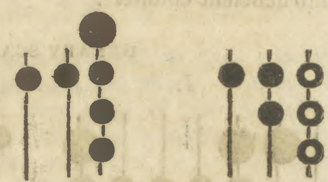
I. II. III.

The last expression, therefore, signifies *two hundred*, abating *thirty-five*.

Again, the number *one hundred* and *sixty-five*, which, on the *Duodenary Scale*, stood as annexed, will be reduced to the simpler expression; by changing the *three* counters, and *six* on the *first* bar for *three* open counters, and an additional counter on the second bar, intimating *one* gross and *two* dozens, abating *three*.

DUODENARY SCALE.

I. II.



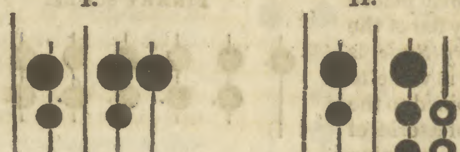
This method of employing open or deficient counters is applicable likewise to the notation of fractions. Thus, *eleven-sixteenths* expressed on the *Quaternary Scale*, may have these *three* different forms:

QUATERNARY SCALE.

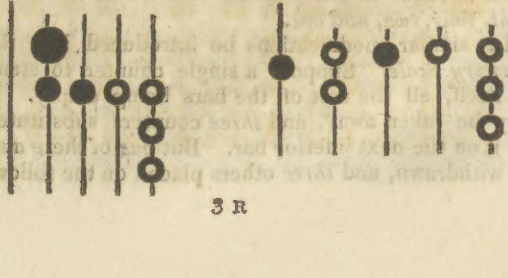
I. II. III.

On the *Senary Scale* this fraction will admit of more varieties:

I. II.



III. IV.

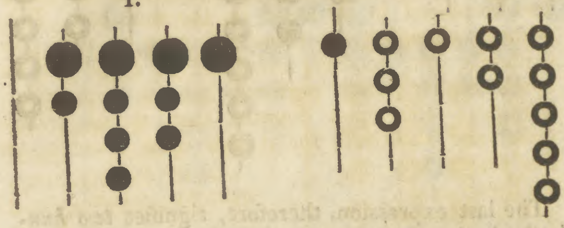


Palpable Arithmetic.

On the *Denary Scale*, this fraction may have its first expression changed, by successive modifications, into a simpler form.

DENARY SCALE.

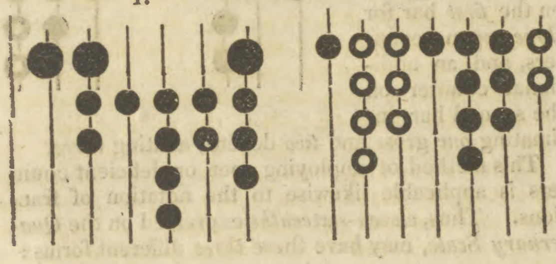
I. II.



The fraction *four-sevenths*, which, on the *Denary Scale*, formed a perpetual recurrence, may be abbreviated in the same way. The first expression is converted into another more commodious one, by changing the counters that exceed *five* on any bar into deficient counters.

DENARY SCALE.

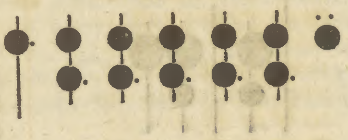
I. II.



General properties of these Scales.

We shall now investigate some general properties of those *Numerical Scales*. Suppose, in the *Binary Progression*, there was standing but a single counter on a high bar. It is obvious, that this might be removed, and *two* placed on the inferior bar. But *one* of these might likewise be removed, and *two* counters substituted for it on the next bar lower. The same process could be pursued through any number of bars, the removed counters being always marked by a dot, and the one which is finally rejected placed on the outside of the last bar with two dots over it. It hence appears, that *one* placed on any bar of the *Binary Scale*, is equal in value to *one* joined to the sum of a series of units running through all the inferior bars. Thus, in the example now produced, *one* counter occupying the *sixth* bar, and therefore indicating the number *thirty-two*, is equal in effect to *one* annexed to the sum of *sixteen*, *eight*, *four*, *two*, and *one*.

BINARY SCALE.

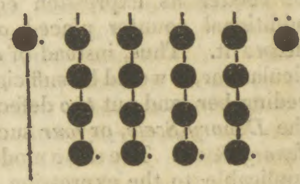


Let similar modifications be introduced into the *Ternary Scale*. Suppose a single counter to stand by itself, all the rest of the bars being empty. It may be taken away, and *three* counters substituted for it on the next inferior bar. But *one* of these may be withdrawn, and *three* others placed on the following bar: Of this triplet, the undermost might again be removed, and *three* substituted for it on the next bar. The same process, it is evident, could be repeated, till the change reached the lowest bar, leaving out an excess of *one*, marked by two dots to signify its being transferred. Hence the single counter on the *Ternary Scale* is, by successive mutations, converted into *two* rows of counters extending through all the inferior counters, and leaving an excess of *one*. Thus the number *two hundred* and *forty-three*, the value of a counter placed on the *fifth* bar of the *Ternary Scale*, is equal to *one* added to double the sum of *eighty-one*, *twenty-seven*, *nine*, *three*, and *one*, the values of counters occupying all the inferior bars.

TERNARY SCALE.

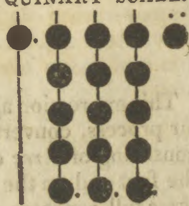
In like manner, if a solitary counter in the *Quaternary Scale* be withdrawn, *four* counters may be substituted on the next bar. Remove the undermost of these, and set *four* more on the succeeding bar. Take away *one* of these again, and put other *four* counters on the adjacent bar. Proceed in the same way, till the quaternion reaches the last bar, and is reduced to a triplet, by the exclusion of *one* counter. By this analysis, therefore, the simple counter is resolved with an excess of *one*, into *three* rows of counters which run through the whole of the lower bars. In the present instance, the number *two hundred and fifty-six*, the import of a counter on the *fifth* bar of the *Quaternary Scale*, is equivalent to *one* joined to *triple* the sum of *sixty-four*, *sixteen*, *four*, and *one*, the values of all the succeeding bars.

QUATERNARY SCALE.



It may seem scarcely necessary to pursue this investigation farther; but we shall extend it likewise to the *Quinary Scale*. A single counter, it is obvious, may now be removed, and *five* substituted for it on the next bar. The undermost of these again may be withdrawn, and *five* placed instead of it on the following bar. One of these may then be taken away, and *five* substituted for it on the adjacent bar. The same procedure is repeated to the last bar, leaving *four* rows, with an excess of *one* counter. In the present instance, a single counter on the *fourth* bar, and corresponding, therefore, on this scale the number to *six hundred and twenty-five*, is equivalent to *one* added to *four* times the sum of *one hundred and twenty-five*, *twenty-five*, *five*, and *one*, the values of all the inferior bars.

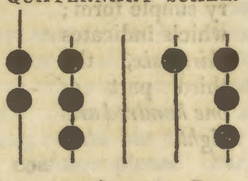
QUINARY SCALE.



Palpable Arithmetic.

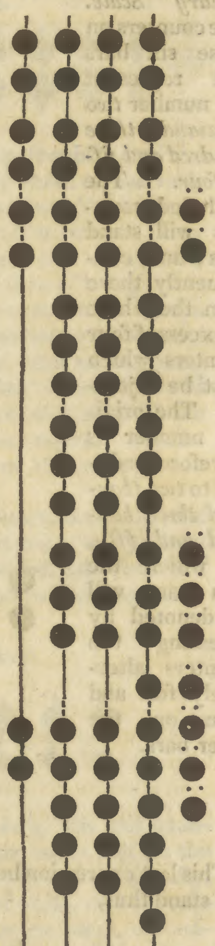
We may hence conclude in general, *that if one be taken from any power of the index of any numerical scale, the remainder will be equal to all the inferior powers repeated as often as the index, when diminished by one, contains unit.* Wherefore if the counters, reckoned as mere units, be separated from any compound expression, the whole will be converted into as many trains of counters, occupying all the inferior bars as correspond to the index of the scale diminished by one. Suppose, for example, the expression here noted, which is disposed on *five* bars, of the *Quaternary Scale*, and is equivalent to *seven hundred and eleven.*

QUATERNARY SCALE.



By decomposing separately each successive bar, and placing the excluded counters close beside the place of units, it will be changed into this regular but complex form, which consists of three rows of double counters, leaving out two; three rows of triple counters, leaving out three; a single counter, leaving out one; and three counters on the last bar left out. If we omit the *nine* excluded counters, and take only each single row of the rest, the result will be greatly simplified. This reduced expression corresponds to *two hundred and thirty-four.* But *seven hundred and eleven,* diminished by nine, the number of counters at first employed, leaves *seven hundred and two;* and this again, being divided by three, gives *two hundred and thirty-four.*

QUATERNARY SCALE.

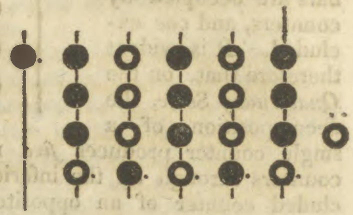


Applying this principle to the *Denary Scale*, it must follow, *that if the sum of the integers be subtracted from any number, the remainder will be divisible by nine, and the quotient will be equal to the sum of the separate numbers denoted by each of those integers repeated through all the inferior places.*

Palpable Arithmetic.

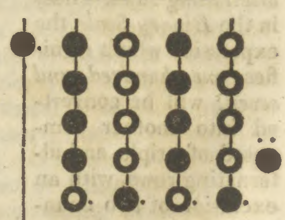
Another similar property, belonging to numerical scales, may be deduced from the combination of the deficient or open counters. Let us begin with the *Binary System.* Suppose a solitary counter to occupy the *sixth* bar. It may be removed, if *two* counters be placed in its stead on the next bar. But, without changing its value, we may to this pair evidently join another, composed of a full and an open counter, which perfectly balance each other. Withdraw the open counter that stands undermost, and substitute for it two open counters on the fourth bar. To these again, add a balanced pair, consisting of an open and a full counter. Take away the undermost counter, set two similar counters on the third bar, and to this pair annex a full and an open counter. By continuing this process, the single counter will be decomposed into *three* rows of counters, alternately full and open; with an excluded counter, which is open when the number of the bars, as in the present case, is even, but a full counter if that number be odd. Thus *thirty-two,* the value of the counter on the sixth bar, is equal to *three* times all the inferior alternating bars, or the excess of *sixteen* above *eight*, joined to the excess of *four* above *two*, and together with *one*, that is, *eleven;* abating, however, the excluded counter which is here open; but thrice *eleven*, omitting *one*, is *thirty-two.*

BINARY SCALE.



Let a similar analysis be applied to the *Ternary Scale.* Change the solitary counter for *three* counters laid on the next bar, and to these join a balanced pair consisting of a full and an open counter. Remove this open counter, and substitute three open counters for it on the succeeding bar, and to the triplet annex an open and a full counter. Take away the full counter, and place three such counters on the following bar. Repeat the procedure, till the *first* bar comes to be occupied; and there will evidently emerge *four* rows of counters extending through all the inferior bars, and alternately full and open, with an excluded counter of an opposite character to those which terminate the decomposition. In the present instance, where the single counter stood on the *fifth* bar, a counter of the ordinary kind is left out. Wherefore the number *eighty-one* is equal to four times the amount of the excess of *twenty-seven* above *nine*, and of that of *three* above *one*, or *twenty*, together with the *unit* excluded.

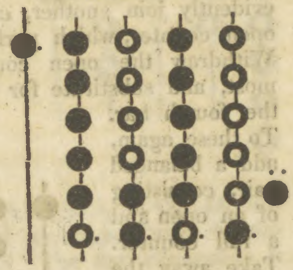
TERNARY SCALE.



It may be deemed sufficient for grounding a general conclusion, to repeat the same process on the

*Quaternary Scale.* Instead of the solitary counter, place *four* counters on the next bar, and conjoin with these a balanced pair of counters, composed of a full and an open one. Remove the undermost of these, and substitute four open counters on the following bar. To these again, add an open and a full counter, which will not affect the value of the column. Pursue the operation till all the bars are occupied by counters, and *one* excluded. It is evident therefore that, on the *Quaternary Scale*, the decomposition of a single counter produces *five* rows of alternating counters through all the inferior bars, with an excluded counter of an opposite nature to that of the row which completes the analysis. In the example now given, the number *two hundred and fifty-six*, the value of the counter on the *fifth* bar, is equal to five times the amount of the excess of *sixty-four* above *sixteen*, and of *four* above *one*, or *fifty-one*, together with the *unit* left out.

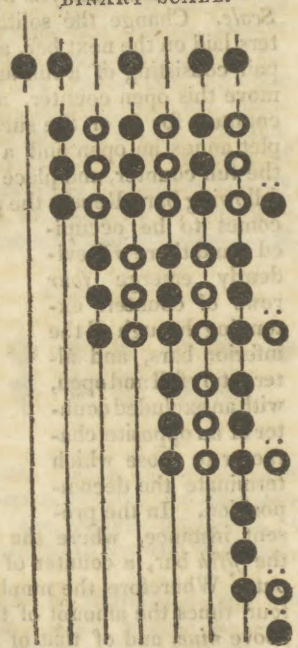
QUATERNARY SCALE.



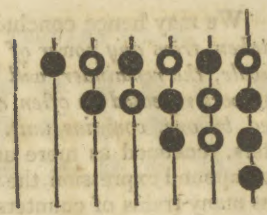
The conclusion may, therefore, be extended to any progressive scale: If the value of unit on a separate bar be increased or diminished by one, according as the rank is even or odd, the remainder will be divisible by one greater than the index of the scale, and the quotient will be equal to the amount of the values of unit as alternating in excess and defect through all the inferior bars.

The same property, it is evident, could be transferred to any compound expression: Nothing is wanted but to change the counters on each successive bar into alternating rows. Thus, in the *Binary Scale*, the expression which signifies *one hundred and seven*, will be converted into another composed of triple and alternating rows, with an exclusion of two counters in excess, and three in defect, or the balance of an open counter.

BINARY SCALE.

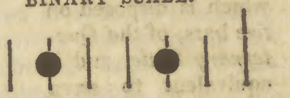


If this arrangement be now divided by three, the result, after restoring the deficient unit, will be



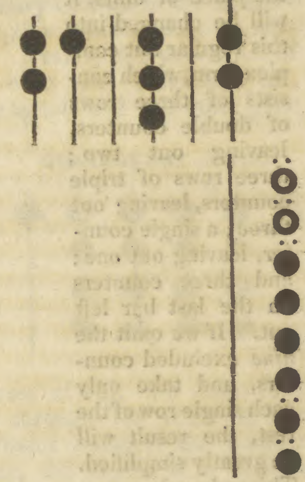
By collecting and condensing the counters on each bar, the whole will be reduced to another very simple form; which indicates *thirty-six*, the third part of *one hundred and eight*.

BINARY SCALE.

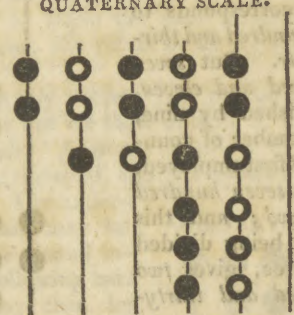


Let another example be selected from the notation of the *Quaternary Scale*. The counters on these six bars will represent the number *two thousand three hundred and fifty-four*. The excluded counters will stand thus; and, consequently, there is on the whole an excess of four counters which must be rejected. The original number is therefore reduced to *two thousand three hundred and fifty*, of which the fifth part will be denoted by repeating the counters alternately full and open on the lower bars.

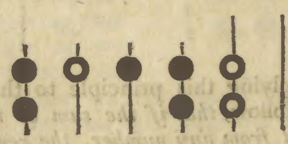
QUATERNARY SCALE.



QUATERNARY SCALE.

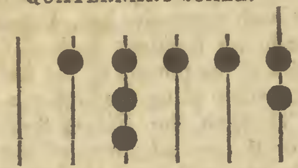


This last expression being condensed and abridged will stand thus,



or with full counters only,

QUATERNARY SCALE.



denoting *four hundred and seventy.*

In all these decompositions, we have stopped at the bar of units; but if we pursue the analysis through the descending bars, we shall discover trains of equivalent fractions which never terminate. Thus, to begin with the *Binary Scale:* A counter on the bar of units may be taken away, and two counters placed instead of it on the following bar. Of this pair again,

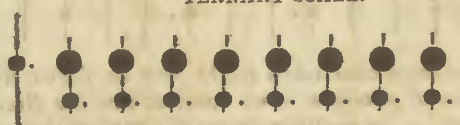
BINARY SCALE.

&c.

one may be removed, and another pair substituted for it on the next lower bar. One of these again may be withdrawn, and two placed on the following bar. The same operation of exchange, it is obvious, may be repeated for ever. Wherefore, the value of a single counter is here the same as that of a single row of counters, extending indefinitely over the lower bars. But the counter on the bar immediately below the place of units, indicates *one-half,* that on the next *one-fourth,* that on the following bar *one-eighth,* and so forth continually. Wherefore the sum of the fractions *one-half, one-fourth, one-eighth, one-sixteenth,* extended without limit, must always approach to *one.*

Let a similar transformation be carried through the *Ternary Scale.* Suppose a half counter to stand on the bar of units: It may be removed, and *three* half counters, or a whole counter and half of one sub-

TERNARY SCALE.

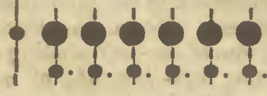


&c.

stituted on the next bar. Take away this half counter, and set *three* such, or a counter and a half on the succeeding bar. Repeat the same process continually, and the half counter on the bar of units, will be converted into a single row of entire counters, extending without limitation through all the inferior bars. But these successive counters signify *one-third, one-ninth, one-twenty-seventh,* &c. Whence the fraction *one-half* is equal to the sum of *one-third, one-ninth, one-twenty-seventh,* &c. continued *ad infinitum.*

In the *Quaternary Scale,* let the *third* of a counter occupy alone the bar of units. It may be withdrawn, and *four* such parts, or a whole counter, and the *third* of one placed in its stead on the next bar.

QUATERNARY SCALE.

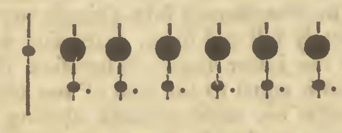


&c.

This *third* again may be removed, and a counter, with another *third,* substituted for it on the following bar. The same procedure being repeated, the *third* part of a counter in the place of units will be changed into a row of entire counters running through all the inferior bars. It therefore follows, that the fraction *one-third,* is equal to the sum of the infinite series *one-fourth, one-sixteenth, one-sixty-fourth,* &c.

Again, let similar modifications be carried through the *Quinary Scale.* The fourth of a counter on the bar of units may be exchanged for *five* such parts, or one counter and a quarter on the following bar; and this quarter may now be removed, and *five quarters,* or *one* counter and a *quarter* set on the next bar. The process of decomposition may thus be continued perpetually, leaving, instead of the *fourth* of a counter, an unlimited range of counters stretching over the inferior bars.

QUINARY SCALE.



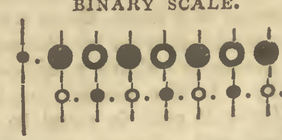
&c.

Consequently the fraction *one-fourth* is equal to the aggregate terms of the progressive *one-fifth, one twenty-fifth, one hundred* and *twenty-fifth, one six hundred* and *twenty-fifth,* continued without termination.

From these very simple analyses, we may therefore conclude in general, that the fraction of unit, which has for its denominator one less than the index of any numerical scale, is equal to the sum of all the descending powers, or the value of a single row of counters, extending indefinitely through the inferior bars. Thus *one-ninth* is equal to a *tenth,* a *hundredth,* a *thousandth,* &c. or *one-eleventh* is equal to a *twelfth* part, a *hundred* and *forty-fourth,* a *thousand seven hundred and twenty-eighth,* &c.

But the summation of a descending series, whose terms alternate, may with equal facility be discovered, by introducing the admixture of deficient counters. Thus, in the *Binary Scale,* if the *third* part of a counter stood on the bar of units, it could be removed, and *two-thirds* of a counter, that is, a whole counter *abating the third part,* substituted for it on the next bar. But this open part of a counter might be taken away, and a *whole* open counter diminished by the *third* part of a full counter placed on the following bar. This *third* again could be withdrawn, and a *full* counter with a deficient *third* part of one set on the next bar.

BINARY SCALE.



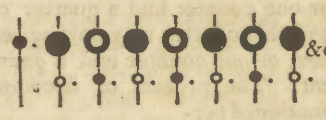
&c.

This alternate exchange might easily be repeated over the suc-

cessive bars. The *third* part of a counter is thus converted into an unlimited row of full and open counters. Hence the fraction *one-third* is equal to the sum of *one-half* abating *one-fourth*, of *one-eighth* abating *one-sixteenth*, of *one-thirty-second* abating *one sixty-fourth*, or equal to the excess of the continued series *one-half, one eighth, one thirty-second*, &c. above the corresponding series *one-fourth, one-sixteenth, one sixty-fourth*, &c.

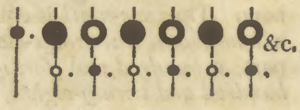
The substitution may, in like manner, be performed on the *Ternary Scale*. Suppose the *fourth* part of a counter to occupy the bar of units. Remove this fragment and substitute *three-quarters*, or a whole counter abating *one-quarter*, on the next bar. Instead of this deficient quarter again, place three such, or one open counter, conjoined with the quarter of a full one, on the succeeding bar. Pursue the same procedure, and the quarter of a counter will be transformed into a single row of counters, alternately full and open, extending without limitation over the lower bars. Wherefore the fraction *one-fourth* is equal to the sum of *one-third* abating *one, ninth*, of *one twenty-seventh* abating *one eighty-first* of *one two hundred* and *forty-third*, abating *one seven-hundred* and *twenty-ninth*, &c.; or *one-fourth* is equal to the excess of the perpetual series *one-third, one twenty-seventh*, &c. above the similar series, *one-ninth, one eighty-first*, &c.

TERNARY SCALE.



Another instance will be sufficient to point out the general principle. Let *one-fifth* part of a counter stand on the bar of units in the *Quaternary Scale*. It may be removed, if *four-fifths*, or one counter wanting a *fifth*, were placed on the next bar. Instead of this open *fifth*, let *four* open *fifths*, or *one* open counter, joined to a *fifth* of excess, be put on the following bar. Change this *fifth* again for a full counter, with a deficient *fifth* on the following bar. A series of alternating counters is thus successively formed. Whence the fraction of *one-fifth* is equal to the continued series *one-fourth*, abating *one-sixteenth, one sixty-fourth*, abating *one two hundred fifty-sixth*, &c.

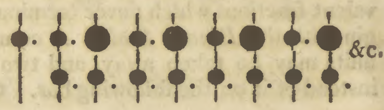
QUATERNARY SCALE.



We may hence infer generally, *that the fraction of unit, divided by one greater than the index of a numerical scale, is equal to the amount of all the descending powers taken alternatively as additive and subtractive.* Thus, *one-eleventh* part is equal to the excess of a *tenth* above a *one-hundredth*, that of a *thousandth* above a *ten-thousandth*, that of a *hundred thousandth* above a *millionth*, and so forth continually. In like manner, on the *Duodenary Scale*, the *thirteenth* part is equal to a *twelfth*, abating the *hundred* and *forty-fourth*, the *seventeen-hundred* and *twenty-eighth*, abating the *twenty thousand seven hundred* and *thirty-sixth*, &c.

In all these transformations of fractions, arising from the index of the numerical scale, increased or diminished by *one*, the operation is repeated or alternated at each successive bar. But similar changes may be made on fractions derived from the same modifications of the powers of the index, which will regularly circulate along the bars at a corresponding interval. Thus, on the *Binary Scale*, the fraction *one-third*, or the second power of the index two diminished by one, will form by decomposition an intermitting row, or a perpetual circulation, passing over the successive alternate bars. For *one-third* of a counter on the bar of units is equivalent to *two-thirds* on the following bar, which again are equal to *four-thirds*, or an entire counter and a *third*, on the next bar. Pursuing the same analysis, a row of counters emerges on the alternate bars. In reality, if the intermediate bars, which here serve only for the transit of the pair of *thirds*, were left out altogether, the notation would pass into that of the *Quaternary Scale*, and obey the general rule.

BINARY SCALE.



Again, on the same *Binary Scale*, the fraction *one-seventh*, or the reciprocal of the third power of two, diminished by *one*, will be found to circulate at every *third* bar. Thus, *one-seventh* of a counter on the bar of units gives *two* such parts for the second bar, *four* for the *third* and *eighth*, or a whole counter and an excess of *one-seventh* for the *fourth* counter; and if this kind of decomposition be carried forward, another counter will appear on the *seventh* bar, a *third* on the *tenth* bar; and so forth in perpetual succession.

BINARY SCALE.

But the same conclusion might also be drawn from the general principle, if we consider that the *Binary Progression*, by omitting always two consecutive bars, is converted into the *Octary Scale*.

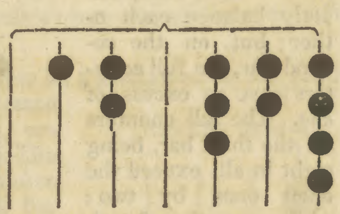
It is not difficult to perceive, that every fraction is capable of being either exactly represented on any given scale, or of being denoted by an expression which circulates after an interval of fewer bars than the denominator of the fraction contains units. In fact, the moment the same set of fractional counters comes to appear a second time, the whole expression must evidently recur in the same order. But all the possible variations or series of remainders must ever lie within the number itself, which constitutes the di-

Palpable Arithmetic.

visor. Thus, it was found that the expression for any fraction having the denominator *seven*, circulates on the *Binary Scale*, at the interval of *three* bars. The same fraction represented on the *Quaternary Scale* has a like recurrence; but, on the *Octary Scale*, the expression is renewed at every *two* bars, while it does not circulate till after passing over *six* bars, in the *Ternary*, *Quaternary*, *Quinary*, and *Denary Scales*. Employing a similar decomposition, it will appear that a fraction, with *eleven* for its denominator, will, in the *Quaternary* and *Quinary Scales*, circulate on *five* bars, but will embrace no fewer than *ten* bars, by its circulation in the *Ternary*, *Quaternary*, *Senary*, *Octary*, and *Denary Scales*.

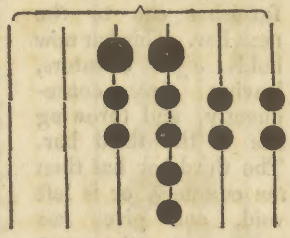
We may hence reverse the operation, and determine the absolute value of any circulating expression, or discover the fraction of which it is only the continued expansion. Suppose the group of counters here presented to circulate perpetually, at an interval of six bars on the *Quinary Scale*. If these counters were all transferred to the *seventh*, or last bar, they would signify *four thousand four hundred and sixty-four*. But another scale might be substituted, such that each single bar shall correspond in effect to this condensed *seventh* bar. Consequently the index of this new scale, or the *sixth* power of *five*, being diminished by *one*, will denote the denominator of the absolute fraction; which is therefore *four thousand four hundred and sixty-four* divided by *fifteen thousand six hundred and twenty-four*, or by reduction *two-sevenths*.

QUINARY SCALE.



In like manner, on the *Denary Scale*, let a set of counters always circulate, spreading over six successive bars. Conceive them transferred to the last bar, and they will express *seventy-six thousand nine hundred and twenty-three*. But if another scale were adopted, each bar of which had a power equal to six of these bars, its index would be *a million*. One less than this is consequently the denominator of the fraction, which is therefore equal to *one thirteenth*.

DENARY SCALE.



Theory, with Examples of Arithmetical Operations.

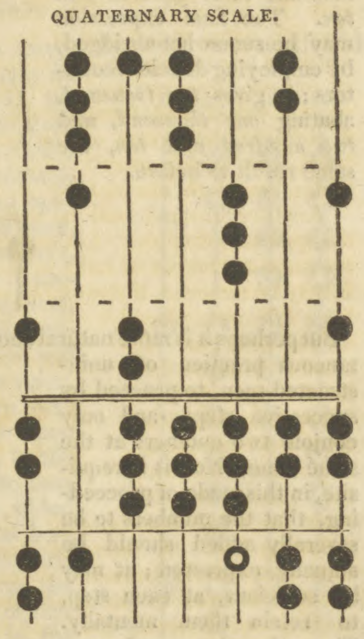
Having considered at some length the properties of numerical scales, and their various transformations, we have now to explain the ordinary operations performed on numbers themselves. These operations are all reducible to two very simple changes,—the *conjoining* and the *separating* of numbers. When two or more numerical expressions are *conjoined*, that is, condensed into a single expression, or collected into one *sum*, the process is called *Addition*. But when one numerical expression is *separated* or drawn out from another, leaving only a *difference* or *remainder*, the process is called *Subtraction*. If the *addition* should be employed merely in repeating the same number, it admits of abbreviation, and is then termed *Multiplication*. On the contrary, if the *subtraction* be limited to the continued withdrawing of the same number from another, the process becomes capable of abridgment, and is termed *Division*.

Palpable Arithmetic.

### Addition.

The whole operation consists in collecting and condensing the separate expressions. Beginning with the lowest bar, the counters are gathered together, and if they exceed the index of the scale, this excess only is retained, and *one* counter annexed or carried to the next bar. But if the counters on any bar should contain the index more than once, the number of repetitions is transferred a place higher, while the remainder of the reckoning is left as it stood. A very few examples will render the mode of proceeding quite clear. Let it be required to collect the expressions here disposed on the *Quaternary Scale*. On the bar of units, *two* counters occur, which are brought together at the bottom. *Two* counters are likewise found on the next bar, and each of the three following bars has each *three* counters. But *four* counters are found on the next bar, which are equal to *one* transferred to the highest bar, leaving a *blank* in their own place. In this case very little change in the notation is wanted; and except in a single transfer to a higher bar, the counters are merely brought closer together, and form the expression at the bottom. This again might be somewhat abridged by introducing open counters, as represented here, below the other. The sum of the three compound numbers thus represented on the *Quaternary Scale*, is therefore by reduction *nine thousand two hundred and ten*.

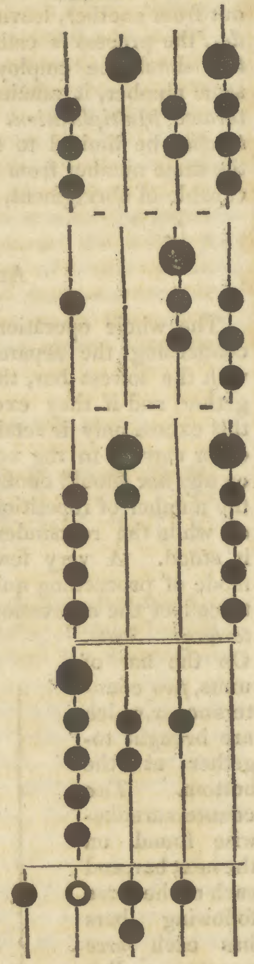
QUATERNARY SCALE.



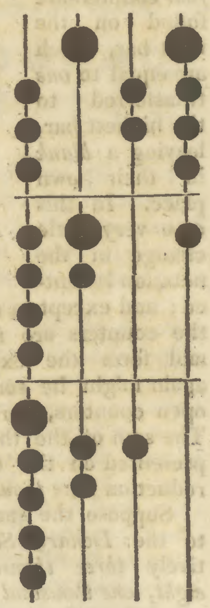
Suppose the same numbers were converted into the *Denary Scale*. They would be respectively *three thousand five hundred and twenty-eight*, *one thousand and seventy-three*, and *four thou-*

sand six hundred and *nine*; which are thus exhibited successively on four bars. Now, collecting all the single counters on the first bar to the right, they amount to ten, which joined to the two *fives* make *twenty*; they consequently, in their summation, leave that bar void, and throw *two* counters to the next. These *two* counters now joined to the *four* which occur on the second bar, make *six*, and again with the *five*, *eleven*, leaving *one* counter on the second bar, and furnishing *one* to the next. This counter, with another already on the third bar, leaves *two*; while the two *fives* on it deliver one on the fourth bar. The result, as before, is *nine thousand three hundred and ten*. The final expression may be somewhat abridged, by employing deficient counters; it gives *ten thousand*, abating *one thousand*, and *two hundred* and *ten*, the same result as before.

DENARY SCALE.

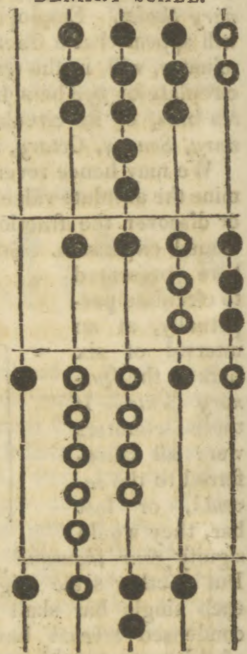


But perhaps it is more natural and more like the spontaneous practice of uninstructed men, to proceed by successive steps, and only conjoin two numbers at the same time. Nor is it requisite, in this mode of proceeding, that the numbers to be severally added should be actually expressed; it may be sufficient, at each step, to retain them mentally. Thus, when the second number is to be added to the first, the *three* counters which should occupy the first bar being joined, the *three* single ones already noted make *six*, or leave *one*, and change the other *five* into *ten*, which furnishes *one* counter to the second bar; and *one* counter on the fourth bar increases its stock to *four*. Again, when the third number is added, it would give *nine* counters to the first bar, and hence change it into *ten*, leaving the bar void, and throwing a counter to the next bar. But the *six* counters on the third bar, convert the *five* counters into *ten*, and thus furnish *one* to the next bar, while they leave *two* counters behind them.



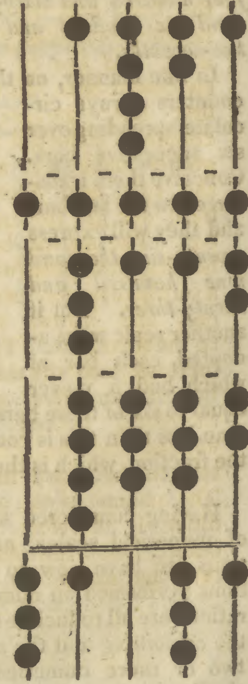
The working of this example would be simplified by employing the notation of deficient counters. Thus the several numbers are changed into other expressions as here expressed. On the first bar, the full and the open counters, being three of each kind, exactly balance each other; but, on the second bar, the full counters leave an excess of *one*. The full counters on the third bar, being eight in all, exceed the open ones by two; while, on the fourth bar, they leave a defect of one.

DENARY SCALE.



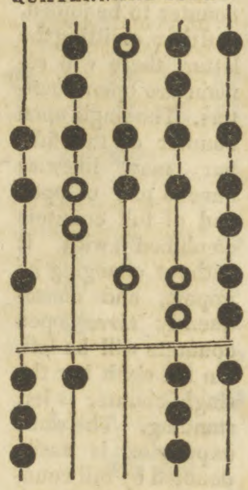
Let another example be taken of addition from numbers arranged on the *Quinary Scale*. The counters on the first bar amount to *six*, which leaves *one* counter, and furnishes *one* to the next bar. This bar now holds *eight* counters, leaving *three* consequently, and throwing *one* to the third bar. The third bar has then *ten* counters, or is left void, and gives *two* counters to the next bar. This bar, holding *eleven* counters, leaves *one*, and supplies *two* to the highest bar. The total amount of the numbers is therefore *three quadruplicate pentads*, one *triplicate pentad*, *three pentads* and *one*, or by reduction, *two thousand and sixteen*.

QUINARY SCALE.



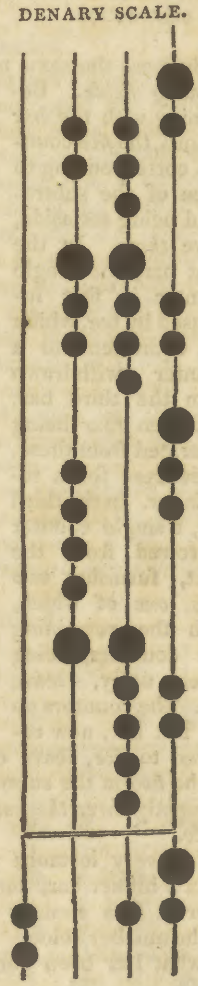
By introducing deficient counters, the process might be simplified and abridged. The first bar continues the same as before; but in the next bar, after *one* had been carried to the second bar, and joined to the full counters, there yet is an excess of *three* full counters. In thethird bar, the oppositecounters, being *two* each, are quite balanced, and leave a void; but the fourth bar yields an excess of *one* full counter, while the fifth collects *three* full counters. The result is every way the same as before.

QUATERNARY SCALE.



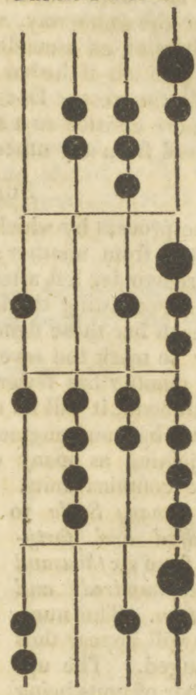
Let these numbers be transformed on the *Denary Scale*. They will stand as here expressed, occupying three bars. The first number furnishes to the successive bar *two*, *three*, and six counters; the next number gives *seven*, *eight*, *and two;* the third number delivers *four* to the third bar, passes over the second, and deposites *seven* on the first; and the last number, supplies *five*, *nine*, *and two* to the successive bars. In the first bar, the *single* counters collected together make *six*, and the two *fives* contribute *one* to the next bar. The second bar, holding four *fives* with a surplus counter, leaves *one*, and throws *two* to the next bar. This increase raises the third bar to four *fives*, and therefore, leaving it void, advances *two* counters to the fourth bar. The amount of the addition is therefore, as before, being *two thousand* and *sixteen*.

DENARY SCALE.



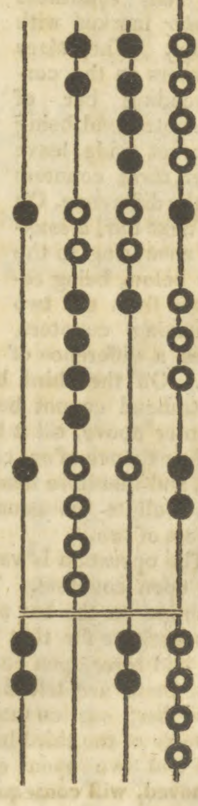
If the operation were performed in its utmost simplicity, by annexing one of the numbers always after the other, the progress of summation would be thus exhibited. The first number being actually represented by counters, the second, which is only retained in the memory, changes by its absorption the several bars, and produces *one thousand and seventeen.* To this again is joined mentally the third number, which gives *one thousand four hundred and twenty-four*, as another step in the progress. And, lastly, the fourth number, being annexed to this, completes the transformation, and produces the final result, *two thousand* and *sixteen.*

DENARY SCALE.



But, in most cases, the work of summing different numbers may be sensibly shortened, by a judicious application of open counters; which, by their intermixture, effecting in a long operation a sort of balance, will, for the most part, save the trouble of carrying to the higher bars. Whenever the full counters on a bar exceed half the index of the scale, it is preferable to substitute for them open counters. Thus, in the last example, the four numbers to be added may be denoted as here expressed. In the first bar, there is, on the whole, an excess of *four* open counters; in the second, an excess of *two* full counters; but, in the third bar, the opposite counters are exactly balanced, and leave a void. The result is consequently *two thousand and twenty*, abating *four*.

DENARY SCALE.

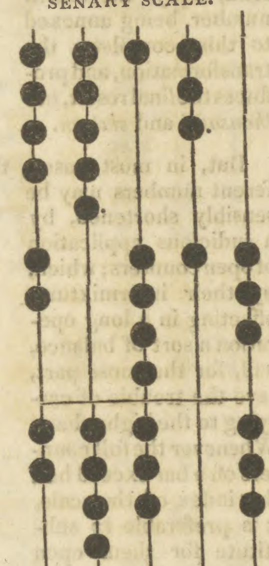


It is evident that all these operations are conducted in the same way, whether the counters occupy the bars of an ascending or of a descending series. The position of the bar of units, determines the values of all the rest. Decimal fractions, are, therefore, no more entitled to a separate discussion than those derived from any other scale.

SUBTRACTION

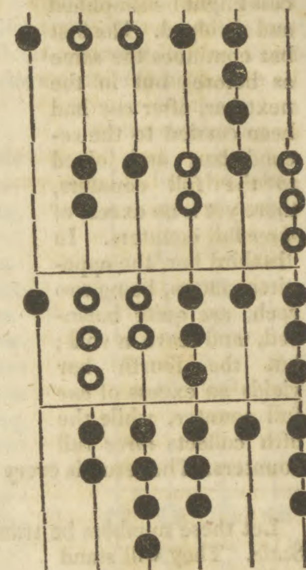
is the process by which a number is separated or extracted from another; the difference sought being the remainder left after this operation. If the counters representing the larger number, should exceed on each bar those denoting the subtrahend, we have only to mark the several excesses. But, if the upper number has fewer counters on any bar than the subtrahend, it will be necessary to take one from the higher bar, and augment the expression of the other, by joining as many counters as the index of the scale contains units. Suppose it were required on the *Senary Scale* to subtract *two thousand seven hundred and forty-five*, from *six thousand three hundred and eighteen*. The numbers will appear thus arranged. The upper bar of units being vacant, we put *six* on it, and withdraw or borrow from the next bar *an equivalent counter* marked with a dot. The *three* counters on the corresponding bar of the subtrahend, being then set aside, leave other *three* counters for the difference. On the next bar, *a counter*, answering to the one below, being removed from the two remaining counters, gives a difference of *one*. On the third bar, the *four* counters of the subtrahend cannot be taken away from the single counter above, till it has been augmented to *seven*, at the expence of *one* counter withdrawn from the next bar, and therefore marked with a dot. The fourth bar leaves all its *four* counters, and the fifth bar drops its excess of *two*.

SENARY SCALE.



The operation is varied and shortened, by adopting open counters. To take away the *three* open counters on the bar of units from the vacuity above it, substitute for that void the counterpoise of *three* full and *three* open counters, and then separating the last, there are left *three* full counters. On the second bar, *one* counter only remains. The *single* counter of the third bar may have annexed to it two full and two open counters, and the latter being removed, will consequently leave *three* full counters. On the fourth bar, conceive an open and a full counter to be joined, and then, omitting the latter, there will remain *two* open counters. The single open counter of the fifth bar may likewise have a pair of open and of full counters combined with it without changing its import, and consequently *three* open counters will be left. On the sixth bar the single counter is left standing. The same expression is easily denoted by full counters, and gives, on reduction, the number *three thousand five hundred and seventy-three*, as the result of the subtraction.

SENARY SCALE.



Suppose the same numbers were expressed on the *Denary Scale*. Beginning with the bar of units, the *five* counters corresponding to those of the subtrahend being set aside, leave *three*. In the next bar, the single counter is first increased by *ten*, which are equivalent to a counter withdrawn from the third bar, and then *four* being separated from these, gives *seven* for a remainder. In the third bar, a single counter borrowed from the next, furnishes two *fives*, *one* of which, with the remaining *two* counters, being taken away, leave *five*. The counters on the last bar, now reduced to *five*, leave only *three*, after the separation of the *two* in the subtraction. The remainder is consequently *three thousand four hundred and seventy-three*.

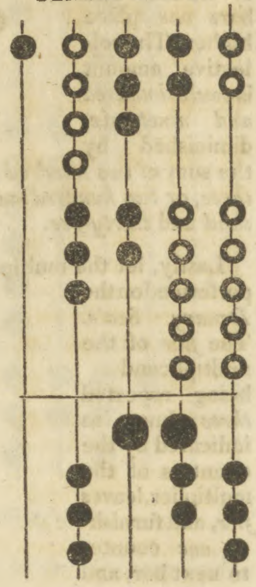
DENARY SCALE.

In every instance where a counter is borrowed from a higher bar, the effect would evidently be unaltered, if a counter were added on the same bar to the number below. This modification of the process is what has been generally termed *carrying*. It is

Palpable Arithmetic.

farther illustrated, by operating with open counters. Conceive *three* open and *three* full counters to be placed on the first bar, and the latter will be left as an excess below. On the second bar, let *five* open and *five* full counters be laid, and then, rejecting the former, there will remain *seven*. Again, annex on the third bar a *pair* of open and *another* of full counters, and *five* will be left. And, in the fourth bar, joining *three* full and *three* open counters, and next setting aside the former, there will be left *seven* open counters; which, omitting the full counter of the fourth bar, are equal to *three* full counters.

DENARY SCALE.

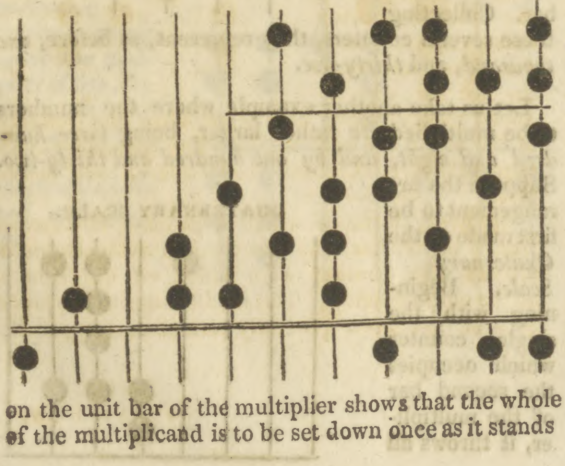


### Multiplication

is nothing but a process of repeated Addition. When the terms, however, to be multiplied are complex, and the index of the *Numerical Scale* is large, the operation will admit of being very considerably abridged. It has been already shown, that a number is virtually multiplied by the *index* of the scale, by advancing its expression *one* bar; that it is multiplied by the *second power* of that index by advancing it *two* bars; and so forth continually, according to the progressive powers. Again, if any term of the multiplier be great, it is preferable, instead of repeating the counters of the multiplicand, to collect them mentally, and only mark the result. The ready performance of multiplication depends entirely on the right application of these two principles. A few examples will elucidate the process.

Suppose it were required to multiply the number *forty-five* by *twenty-three*, that is, to add the units contained in forty-five *twenty-three* times. First, let those numbers be disposed on the *Binary Scale*. The counter

BINARY SCALE.



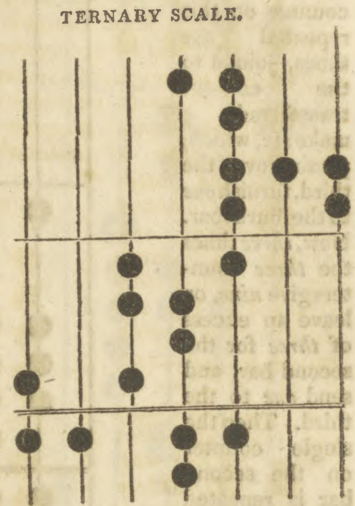
on the unit bar of the multiplier shows that the whole of the multiplicand is to be set down once as it stands

Palpable Arithmetic.

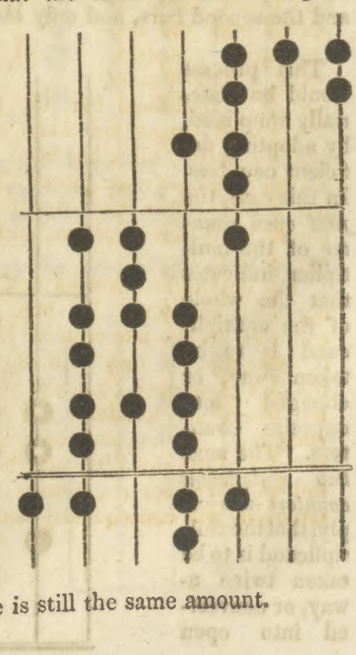
The next counter indicates, that the whole of the upper range of counters must be advanced *one* bar; the counter on the third bar intimates, that the same row should be carried *another bar* higher. The last counter, occupying the fifth bar, shows that the counters of the multiplicand should be advanced *four* bars, or that the first of them should be placed on the same bar below it. These counters, again, collected into a single row, give by reduction, *one thousand and thirty-five*.

Next, let the same numbers be arranged on the *Ternary Scale*. Following the terms of the multiplier, therefore, the multiplicand must be repeated *twice* as it stands, then *once* on a bar higher, and again *twice* on the bar above this. But twice *two* make four, leaving *one* on the third bar, and throwing *one* to the fourth bar, which produces *three*, or leaves that bar empty, and delivers *one* to the next bar. Again, the multiplicand is repeated on a bar higher, and doubled on a bar two steps higher. Collecting then the counters on each successive bar, amounting to *one* on the seventh bar, *one* on the sixth, *two* on the fourth, and *one* on the second, the result will, after being reduced, appear the same as before.

TERNARY SCALE.



It is obvious, that the units contained in *forty-five* must give the very same amount when repeated *twenty-three* times, as those in *twenty-three* after a repetition of *forty-five* times. But the interchange of multiplier and multiplicand, would, in this case, rather simplify the process. The upper counters are here advanced at once *two* bars and redoubled, and then repeated *once* on the next set of bars. Being collected, there is still the same amount.

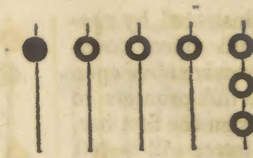


Again, suppose the same numbers to be referred to the *Senary Scale*. The three counters on the unit bar of the multiplicand being repeated *five* times, make *fifteen*, or leave *three* on that bar, and give *two* to the next. But *five* times the simple counter on the next bar, together with the *two* carried, make *seven* or leave *one*, and furnish *one* to the third bar; and the single counter on this repeated *five* times, joined to the counter transferred, make *six*, which, passing over the third, furnish *one* to the fourth bar. Now, *three* times the *three* counters give *nine*, or leave an excess of *three* for the second bar, and send *one* to the third. Then the single counter on the second bar is repeated *three* times and *one* added to it, and the next counter likewise repeated *three* times, but without addition. Collecting now the counters on the several bars, there appear *four* on the fourth, the third, and the second bars, and only *three* on the first.

SENARY SCALE.

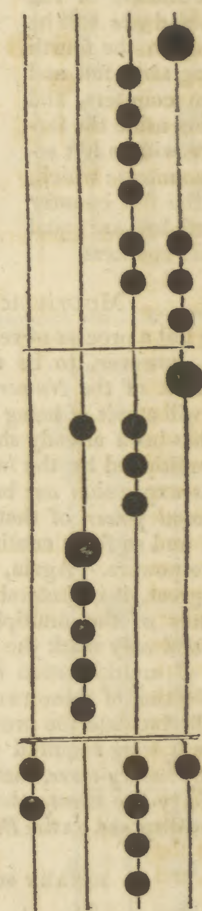
This process would be materially simplified, by adopting deficient counters. In this case, the *first open counter* of the multiplier indicates that the whole of the multiplicand is to be taken away, or changed into opposite counters. The next *two deficient counters* also imply, that the multiplicand is to be taken twice away, or converted into open

counters on the bars *one* place higher. The collective amount is *twelve hundred and ninety-six*, diminished by the sum of *two hundred and sixteen*, *thirty-six*, *six* and *three*, or *two hundred* and *sixty-one*; that is, *one thousand* and *thirty-five*.



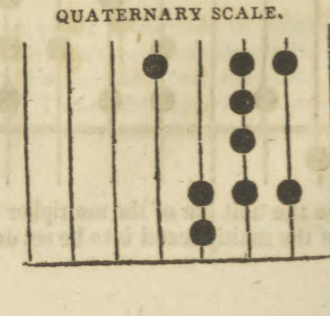
Lastly, let the multiplication of those numbers be performed on the *Denary Scale*. The *five* of the multiplicand being repeated *three* times, as indicated by the counters of the multiplier, leaves *five*, and furnishes *one* counter to next bar, and the *four* counters of the second bar being tripled, and acquiring the one carried, leave *three*, with another counter for the third bar. The *five* being next doubled by the two counters of the *second* bar of the multiplier, give *ten* for the place of the second bar, or *one* for the third; and the four counters being doubled and augmented by this transferred one, give *nine* for the third bar. Collecting these several counters, they represent, as before, *one thousand*, and *thirty-five*.

DENARY SCALE.

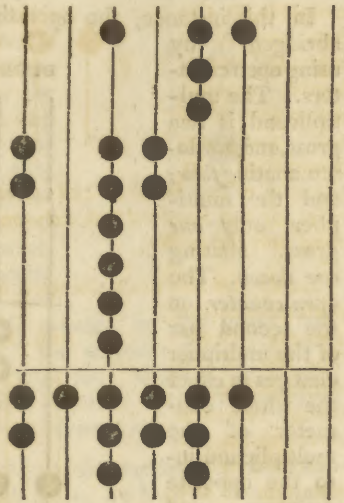


Let us take another example where the numbers to be multiplied are rather larger, being *three hundred and eight, and by one hundred and thirty-two*. Suppose the arrangement to be first made on the *Quaternary Scale*. Beginning with the single counter which occupies the second bar of the multiplier, it throws all

QUATERNARY SCALE.

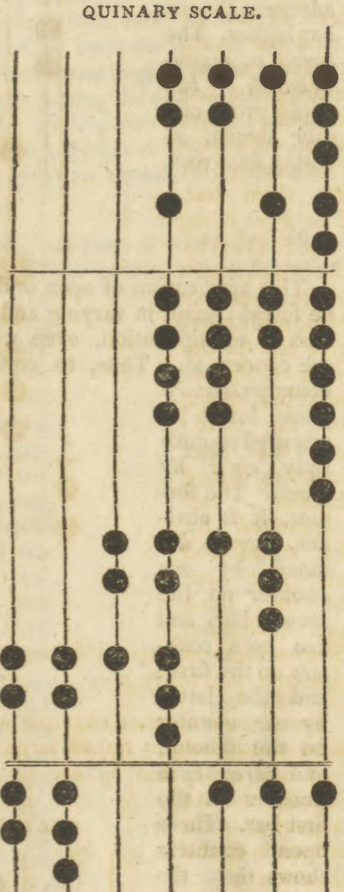


the terms of the multiplicand a bar forward, or sets the units immediately below itself. The *two* counters again, which stand on the fourth bar, redoubles all the former, and advances them *three* bars. Collecting then the counters on the several bars, and reducing their values, the result of the whole is *forty thousand, six hundred* and *fifty-six.*



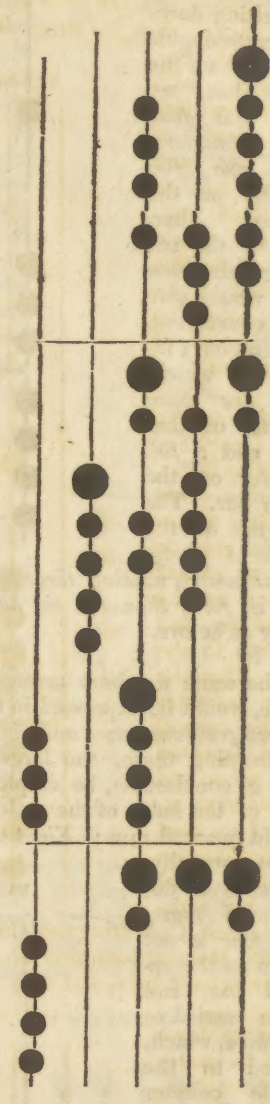
Transfer the same numbers to the *Quinary Scale,* and they will present this form. The *two* counters of the multiplier intimate, that the terms of the multiplicand are to be *doubled* in the same ranks; the single counter shows, that they are to be repeated a bar higher, and the counter on the fourth bar signifies that they are to be placed again three bars in advance. Collecting all the counters on the several bars, and condensing them by carrying higher the multiplier of five, the amount is the same as before, that is, *forty thousand six hundred and fifty-six.*

QUINARY SCALE.



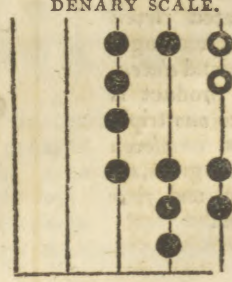
In the *Denary Scale,* more counters will be required, though a large one be adopted, for the sake of conciseness, to represent *five,* the half of the index. Beginning as usual at the right hand, the terms of the multiplicand are first *doubled* mentally, as intimated by the two counters of the multiplier; and as *twice eight* makes *sixteen,* the *six* is placed on the bar of units, and *one* carried to the next bar; then the double of *three* gives *six* counters for the third bar. Again, those terms are tripled; as signified by the counters on the second bar of the multiplier; but thrice *eight* are *twenty-four,* leaving *four* on the second bar, and throwing *two* to the third, while the triple of *three* gives *nine,* for the fourth bar. And, lastly, the whole of the multiplicand is set down *two* bars in advance. The several rows of counters being collected, give still the same result, or *forty thousand, six hundred* and *fifty-six.*

DENARY SCALE.



The operation may be somewhat abridged by employing, as circumstances will permit, open counters. Thus, instead of *eight* in the multiplicand, we may assume *ten* wanting *two,* or *one full counter* on the second bar, and *two open counters*

DENARY SCALE.



Palpable Arithmetic.

on the first. In the first duplication, instead of setting down *six* for the double of *three* on the third bar, we may put *four open counters,* and *one full counter* on the higher bar. Again, the tripling of the same row would give *nine* counters on the fifth bar; instead of which, set *one open counter* on that bar, and a *full counter* on the sixth bar. The amount of the whole is, *forty-one thousand,* abating *three hundred and forty-four;* that is, *forty thousand six hundred and fifty-six,* exactly as before.

The same numbers arranged on the *Duodenary Scale,* would be expressed in the language of traders, by *two gross one dozen and eight,* and by *eleven dozen.* In denoting these, the large counter may, for the sake of conciseness, be employed to express *six,* the half of the index of the scale. Their multiplication would proceed thus: *Eight* counters repeated *eleven* times mentally, makes *seven* dozen and *four;* this *four* is set down on the *second* bar, and *seven* carried to the *third,* which, joined to the single counter repeated eleven times, gives a *dozen* and *six.* Having marked the *six* on the *third* bar, *one* is joined to the *two* repeated *eleven* times, making a *dozen* and *eleven.* The product is hence *one* triple gross, *eleven* double gross, *six* gross, and *four* dozen.

DUODENARY SCALE.

Palpable Arithmetic.

In this instance, the operation would be greatly abridged, by using open counters. The multiplicand is *two* gross, and *two* dozen, abating *four;* and the multiplier only *one* gross, abating *one dozen.* The *open counter* on the second bar of the multiplier changes in effect the whole character of the multiplicand into the opposite counters, and the *full counter* on the third bar repeats the same counters, and advances them a bar higher. The result is, consequently, *two* triple gross and *four* dozen, abating *five* gross.

DUODENARY SCALE

The application of open or deficient counters will be found useful, in varying and simplifying the process of multiplication, even where smaller numbers are concerned. Thus, to confine our views to the common *Denary Scale,* let it be required to multiply *eight* by *seven.* The former, it is obvious, may be denoted by *one* counter on the second bar, and *two open counters* on the first; and the latter by *one* counter on the second, and *three open counters* on the first bar. These open counters show that the terms of the upper number should be sub-

DENARY SCALE.

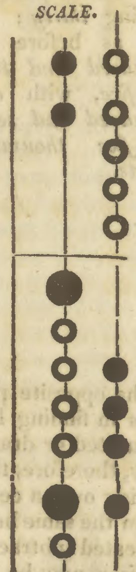
Palpable Arithmetic.

tracted *three* times; that is, repeated *thrice* with an opposite character; which gives *six full counters* for the first bar, and *three open ones* for the second. Again, the *full counter* on the second bar indicates that those terms are to be repeated unchanged, but placed one bar in advance. This combination exhibits the product. But instead of the *single counter* on the third bar, substitute *two fives* on the second; the result will then be decomposed into *five*, abating *three*, and *five* abating *two*, TENS, together with the counters *on the first bar*, or twice *three*, UNITS.

Hence the explication of the method for multiplying any numbers under ten, by help of the fingers merely; an arithmetical curiosity, very long known to mathematicians, but lately introduced, among other improvements, into the practice of the elementary schools. Beginning at the left, and proceeding to the right, *seven* fingers (including the thumbs) are counted in this example, which leave *three* fingers to close. Again, proceeding backwards from right to left, the number *eight* leaves *two* fingers, which are shut on the left hand. Then joining the projecting fingers of both hands, or *five* abating *two* and *five* abating *three*, we obtain *five tens* or *fifty*; while the product of the closed fingers, gives an accession of *six units*, making in all *fifty-six*.

As another example, suppose it were desired to multiply *nine* by *six*. These numbers may be severally expressed by *ten* abating *one*, and by *ten* abating *four*. But the *four open counters* of the multiplier, signify that the upper counters are to be changed and there repeated *four* times; while the *full counter* intimates that those counters are, without alteration, to be advanced a whole bar. Instead, however, of the single counter on the *third* bar, *two fives* may be combined with the open counters on the *second*. But this procedure can be imitated by the play of the fingers. Counting *nine* fingers, beginning with the left hand, and passing to the right, we leave *one* finger to close; and again reckoning *six*, by proceeding from the right to the left, we have *four* fingers remaining to close. If we now bring together the projecting fingers of both hands, we shall have, of TENS, *five*, abating *four*, and *five* abating *one*; that

DENARY SCALE.

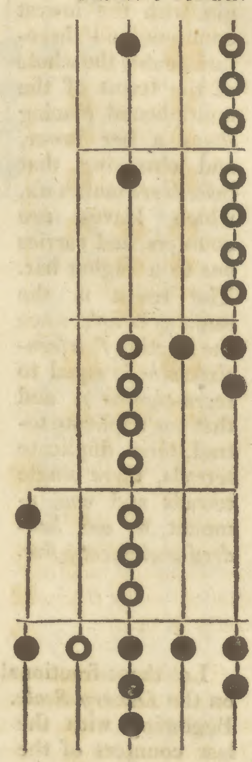


is, *fifty*, together with the product of the shut fingers, or *six* units, told *once*.

Palpable Arithmetic.

This philosophical trick cannot fail to appear striking to young practitioners, and may prove really useful, by helping to fix thoroughly and accurately in their memory the ordinary multiplication table. But the same principle can be extended farther. Suppose it were required to multiply *ninety-seven* by *ninety-six*. These numbers are merely *one hundred*, abating *three* and *four*. The product is, therefore, of *hundreds*, one hundred fold, abating *four*, and then *three*; that is, *nine thousand, three hundred*; together with *three* times *four* units, or *twelve*.

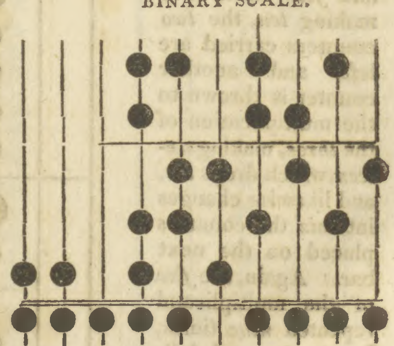
DENARY SCALE.



But instead of *seven open counters* on the third bar, the defect from ten, or *three full counters* may be placed, and an *open counter* set on the fourth bar. This result is consequently *ten thousand, three hundred and twelve*, abating *one thousand*.

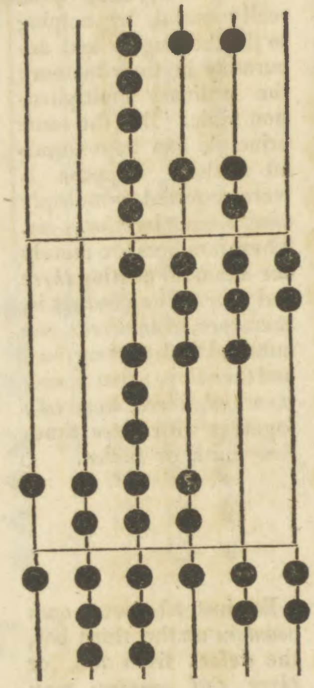
When fractions are expressed on the same numerical scale, their multiplication proceeds with equal facility as that of integers; it being only requisite to begin with the bar of units, and to descend with the lower bars. Thus, if it were sought to multiply *thirteen and a quarter*, by *nine and a half*. Let these quantities be first arranged on the *Binary Scale*, and they will stand thus: Begin therefore with the counter on the bar of units, and mark the upper row in the same ranks in which it stands; or, what must evidently give the same result, take the extreme counter which occupies the next lower bar, and depress all the counters in the row by the interval of a whole bar. Proceed in like manner with the other counters. The collective amount is *one hundred and twenty-five*, and *seven-eighths*.

BINARY SCALE.



Suppose the same fractional quantities were transferred to the *Quaternary Scale*. Instead of commencing with the bar of units, begin with the lowest counters, and therefore double the whole of the terms of the multiplicand, placing them a bar lower, and observing that *twice three* makes *six*, which leaves *two* counters, and carries *one* to a higher bar. The result is the same as before, since the fraction *fourteen-sixteenths* is equal to *seven-eighths*; and that *one* triplicate tetrad, *three* duplicate tetrads, *three* single tetrads and *one*, amount to *one hundred and twenty-five*.

QUATERNARY SCALE.



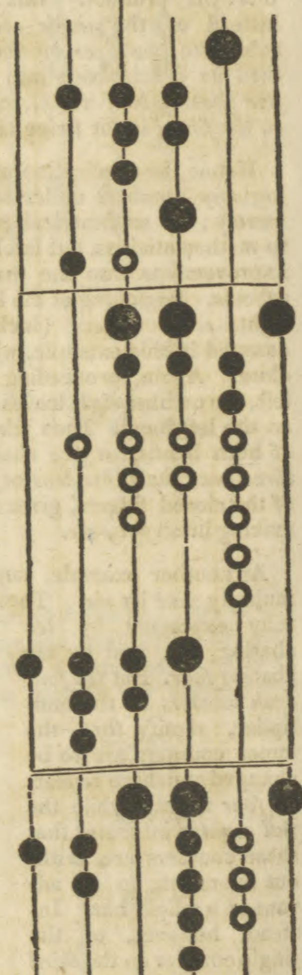
Let those fractional numbers be now represented on the *Denary Scale*. They will be thus expressed.

DENARY SCALE.

Beginning with the last counters of the multiplier, or the *five* on the bar next that of units, its product into the upper *five*, making *twenty-five*, should be placed on a bar lower. This leaves *five*, and throws *two* to the higher bar; and *five* times *two* making *ten*, the *two* counters carried are left, and another counter is thrown to the multiplication of the *three*, making *sixteen*, which drops *six*, and likewise changes into *six* the counters placed on the next bar. Again, the *five* of the multiplicand repeated *nine* times, leaves *five*, and delivers *four* to the next bar, increasing the counters on it from *eighteen* to *twenty-two*, or leaving *two* and transferring *two*. The multiplication into the *three* leaves *nine*, and gives over *two*, converting the counters on the next bar to *eleven*, or *one* counter left and *one* advanced. Collecting the counters on the different bars, we get *one hundred and twenty-five*, and *eight hundred and seventy-five thousandth parts*.

But the operation will be materially simplified, by introducing an open counter into the second term of the multiplier, as here expressed. The first step of the multiplication by *five* is the same as before; but the *open counter* on the next bar indicates, that the whole of the multiplicand is to be set down with opposite counters; and the *full counter* on the highest bar shows, that it must be repeated in advance without alteration. Collecting the counters together, and observing their mutual influence, the general result is *one hundred and twenty-five*, with *nine hundred and five thousandth parts*, abating *thirty*; that is, as before, *one hundred and twenty-five*, with *eight hundred and seventy-five thousandth parts*.

DENARY SCALE.

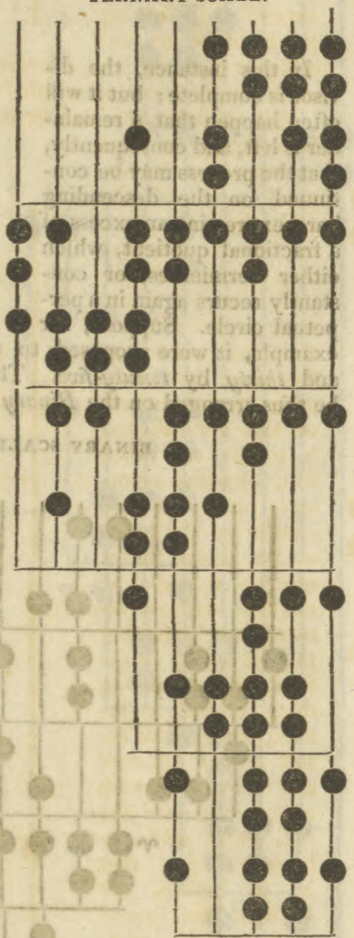


### Division

is the opposite process to Multiplication, and consists in finding how often the same number can be separated or drawn out from another. In the rudest way, therefore, this operation would be performed, by telling over a certain number of counters repeatedly from the same heap. But instead of a slow process of repeated subtraction, the number to be severed, or the *divisor*, may be first multiplied to approach the mass to be shared, or the *dividend*. The remainder can again be treated in the same manner, and the operation renewed, till nothing is left of the dividend, or a difference less than the divisor itself. Those

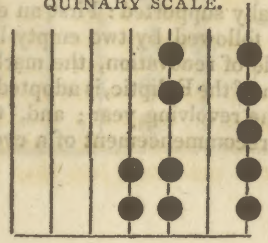
multipliers, collected together, will express the *quotient*, or the number of subtractions required to exhaust the mass. A few examples shall be taken for illustration. Suppose *sixteen thousand* and *six* were to be divided by *fifty-three*. Let these numbers be arranged first on the *Ternary Scale*, the *dividend* being lowermost, and space left for putting the *quotient* immediately under the *divisor*. Beginning at the left hand, the divisor is evidently contained *once* in the first four bars; place a counter then for the quotient, on the last of these bars; set the divisor immediately under the dividend, and note the difference, which is a counter on both the seventh and eighth bars. Of this difference, with the remaining counters brought down, four bars are less than the divisor, but it may be contained *twice* in five bars. Passing over one bar, therefore, *two* counters, joined to the quotient, are placed on the fourth bar of the range. The multiplicand is then doubled, and set down. But four bars of the remainder being less than the divisor, it may be found *once* in five bars, and consequently, omitting the third bar, *one* counter is placed on the second bar; and the remainder of the multiplicand is so great, that *two* counters may be set on the last bar; which duplication of the divisor finally exhausts the dividend. The quotient is hence *three hundred* and *two*.

TERNARY SCALE.



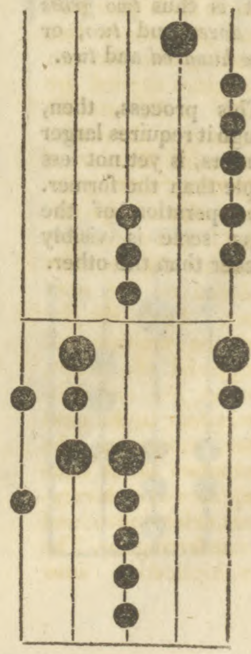
Let the same operation be performed on the *Quinary Scale*. The divisor, which here occupies three bars, is evidently not contained in the three first bars of the dividend, but it is contained *twice* in four of those bars. *Two* counters, representing this quotient, are therefore set down on the last of those bars, and the counters of the divisor, being doubled, are placed under the higher terms of the dividend. The remainder on three bars, being four and two counters, again contain the divisor *twice* on a lower bar. The double of the divisor being subtracted, the residue, or four counters, is not divisible, without including likewise the two lowest bars, when it gives *two* for the rest of the quotient. The divisor being now doubled, equals the remainder exactly.

QUINARY SCALE.



The operation will be shorter on the *Denary Scale*. The divisor, consisting of *five* counters on the second bar and *three* on the first, which includes a counter on the fifth and fourth, and six on the first, is contained *thrice* in the three first bars of the dividend. On the third bar, therefore, place *three* counters. The divisor being then tripled, leaves a remainder of one counter, which, being extended, the last bar becomes again divisible, yielding

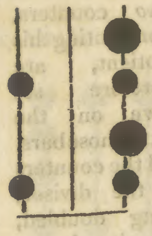
DENARY SCALE.



Palpable Arithmetic.

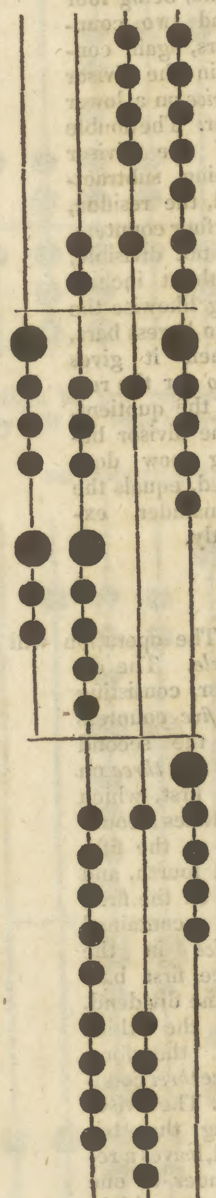
*two*, as the residuary part of the quotient.

The quotient is thus *three hundred* and *two*, the same as before.



Suppose the division were to be performed on the *Duodenary Scale*. Transferred to that scale, the divisor would, in the mercantile phrase, be called *four dozen* and *five*, and the dividend *nine double gross, three gross, one dozen* and *ten*. In the two first bars of this number, the divisor is evidently contained *twice;* therefore, *two* counters are set down on the *third* bar, and the divisor *doubled* and subtracted, leaving a remainder of *five gross, one dozen and ten*. *Two* bars of this again, contains the divisor *once;* and *one* counter, to denote it, being placed on the second bar, the subtraction is made, giving a remainder of *eight dozen and ten*, exactly double of the divisor, and consequently marked by *two* counters. The quotient is thus *two gross one dozen* and *two*, or *three hundred* and *two*.

DUODENARY SCALE.

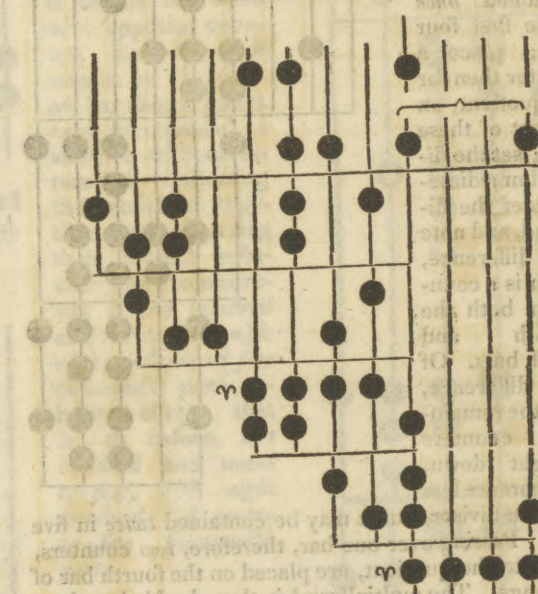


This process, then, though it requires larger counters, is yet not less simple than the former. The operation of the larger scale is visibly quicker than the other.

Palpable Arithmetic.

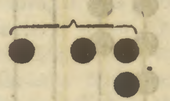
In this instance, the divisor is complete; but it will often happen that a remainder is left, and consequently, that the process may be continued on the descending bars, expressing an excess of a fractional quotient, which either terminates, or constantly recurs again in a perpetual circle. Suppose, for example, it were proposed to divide *three hundred* and *thirty* by *twenty-five*. These numbers would be thus arranged on the *Binary Scale:*

BINARY SCALE.



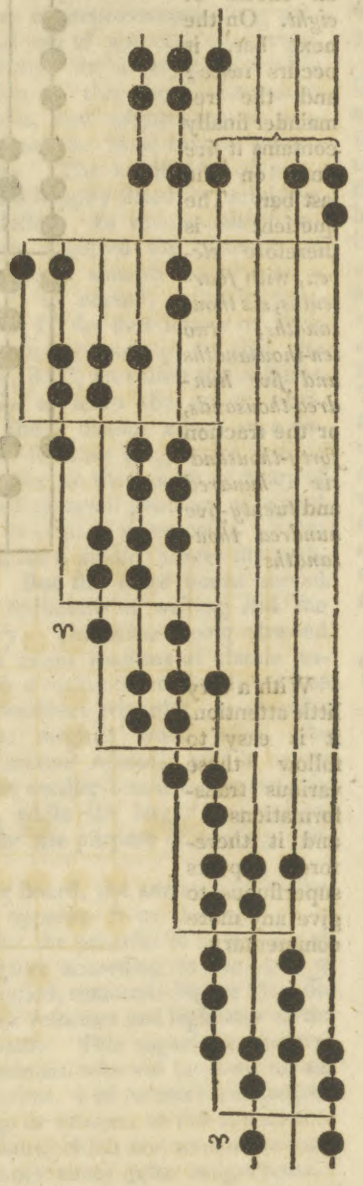
Under the fourth bar, the divisor is contained *once*, leaving a counter on the eighth and one on the second bar. Under the third bar, it is again found *once*, with the remainder of four consecutive counters. Passing over the second bar, the divisor is contained *once* under the first; but not again till after an interval of two bars, when there is left, as under the second bar, four consecutive counters. At this point, therefore, a circulation must take place, since the third bar below that of units, thus corresponds to the next above it. The same sequence will be continually supported: First an empty bar, then a counter, followed by two empty bars.—To indicate this circle of renovation, the mark ♈ for *Aries*, the first Sign of the Ecliptic, is adopted, as intimating the birth of the revolving year; and, therefore, by extension, the recommencement of a cycle.

Let the division be now performed on the *Ternary Scale*. Under the third bar, the divisor is evidently contained *once;* and *once* again successively under the second and the first bar. But the remainder is now so small, that the divisor must be depressed to the second bar below that of units, to be found in it. On the next bar lower, it is contained *twice*, with the remainder of a counter, a blank, and again a counter; the same as what occurred under the second bar. Here the circulation commences, and forms this perpetual series



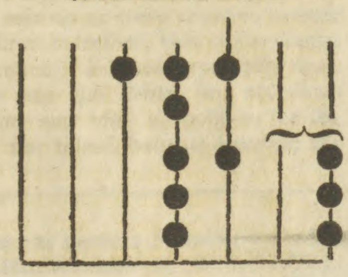
The symbol ♈ is placed to denote the alternate counters ● ● which intimate the commencement of the sequence.

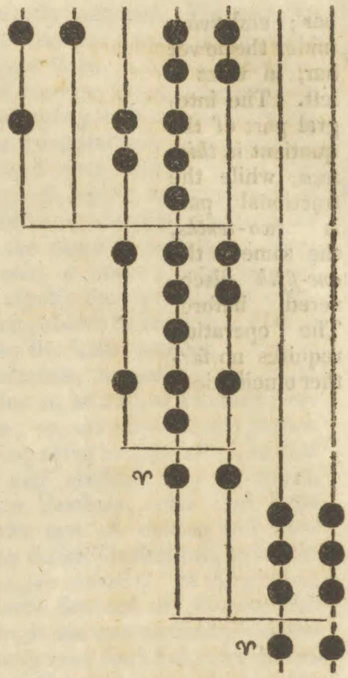
TERNARY SCALE.



Suppose the numbers *twenty-five and three hundred and thirty*, were now arranged on the *Quaternary Scale*. The divisor is contained *thrice* in the dividend, under the *second* bar, and *once* again below the place of units in the remainder. After this division, there is left only *two* consecutive counters, noted by the sign ♈, in which the divisor, at the interval of *two* bars, is contained *three* times, with the same remainder. It is evident, therefore, that the fractional part of the quotient will be afterwards continually repeated, being exhibited by a column of *three* counters alternating with *a vacant bar.*

QUATERNARY SCALE.



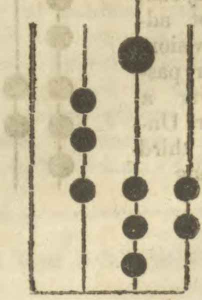


On the *Quinary Scale*, this example of division becomes almost intuitive. The divisor being here expressed by a single counter on the *third* bar, the quotient must evidently be the same as the dividend, only thrown *two* bars lower. The result of the division is consequently *thirteen* and a *fifth.*

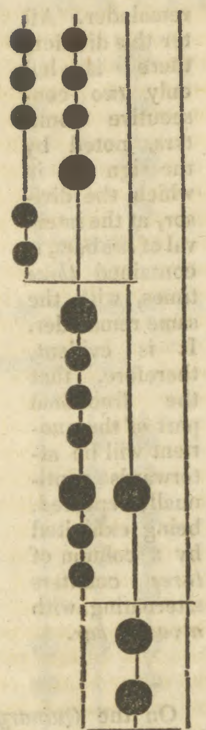
QUINARY SCALE.

Lastly, let the operation be performed on the *Denary Scale.* The divisor *twenty-five* is obviously contained *once* under the bar of *tens;* in the remainder, it is contained *three* times, under the next

DENARY SCALE.



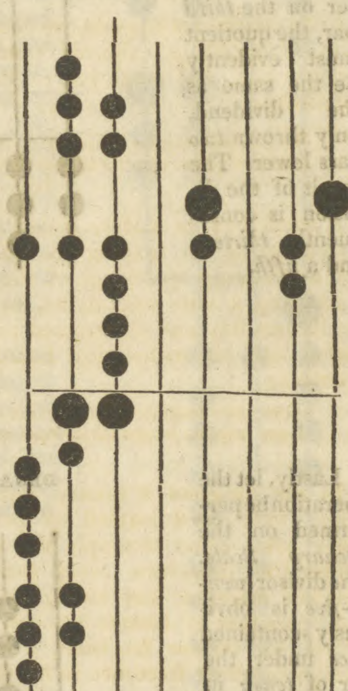
bar; and *twice*, under the lower bar, in what is left. The integral part of the quotient is *thirteen*, while the fractional part is *two-tenths*, the same as the *one-fifth* discovered before. The operation requires no farther elucidation.



bar, the divisor is found *six* times, with an excess of *eight*. On the next bar, it occurs *twice*; and the remainder finally contains it *five* times on the last bar. The quotient is therefore *eleven*, with *four-tenths*, *six thousandths*, *two ten-thousandths* and *five hundred-thousands*, or the fraction *forty-thousand six hundred* and *twenty-five hundred thousandths*.

Another example shall conclude this part of the subject. Let it be required to find the quotient of *three hundred* and *sixty-five* by *thirty-two*. And to avoid prolixity, we may confine it to the *Denary Scale*. Under the bar of *tens*, the divisor is evidently contained *once*, and in the remainder *once* again below the units. Under the next bar, it occurs *four* times; after which, the remainder, being only *two*, does not admit of division, till after passing over a whole bar. Under the third descending

DENARY SCALE.



With a very little attention, it is easy to follow these various transformations; and it therefore appears superfluous to give any more commentary.

Palpable Arithmetic.

Such is the natural process of analysing numbers, and of variously combining and separating them; and such are by consequence the simpler modes of abridging the labour of computation. Palpable arithmetic has, in the course of improvement, long preceded the invention and use of numeral characters. It was retained in Europe for a very considerable time after the adoption of this more convenient and powerful instrument, and might even at present be employed in practice to a certain extent with obvious advantage. The exhibition of numbers by counters appears happily fitted for unfolding the principles of calculation. In the schools of ancient Greece, the boys acquired the elements of knowledge by working on a smooth board with a narrow rim,—the *Abax;* so named, evidently from the combination of A, B, Γ, the first letters of their alphabet, resembling, except perhaps in size, the tablet likewise called A, B, C, on which the children with us used to begin to learn the art of reading. The pupils, in those distant ages, were instructed to compute, by forming progressive rows of counters, which, according to the wealth or fancy of the individual, consisted of small pebbles, of round bits of bone or ivory, or even of silver coins. From ψηφος, the Greek word for a *pebble*, comes the verb, ψηφιζεῖν, to *compute*. But the same board served also for teaching the rudiments of writing and the principles of Geometry. The *Abax* being strewed with green sand, the *pulvis eruditus* of classic authors, it was easy, with a *radius* or small rod, to trace letters, draw lines, construct triangles, or describe circles.—Besides, the original word Αβαξ, the Greeks had the diminutive Αβακιον; and it seems very probable, that this smaller board was commonly used for calculations, while the larger one was reserved among them for the purpose of tracing geometrical diagrams.

Grecian Abacus.

To their calculating board, the ancients make frequent allusions. It appears, from the relation of Diogenes Laërtius, that the practice of bestowing on pebbles an artificial value according to the rank or place which they occupied, remounts higher than the age of Solon, the great reformer and legislator of the Athenian commonwealth. This sagacious observer and disinterested statesman, who was however no admirer of regal government, used to compare the passive ministers of kings or tyrants, to the counters or pebbles of arithmeticians, which are sometimes most important, and at other times quite insignificant.* Æschines, in his oration for the Crown, speaking of balanced accounts, says, that *the pebbles were cleared away, and none left.*† His rival, Demosthenes, repeating his expression, employs farther the verb ἀνλανελεῖν, which means *to take up as many counters as were laid down*. It is evident, therefore, that the ancients, in keeping their accounts, did not separately draw together the credits and the debts, but set down pebbles for the former, and took up pebbles for the latter. As soon as the board became cleared, the opposite claims were exactly balanced. We may observe, that the phrase *to clear one's scores or accounts*, meaning to settle or adjust them, is still preserved in the popular language of Europe, being suggested by the same practice of reckoning with counters, which prevailed indeed until a comparatively late period.

Roman Abacus.

The Romans borrowed their *Abacus* from the Greeks, and never aspired higher in the pursuit of science. To each pebble or counter required for that board, they gave the name of *calculus*, a diminutive formed from *calx, a stone;* and applied the verb *calculare*, to signify the operation of combining or separating such pebbles or counters. Hence innumerable allusions by the Latin authors. *Ponere calculum—subducere calculum, to put down a counter*, or *to take it up;* that is, to add or subtract; *vocare aliquid ad calculum, ut par sit ratio acceptorum et datorum—to submit any thing to calculation, so that the balance of debtor and creditor may be struck.* The Emperor, Helvius Pertinax, who had been taught, while a boy, the arts of writing and casting accounts, is said, by Julius Capitolinus, to be *litteris elementariis et calculo imbutus.* St Angustine, whose juvenile years were devoted to pleasure and dissipation, acquaints us, in his extraordinary Confessions, that to him no song ever sounded more odious than the repetition or *cantio*, that *one* and *one* make *two*, and *two* and *two* make *four*. The use of the *Abacus*, called sometimes likewise the *Mensa Pythagorica*, formed an essential part of the education of every noble Roman youth:

> Nec qui *abaco numeros, et secto in pulvere metas*
> Scit risisse vafer. ——— *Pers.* Sat. i. 132.

From Martianus Capella, we learn that, as refinement advanced, a coloured sand, generally of a greenish hue, was employed to strew the surface of the *abacus*.

> Sic *abacum* perstare jubet, sic *tegmine glauco*
> Pandere pulvereum formarnm ductibus æquor.
> Lib. vii. *De Arithmetica.*

A small box or coffer, called a *Loculus*, having compartments for holding the *calculi* or counters, was a necessary appendage of the *abacus*. Instead of carrying a slate and satchel, as in modern times, the Roman boy was accustomed to trudge to school, loaded with his arithmetical board, and his box of counters:

> Quo pueri magnis e centurionibus orti,
> *Lævo suspensi loculos tabulamque lacerto.*
> *Horat.* Sat. i. 8.

In the progress of luxury, *tali* or dies made of ivory, were used instead of pebbles, and small silver coins came to supply the place of counters. Under the Emperors, every patrician living in a spacious mansion, and indulging in all the pomp and splendour of eastern princes, generally entertained, for various functions, a numerous train of foreign slaves or freedmen in his palace. Of these,

---

* Ἔλεγε δὲ τοὺς παρὰ τοις τυραννοις δυναμένους παραπλησιους εἶναι ταῖς Ψηφοις ΤΑΙΣ ΕΠΙ ΤΩΝ ΛΟΓΙΣΜΩΝ καὶ γαρ εκεινων εκάστην πότὲ μὲν ΠΛΕΙΩ σημαίνειν, πότε δε ἩΤΤΩ. *Diog. Lært.* in vitâ Solonis.

† Κᾂν καθαραὶ ὦσιν ἁι Ψῆφοι και μηδὲν περιῇ. *Demosthenes* pro Corona.

the *librarius* or *miniculator*, was employed in teaching the children their letters; but the *notarius* registered expences, the *rationarius* adjusted and settled accounts, and the *tabularius* or *calculator*, working with his counters and board, performed what computations might be required. Sometimes these laborious combiners of numbers were termed reproachfully *canculones* or *calculones*. In the fervour of operation, their gestures must often have appeared constrained and risible.

> *Computat, ac cevet.* Ponatur calculus adsint
> Cum tabulâ pueri.—
> *Juv.* Sat. ix. 40.

The nicety acquired in calculation by the Roman youth, was not quite agreeable to the careless and easy temper of Horace.

> Romani pueri *longis rationibus* assem,
> Discunt in parteis centum diducere: dicat
> Filius Albini, si de quincunce remota est
> Uncia, quid superat? poteras dixisse Triens heu.
> Rem poteris servare tuam, redit uncia, quid fit?
> Semis.———
> Epist. *ad Pisonem.*

It was a practice among the ancients to keep a diary, by marking their fortunate days by a *lapillus*, or small white pebble, and their days of misfortune by a black one. Hence the frequent allusions which occur in the Classics:

> O! diem lætum, notandumque mihi *candidissimo calculo.*
> Plin. *Epist.* vi. 11.

> ——— diesque nobis
> Signanda *melioribus lapillis*——
> Mart. ix. 53.

> Hunc, Macrini, diem numera *meliore lapillo,*
> Qui tibi labentes apponit candidus annos.
> Pers. *Sat.* ii. 1, 2.

To facilitate the working by counters, the construction of the *abacus* was afterwards improved. Instead of the perpendicular lines or bars, the board had its surface divided by sets of parallel grooves, by stretched wires, or even by successive rows of holes. It was easy to move small counters in the grooves, to slide perforated beads along the wires, or to stick large knobs or round-headed nails in the different holes. To diminish the number of marks required, every column was surmounted by a shorter one, wherein each counter had the same value as five of the ordinary kind, being half the index of the Denary Scale. The *abacus*, instead of wood, was often, for the sake of convenience and durability, made of metal, frequently brass, and sometimes silver. In Plate XXVII. we have copied, from the third volume of the Supplement added by Polenus to the immense Thesaurus of Grævius, two varieties of this instrument, as used by the Romans. They both rest on good authorities, having been delineated from antique monuments,—the first kind by Ursinus, and the second by Marcus Velserus. In the one, the numbers are represented by flatish perforated beads, ranged on parallel wires; and, in the other, they are signified by small round counters moving in parallel grooves. These instruments contain each seven capital bars, expressing in order *units, tens, hundreds, thousands, ten thousands, hundred thousands*, and *millions;* and above them are shorter bars following the same progression, but having five times the relative value. With *four* beads on each of the long wires, and *one* bead on every corresponding short wire, it is evident that any number could be expressed, as far as *ten millions*.

In all these, the *Denary Scale* is followed uniformly; but there is, besides, a small appendage to the arrangement founded on the *Duodenary System*. Immediately below the place of units, is added a bar, with its corresponding branch, both marked Θ, being designed to signify *ounces*, or the twelfth parts of a pound. *Five* beads on the long wire, and *one* bead on the short wire, equivalent now to *six*, would therefore denote *eleven* ounces. To express the simpler fractions of an ounce, three very short bars are annexed behind the rest; a bead on the one marked S or Ʒ, the contraction for *Semissis*, denoting *half-an-ounce;* a bead on the other, which is marked by the inverted Ɔ. the contraction for *Sicilicum*, signifying the *quarter of an ounce;* and a bead on the last very short bar, marked Ƨ, a contraction for the symbol ϟ or *Binæ Sextulæ*, intimating a *duella* or *two-sixths*, that is, *the third part of an ounce.* The second form of the *abacus* differs in no essential respect from the first, the grooves only supplying the place of parallel wires.

We should observe that the Romans applied the same word *abacus*, to signify an article of luxurious furniture, resembling in shape the arithmetical board, but often highly ornamental, and destined for a very different purpose,—the relaxation and the amusement of the opulent. It was used in a game apparently similar to that of chess, which displayed a lively image of the struggles and vicissitudes of war. The infamous and abandoned Nero took particular delight in this sort of play, and drove along the surface of the abacus with a beautiful *quadriga*, or chariot of ivory.

The civil arts of Rome were communicated to other nations by the tide of victory, and maintained through the vigour and firmness of her imperial sway. But the simpler and more useful improvements survived the wreck of empire, among the various people again restored by fortune to their barbarous independence. In all transactions wherein money was concerned, it was found convenient to follow the procedure of the Abacus, in representing numbers by counters placed in parallel rows. During the middle-ages, it became the usual practice over Europe for merchants, auditors of accounts, or judges appointed to decide in matters of revenue, to appear on a covered *bank* or *bench*, so called, from an old Saxon or Franconian word, signifying a *seat.* Hence those terms were appropriated to offices for receiving pledges, chambers for the accommodation of money-dealers, or courts for the trying of questions respecting property or the claims of the Crown. Hence also the word *bankrupt*, which occurs in all the dialects of Europe. The term *scaccarium*, from which was derived the French, and thence the English, name for the *Exchequer*, anciently signified merely a *chess-board*, being formed from *scaccum*, denoting one of the moveable pieces in that intricate game. The reason of this application of the term is

Palpable Arithmetic.

sufficiently obvious. The table for accounts was, to facilitate the calculations, always covered with a cloth, resembling the surface of the *scaccarium or abacus*, and distinguished by perpendicular and *chequered* lines. The learned Skene was therefore mistaken in supposing that the Exchequer derived its name from the play of chess, because its suitors appear to fight a keen and dubious battle. *

Exchequer Board, and other Contrivances.

The Court of Exchequer, which takes cognizance of all questions of revenue, was introduced into England by the Norman conquest. Richard Fitz-Nigel, in a treatise or dialogue on the subject, written about the middle of the twelfth century, says that the *scaccarium* was a quadrangular table about ten feet long and five feet broad, with a ledge or border about four inches high, to prevent any thing from rolling over, and was surrounded on all sides by seats for the judges, the tellers, and other officers. It was covered every year, after the term of Easter, with fresh black cloth, divided by perpendicular white lines, or distinctures, at intervals of about a foot or a palm, and again parted by similar transverse lines. In reckoning, they proceeded, he says, according to the rules of arithmetic, † using small coins for counters. The lowest bar exhibited *pence*, the one above it *shillings*, the next *pounds ;* and the higher bars denoted successively *tens, twenties, hundreds, thousands*, and *ten thousands* of pounds; though, in those early times of penury and severe economy, it very seldom happened that so large a sum as the last ever came to be reckoned. The first bar, therefore, advanced by *dozens*, the second and third by *scores*, and the rest of the stock of bars by the multiples of *ten*. The teller sat about the middle of the table; on his right hand, *eleven* pennies were heaped on the first bar, and a pile of *nineteen* shillings on the second; while a quantity of pounds was collected opposite to him, on the third bar. For the sake of expedition, he might employ a different mark to represent half the value of any bar, a silver penny for ten shillings, and a gold penny for ten pounds.

In early times, a chequered board, the emblem of calculation, was hung out, to indicate an office for changing money. It was afterwards adopted as the sign of an inn or *hostelry*, where victuals were sold, or strangers lodged and entertained. We may perceive traces of that ancient practice existing even at present. It is customary in London, and in some provincial towns, to have a chequer, diced with red and white, painted against the sides of the door of a chop-house.

The use of the smaller *abacus* in assisting numerical computation was not unknown during the middle ages. In England, however, it appears to have scarcely entered into actual practice, being mostly confined to those "slender clerks" who, in such a benighted period, passed for men of science and learning. The calculator was styled, in correct Latinity, *abacista ;* but, in the Italian dialect, *abbachista*, or *abbachiere*. A different name came afterwards to be imposed. The Arabians, who, under the appellation of Saracens or Moors, conquered Spain, and enriched that insulated country by commendable industry and skill, had likewise introduced their mathematical science. Having adopted a most refined species of numeration, to which they gave the barbarous name of *algarismus, algorismus*, or *algorithmus*, from the definite article *al*, and the Greek word ἀριθμος, or *number*, this compound term was adopted by the Christians of the West, in their admiration of superior skill, to signify calculation in general, long before the peculiar mode had become known and practised among them. The term *algarism* was corrupted in English into *augrim* or *awgrym*, as printed by Wynkyn de Worde, at the end of the fifteenth century; and applied even to the pebbles or counters used in ordinary calculation. In confirmation of this remark, we shall not scruple to quote a passage from our ancient poet Chaucer, who flourished about a century before, and whose verses, however rude, are sometimes highly graphic.

> "This clerk was cleped hendy Nicholas;
> Of derne love he coude and of solas;
> And therto he was slie and ful prive,
> And like a maiden meke for to se.
> A chambre had he in that hostelrie,
> Alone withouten any compagnie,
> Full fetisly ydight with herbes sote,
> And he himself was swete as is the rote
> Of licoris, or any setewale.
> His almageste and bokes grete and smale,
> His astrelabre, longing for his art,
> *His augrim-stones, layen faire apart*
> *On shelves couched at his beddes hed,*
> His presse ycovered with a falding red.
> And all about there lay a gay sautrie,
> On which he made on nightes melodie
> So swetely, that all the chambre rong.
> And *Angelus ad verginem* he song,
> And after that he song the kinge's note;
> Ful often blessed was his mery throte.
>
> *Miller's Tale*, v. 13—36.

The *abacus*, with its store of counters, wanted the valuable property of being portable, and was at all times evidently a clumsy and most incommodious implement of calculation. In many cases, it became quite indispensable to adopt some sure and ready method of expressing at least the lower numbers. The ancients employed the variously combined inflexions of the fingers on both hands to signify the numerical series, and on this narrow basis they framed a system of considerable extent. In allusion to the very ancient practice of numbering by the arbitrary play of the fingers, Orontes, the son-in-law of Artaxerxes, having incurred the weighty displeasure of that monarch, is reported by Plutarch to have exclaimed in

Digital Numeration.

* "Because mony persons conveenis in the Checker to playe their causes, contrare uthers, as gif they were fechtand in an arrayed battell, quilk is the forme and ordour of the said playe." *Skene*, ad. voc. *Scaccarium*.

† He calls it *Arismetica :* In the *Myrrour of the Worlde*, printed by Caxton, in 1481, it is strangely named *Ars Metrike*, a proof of the total ignorance of Greek at that period in England.

Palpable Arithmetic.

terms exactly of the same import as those before ascribed to Solon, that "the favourites of kings resemble the fingers of the arithmetician, being sometimes at the top and sometimes at the bottom of the scale, and are equivalent at one time to ten thousand, and at another to mere units."*

Among the Romans likewise, the allusions to the mode of expressing numbers by the varied inflexion of the fingers, are very frequent. Hence the classical expressions, *computare digitis*, and *numerare per digitos;* and hence the line of Ausonius,

> "Quot ter luctatus cum pollice computat index."

In this play of the fingers great dexterity was acquired; and hence the phrase which so frequently occurs in the Classics—*micare digitis*. It was customary to begin with the left hand, and thence proceed to the right hand, on which the different combined inflexions indicated exactly one hundred times more. Hence the peculiar force of this passage from Juvenal:

> "Rex Pylius, magno si quicquam credis Homero,
> Exemplum vitæ fuit à cornice secundæ;
> Felix nimirum, qui tot per sæcula mortem
> Distulit, atque suos jam *dextrâ* computat annos."
> *Sat.* x. 246—250.

Many such allusions to the mode of indicating numbers by the varied position of the fingers or the hands, occur in the writings of Cicero and Quintilian. The ancients, indeed, for want of better instruments, were tempted to push that curious art to a very great extent. By a single inflexion of the fingers of the left hand, they proceeded as far as ten; and by combining another inflexion with it, they could advance to an hundred. The same signs on the right hand, being augmented, as we have seen, an hundred fold, carried them as far as ten thousand; and by a farther combination, those signs, being referred successively to different parts of the body, were again multiplied an hundred times, and therefore extended to a *million*. This kind of pantomime outlived the subversion of the Roman empire, and was particularly fitted for the slothful religious orders who fattened on its ruins, and, relinquishing every manly pursuit, recommended silence as a virtue, or enjoined it as an obligation. Our venerable Bede has explained the practice of manual numeration at some length; and, in Plate XXVII. we have given a small specimen of such inflexions and digital signs.

These signs were merely fugitive, and it became necessary to adopt other marks, of a permanent nature, for the purpose of recording numbers. But of all the contrivances adopted with this view, the rudest undoubtedly is the method of registering by *tallies*, introduced into England along with the Court of Exchequer, as another badge of the Norman conquest. These consist of straight well-seasoned sticks, of hazel or willow, so called from the French verb *tailler*, to *cut*, because they are squared at each end. The sum of money was marked on the side with notches, by the cutter of tallies, and likewise inscribed on both sides in Roman characters, by the writer of the tallies. The smallest notch signified a penny, a larger one a shilling, and one still larger a pound; but other notches, increasing successively in breadth, were made to denote ten, a hundred, and a thousand. The stick was then cleft through the middle by the deputy-chamberlains, with a knife and a mallet; the one portion being called the *tally*, or sometimes the *scachia*, *stipes*, or *kancia;* and the other portion named the *counter-tally*, or *folium*.

After the union with Scotland had been concluded in 1707, a store of hazel-rods for tallies was sent down to Edinburgh, being intended, no doubt, as a mighty refinement on the Scottish mode of keeping accounts. Their advantages, however, were not perceived or acknowledged, and they have since been suffered, we believe, to lie as so much useless lumber. But the case is very different in England, where a blind and slavish attachment to ancient forms, however ridiculous they may through time have become, is almost constantly opposed to the general progress of society. Were a sensible traveller from India or China to visit our metropolis, and report, on his return home, that a nation highly polished, enlightened, and opulent, yet keep their accounts of the public revenue, surpassing annually many millions of pounds, by means of notches cut on willow rods,—he would certainly not be credited, but supposed to use the licence of substituting a description of the practice of the most savage tribes of the American Continent.

Chinese Swan-Pan.

The Chinese have, from the remotest ages, used in all their calculations, an instrument called the *Swan-Pan*, or *Computing Table*, similar in its shape and construction to the *abacus* of the Romans, but more complete and uniform. It consists of a small oblong board surrounded by a high ledge, and parted lengthwise near the top by another ledge. It is then divided vertically, by ten smooth and slender rods of bamboo, on which are strung two small balls of ivory or bone in the upper compartment, and five such balls in the lower and larger compartment; each of the latter on the several bars denoting unit, and each of the former, for the sake of abbreviation, expressing five. See Plate XXVII., where the balls are actually set to signify the numbers annexed.

The system of measures, weights, and coins, which prevails throughout the Chinese empire, being entirely founded on the decimal subdivision, the swan-pan was admirably suited for representing it. The calculator could begin at any particular bar, and reckon with the same facility either upwards or downwards. This advantage of treating fractions exactly like integers was, in practice, of the utmost consequence. Accordingly, those arithmetical machines, but of very different sizes, are constantly used in all the shops and booths of Canton and other cities, and are said to be handled by the native traders with such rapidity and address as quite astonish the European factors.

---

* Καθάπερ ὁι τῶν ἀριθμητικῶν ΔΑΚΤΥΛΟΙ νῦν μὲν ΜΥΡΙΑΔΑΣ, νῦν δε ΜΟΝΑΔΑ τιθέναι δυνανται. τὸ αὐτό καὶ τῶν βασιλέων φιλους, νῦν μεν το πᾶν δύνασθαι, νῦν δε ἐλάχιστον. Plut. *Apothegm.*

But the Chinese have also contrived a very neat and simple kind of digital signs for denoting numbers, greatly superior, both in precision and extent, to the method practised by the Romans. Since every finger has three joints, let the thumb-nail of the other hand touch those joints in succession, passing up the one side of the finger, down the middle, and again up the other side, and it will give nine different marks, applicable to the *Denary Scale* of arrangement. On the little finger, those marks signify units, on the next finger tens, on the mid-finger hundreds, on the index thousands, and on the thumb hundred thousands. With the combined positions of the joints of the one hand, therefore, it was easy to advance by signs as far as a million. To illustrate more fully this ingenious practice, we have, immediately below the *koua* of the Emperor Fou-hi, copied, in plate XXVII., from a Chinese elementary treatise of education, the figure of a hand, noted at the several joints of each finger, by characters along the inside, corresponding to *one*, *two*, and *three*, down the middle by those answering to *four*, *five*, and *six*, and again up the outside by characters expressing *seven*, *eight*, and *nine*. It is said that the merchants in China are accustomed to conclude bargains with each other by help of those signs; and that often, from selfish or fraudulent views, they conceal the pantomime from the knowledge of by-standers, by only seeming to seize the hand with a hearty grasp.

Having thus treated at sufficient length the principles and application of PALPABLE ARITHMETIC; we shall now proceed to consider the second branch of the subject, which may be denominated FIGURATE ARITHMETIC; since, to denote the range of numbers, it employs conventional symbols, or certain artificial characters disposed in a particular order, and performs, by help of these, all the ordinary operations implied in the combining and separating of numbers.

## FIGURATE ARITHMETIC

includes, first the mode of *Notation*, and next the various operations themselves which are required in compounding and resolving numbers. We shall consider these subdivisions in their order.

Invention of Numeral Characters.

NOTATION. The various attempts of men in every state of society at representing numbers, all spring from the same feeling so strongly implanted in our breasts, which unceasingly prompts them to seek the approbation and applause of their fellows. Other passions are spent in the mere support and continuance of the race; it is the love of distinction alone that elevates the human character, infuses life and action through the mass, and vigorously impels it to undertake and achieve mighty projects. The daring and restless spirit of improvement often produces much transient misery by its failures; yet, amidst all the vicissitudes which chequer and darken the tide of human affairs, it opens cheering prospects of the permanent amelioration of our species. The aspiring leader of a successful band, or the petty legislator of a rising community, is anxious to preserve the memory of the exploits he performed, or the benefits he conferred. But he is not content with obtaining the applause of his contemporaries; this fleeting existence is insufficient to fill his imagination; he looks anxiously beyond the grave, and sighs for the admiration of generations yet unborn. Hence the anxiety among all people to erect monuments of high achievements or illustrious characters. In the early periods of society, a vast mound of earth, or a huge block of stone, was the only memorial of any great event. But, after the simpler arts came to be known, efforts were made to transmit to posterity the representations of the objects themselves. Sculptures of the humblest kind occur on monumental stones in all parts of the world, sufficient to convey tolerably distinct images of the usual occupation and employments of the personages so commemorated. The next step in the progress of society was to reduce and abridge those rude sculptures, and thence form combinations of figures approaching to the hieroglyphical characters. At this epoch of improvement, the first attempts to represent numerals would be made. Instead of repeating the same objects, it was an obvious contrivance to annex to the mere individual the simpler marks of such repetition. Those marks would of necessity be suited to the nature of the materials on which they were inscribed, and the quality of the instruments employed to trace them. In the historical representations, for instance, which the Mexicans and certain Tartar hordes painted on skins, a small coloured circle, as exhibiting the original counter, shell, or pebble, was repeated to denote numbers. But, on the Egyptian Obelisks, the lower numerals, at least, are expressed by combined strokes. None but straight lines, indeed, are fitted for carving on pillars of stone, and especially for cutting on wooden posts. Curve lines were not admitted in the earliest rudiments of writing. Even after the use of hieroglyphics had been laid aside, and the artificial system of alphabetic characters adopted, the rectilineal forms were still preferred, as evidently appears in the Greek and Roman capitals, which, being originally of the lapidary sort, are much older than the small or current letters. One of the most ancient set of characters, the Runic, in which the northern languages were engraved, combines almost exclusively simple strokes at different angles.

The primary numeral traces may, therefore, be regarded as the commencement of a philosophical and universal character, drawn from nature itself, and alike intelligible to all ages and nations. They are still preserved, with very little change, in the Roman notation. Those forms, prior to the adoption of the alphabet itself, were no doubt imported by the Grecian colonies that settled in Italy, and gave rise to the Latin name and commonwealth. Assuming a perpendicular stroke I to signify *one*, another such II would express *two*, the junction of a third III *three*, and so repeatedly till the reckoner had reached *ten*. See Plate XXVII. The first class was now completed, and to intimate this, the carver threw a dash across the stroke or common unit; that is, he employed two decussating strokes X to

denote *ten*. He next repeated this mark to express *twenty*, *thirty*, and so forth, till he finished the second class of numbers. Arrived at *an hundred*, he would signify it, by joining another dash to the mark for ten, or by merely connecting three strokes thus ⊏. Again, the same spirit of invention might lead him to repeat this character, in denoting *two hundred*, *three hundred*, and so forth, till the *third* class was completed. *A thousand*, which begins the fourth class on the *Denary Scale*, was therefore expressed by four combined strokes M; and this was the utmost length to which the Romans first proceeded by direct notation.

But the division of these marks afterwards furnished characters for the intermediate numbers, and hence greatly shortened the repetition of the lower ones. Thus, having parted in the middle the two decussating strokes X denoting *ten*, either the under half Λ, or the upper half V, was employed to signify *five*. Next, the mark ⊏ for an hundred, consisting of a triple stroke, was largely divided into Γ and L, either of which represented *fifty*. Again, the four combined strokes M, which originally formed the character for *a thousand*, came afterwards, in the progress of the arts, to assume a rounded shape ↀ, frequently expressed thus CIↃ, by two disparted semicircles divided by a diameter: This last form, by abbreviation on either side, gave two portions cI and Iↄ to represent *five hundred*.

## Origin of Roman Numerals.

It was an easy process, therefore, to devise an universal character for expressing numbers. But the task was very different, to reduce the exhibition of language in general to such concise philosophical principles. This attempt seems accordingly to have been early abandoned by all nations, except the Chinese. The inestimable advantage of uniting again the whole human race, in spite of the diversity of tongues, by the same permanent system of communication, was sacrificed for the easier attainment, of representing, by artificial signs, those elementary and fugitive sounds, into which the words of each particular dialect could be resolved. Hence the ALPHABET was invented, which, notwithstanding its obvious defects, must ever be regarded as the finest and happiest effort of genius. More letters were afterwards added in succession, as the analysis of the primary sounds became extended; but the alphabet had very nearly attained its present form, at the period when the Roman commonwealth was extending its usurpation over Italy. About that epoch, a sort of reaction seems to have arisen between the artificial and the natural systems, and the numeral strokes were finally displaced by such alphabetic characters as the most resembled them. See Plate XXVII. The ancient Romans employed the letter I to represent the single stroke or mark for *one*; they selected the letter V, since it resembles the upper half of the two decussating strokes, or symbol for *five*; the letter X exactly depicted the double mark for *ten*; again, the letter L was adopted as resembling the divided symbol for *fifty*; while the entire symbol, or the tripled stroke, denoting an *hundred*, was exhibited by the hollow square ⊏, the original form of the letter C before it became rounded over. The quadrupled stroke for a *thousand* was distinctly represented by the letter M, and its variety by the compound character cIↄ, consisting of the letter I inclosed on both sides by C and by the same letter reversed; a portion of this again, or Iↄ, being condensed into the letter D, expressed *five hundred*. The letters C and M, beginning the words *Centum* and *Mille*, might have a farther claim to represent an *hundred* and a *thousand*. But the coincidence was merely accidental, since these terms migrated probably from the corresponding Greek words ἑκατον and χιλια.

This was the limit of numeration among the early Romans; but, in the progress of refinement, they repeated the symbols of a thousand to denote the higher terms of the Denary Scale. Thus, ccIↄↄ was employed to represent *ten thousand*, and cccIↄↄↄ to signify *an hundred thousand*; the letter I, inclosed between the cↄ, being, for the sake of greater distinctness, elongated. Again, each of these being divided, gives Iↄↄ for *five thousand*, and Iↄↄↄ for *fifty thousand*. These characters, however, were often modified and abbreviated in monumental inscriptions. By drawing a horizontal line over the letters, their value was augmented *one thousand times*. In the plate, so often referred to, we have endeavoured, from the best authorities, to exhibit, under the title of *Lapidary Numerals*, a complete specimen of the various contractions used by stone-cutters among the Romans. It was customary, with them, for the sake of abbreviation, to reckon, as rude tribes are apt to do, partly backwards. Thus, instead of *octodecem*, and *novemdecem*, the words for *eighteen* and *nineteen*, they frequently used *duodeviginti* and *undeviginti*, as more elegant and expressive. This practice led to the application of *deficient* numbers; an improvement scarcely to be expected from a people so little noted for invention. Instead of writing *nine*, thus VIIII, by joining *four* to *five*, they counted *one* back from *ten*, or placed I before X. In the same way, they represented *forty*, and *four hundred*, *ninety*, and *nine hundred*, by XL, and CD, XC, and CM.

Such, we have no doubt, is the real account of the rise and progress of the Roman numerals. It perfectly agrees with the few hints left us by Aulus Gellius, who expressly says, that I and X were anciently represented by one and two strokes; though Philologers, misled by partial glimpses, have indeed given a very different statement. Priscian, the Grammarian, who flourished in the reign of the Emperor Justinian, asserts, that the mark I was only borrowed from the Athenians, being adopted by them as the principal letter of the word MIA, or *one*, the M of which is considered as mute; that V or U was employed by the Romans to denote *five*, because it is the fifth vowel in the common order; that X was assumed to represent *ten*, as being the tenth consonant, and likewise following the V; that L was taken to signify *fifty*, being sometimes interchanged with N, which, as a small letter, expressed that number among the Greeks; that C was adopted to mark

Figurate Arithmetic.

an hundred, because it is the first letter of the word *Centum;* that D, being the next letter of the alphabet, was employed to signify *five hundred;* and that M was borrowed from the Greek letter X for ΧΙΛΙΑ, or a *thousand;* only that it was rounded at the ends, to distinguish it from the symbol for ten.—But it would be idle to pursue these fanciful remarks, or to engage in serious refutation of random conjectures, which betray such a total want of general views.

After the system of Roman numerals, however, had acquired its full extent, the solicitude of superstition long preserved some traces of the rudest and most primitive mode of chronicling events. At the close of each revolving year, generally on the Ides of September, the Prætor Maximus was accustomed, with great ceremony, to drive a *nail* in the door on the right side of the temple of Jupiter, next that of Minerva, the patron of learning and the inventor of numbers. In times of public distress, when pestilence raged, and famine spread desolation abroad, the warlike, yet superstitious Romans, anxious to stay those calamities, sought to anticipate the return of the season. On such occasions, they elected a Dictator, for the sole purpose of driving the sacred nail, and beginning a more propitious year. Hence the expression of Cicero—*Ex hoc die, clavum anni movebis.*

Chinese Numerals.

As the Chinese had constructed the Swan-pan on the principles of the Roman Abacus, so they had likewise, at the remotest epoch of the Empire, framed a system of numerals, in many respects similar to those which the Romans probably derived from their Pelasgic ancestors. This will appear from the inspection of the characters engraved on Plate XXVII. It is only to be observed, that the Chinese mode of writing is the reverse of ours; and that, beginning at the top of the leaf, they descend in parallel columns to the bottom, proceeding, however, from right to left, as practised by most of the Oriental nations.

Instead of the vertical lines used by the Romans, we therefore meet with horizontal ones, in the Chinese notation. Thus, *one* is represented by a horizontal stroke, with a sort of barbed termination; *two* by a pair of such strokes; and *three* by as many parallel strokes; the mark for *four* has four strokes, with a sort of flourish; three horizontal strokes, with two vertical ones, form the mark for *five;* and the other symbols exhibit the successive strokes abbreviated, as far as *nine. Ten* is figured by a horizontal stroke, crossed with a vertical score, to show that the first rank of the Denary Scale was completed; *an hundred* is signified by two vertical scores, connected by three short horizontal lines; *a thousand* is represented by a sort of double cross; and the other ranks, ascending to *an hundred millions,* have the same marks successively compounded. Since the figures in Plate XXVII. were engraved from two elegant Chinese manuscripts, we have met with impressions of a more complete set of numerals, printed with metallic types in 1814, at Serampore, in the Elements of Chinese Grammar, by the Reverend Dr Marshman, one of the Baptist Missionaries, whose zeal, talents, enterprise, and indefatigable assiduity, in exploring the recondite dialects of the East, have reflected unfading lustre on their sect and profession. We have caused very correct *fac similes* to be taken of those characters, as represented below; in which it will be perceived, that each symbol has, for sake of distinction, a small zero or ∘ annexed to it.

| | | |
|---|---|---|
| *One,* | 一 | *Yĭh.* |
| *Two,* | 二 | *Irr.* |
| *Three,* | 三 | *San.* |
| *Four,* | 四 | *Sè.* |
| *Five,* | 五 | *Ngóo.* |
| *Six,* | 六 | *Lyeù.* |
| *Seven,* | 七 | *Ts'hīh.* |
| *Eight,* | 八 | *Păh.* |
| *Nine,* | 九 | *Kyéu.* |

| | | |
|---|---|---|
| *Ten,* | 十 | *Shĭh.* |
| *A Hundred,* | 百 | *Pŭh.* |
| *A Thousand,* | 千 | *Ts'hyen.* |
| *Ten Thousand,* | 萬 | *Wàn.* |
| *A hundred Thousand,* | 億 | *Eè.* |
| *A Million,* | 兆 | *Chaò.* |
| *Ten Millions,* | 京 | *King.* |
| *A hundred Millions,* | 垓 | *Kyai.* |

The numbers *eleven, twelve,* &c. are represented by putting the several marks for *one, two,* &c. the excesses above *ten,* immediately below its symbol. But, to denote *twenty, thirty,* &c. the marks of the multiples *two, three,* &c. are placed above the symbol for *ten.* This distinction is pursued through all the other cases. Thus, the marks for *two, three,* &c. placed over the symbols of *an hundred* or of *a thousand,* signify so many *hundreds* or *thousands.*—The character for *ten thousand,* called *wàn,* appears to have been the highest known at an early period of the Chinese history; since, in the popular language at present, it is equivalent to *all.* But the Greeks themselves had not advanced farther. In China, *wàn wàn* signifies *ten thousand* times *ten thousand,* or *an hundred millions;* though there is also a distinct character for this high number. In the Eastern strain of hyperbole, the phrase *wàn wàn,* far out-doing *a thousand years,* the measure of Spanish loyalty, is the usual shout of Long Live the Emperor! The Chinese character *chaò* for a *million,* though not of the greatest antiquity, is yet as old as the time of Confucius. The characters for *ten,* and for an *hundred, millions,* are not found in their oldest books, but occur in the Imperial Dictionary.

Such is the very complete but intricate system of Chinese numerals. It has been constantly used, from the remotest times, in all the historical, moral, and philosophical compositions of that singular people. The ordinary symbols for words, or rather things, are, in their writings, generally blended with skill among those characters. But the Chinese merchants and traders have transformed this system of notation into another, which is more concise, and better adapted for the details

Figurate Arithmetic.

of business. The changes made on the elementary characters, it will be seen, are not very material. The *one*, *two*, and *three*, are represented by perpendicular strokes; the symbols for *four* and *five* are altered; *six* is denoted by a short score above an horizontal stroke, as if to signify that *five*, the half of the index of the scale, had been counted over; *seven* and *eight* are expressed by the addition of one and two horizontal lines; and the mark for *nine* is composed of that for six, or perhaps at first a variety of five, joined to that of *four*.

| | |
|---|---|
| 〡 | *One.* |
| 〢 | *Two.* |
| 〣 | *Three.* |
| 〤 | *Four.* |
| 〥 | *Five.* |
| 〦 | *Six.* |
| 〧 | *Seven.* |
| 〨 | *Eight.* |
| 〩 | *Nine.* |

To represent *eleven*, *twelve*, &c. in this mode, a single stroke is placed on the left of the cross for ten, and the several additions of *one*, *two*, &c. annexed on the right.

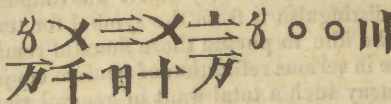
From *twenty* to *an hundred*, the signs of the multiples are prefixed to the mark for *ten*.

| | | | |
|---|---|---|---|
| 〢十 | *Twenty.* | 〢一 十 | *Twenty-one.* |
| 〣十 | *Thirty.* | 〣一 十 | *Thirty-one.* |
| 〤十 | *Forty.* | 〤一 十 | *Forty-one.* |
| 〥十 | *Fifty.* | 〥一 十 | *Fifty-one.* |
| 〧十 | *Seventy.* | 〧三 十 | *Seventy-three.* |

The same method is pursued through the hundreds, the marks of the several multiples being always placed on the left hand before the contracted symbol of *pih*, or *an hundred*. The additions are made on the right, with a small cipher or circle (o), called *ling*, when necessary, to separate the place of units. The distinction between *two hundred and three*, and five hundred and thirty, deserves to be particularly remarked.

| | | | |
|---|---|---|---|
| 〢百 | *Two hundred.* | 〢〇三 百 | *Two hundred and three.* |
| 〥百 | *Five hundred.* | 〥三 百 | *Five hundred and thirty.* |
| 〧百 | *Seven hundred.* | 〧〨〡 百 | *Seven hundred and eighty-two.* |

A similar process extends to the notation of thousands; but, for ten thousand, the character *wàn* is abbreviated. As a specimen of their combination, we select the following complex expression,



which denotes *five hundred and forty-three millions, four hundred and seventy-five thousand, and three*. The same number would be thus represented in the regular system of Chinese notation:

零萬四千五
三五十三萬
千七百四

Where the first column on the right hand presents the marks for *fifty* and *four*, with the interjacent character *wàn*, or *ten thousand*; the next column to the left has the several marks for a *thousand*, *three*, and *an hundred*; the middle column exhibits the symbols of *forty* and of *seven*; the adjacent column repeats the character *wàn*, or *ten thousand*, and then presents those for *five* and *a thousand*; and the last column has the symbol *ling*, or the *rest*, which fills up the blank, with the mark for *three*.

The last expression seems abundantly complicated, and yet it is unquestionably simpler and clearer than the corresponding notation with Roman numerals, as represented below.

IↃↃↃↃↃↃↃ · CCCCCIↃↃↃↃↃ ·
CCCCCIↃↃↃↃↃ · CCCCCIↃↃↃↃↃ ·
CCCCCIↃↃↃↃↃ · CCCCIↃↃↃↃ ·
CCCCIↃↃↃ . CCCCIↃↃↃↃ · CCCIↃↃↃ ·
CCCIↃↃↃ · CCCIↃↃↃ · CCCIↃↃↃ ·
IↃↃↃ · CCIↃↃ · CCIↃↃ · IↃↃ · III.

From such an intricate example, the imperfection of the Roman system will appear the more striking.

The abbreviated process of the Chinese traders was probably suggested by the communication with India, where the admirable system of denary notation has, from the earliest ages, been understood and practised. The adoption of a small cipher to fill the void spaces, was a most material improvement on the very complex character *ling*, used formerly for the same purpose.

About the close of the seventeenth century, the Jesuit missionaries Bouvet, Gerbillon, and others, then residing at the Court of Pekin, and able mathematicians, appear to have still farther improved the numeral sym-

bols of the Chinese traders, and reduced the whole system to a degree of simplicity and elegance of form scarcely inferior to that of our modern ciphers. With these abbreviated characters they printed, at the imperial press, Vlacq's *Tables of Logarithms*, extending to ten places of decimals, in a beautiful volume, of which a copy was presented by Father Gaubil on his return to Europe, about the year 1750, to the Royal Society of London. From this very curious work, the marks in Plate XXVII. entitled improved Chinese numerals, were carefully copied. No more than nine characters, it will be seen, are wanted, the upright cross + for ten being a mere redundancy. The marks for *one*, *two*, and *three*, consist of parallel strokes as before; an oblique cross × denotes *four*; and a sort of bisected ten signifies *five*. This symbol again, being contracted into the angular mark ∠, and combined with *one*, *two*, or *three* strokes drawn below it, represents *six*, *seven*, or *eight*; and still more abridged and annexed to the sign of four, it denotes *nine*. The distinction of units, tens, hundreds, &c. is indicated by giving the strokes alternately an horizontal and vertical position; while the blanks or vacant bars are expressed by placing small zeros.—The very important collection of logarithmic tables just mentioned, was printed by the command of the Emperor Kang-hi, a man of enlarged views, who governed China with dignity and wisdom during a long course of years. This enlightened Prince was much devoted to the learning of Europe, and is reported to have been so fond of calculation, as to have those tables abridged and printed in a smaller character, which precious volume he carried constantly fastened to his girdle. The late Emperor, Kien-long, who, after a beneficent reign of sixty years, in the decline of a protracted life, spontaneously resigned the imperial office to his son, discovered a similar taste for the Mathematical sciences.

Greek Numerals.

The Greeks, after having communicated to the founders of Rome the elements of the numeral characters, which are still preserved, again exercised their inventive genius in framing new systems of notation. Discarding the simple original strokes, they sought to draw materials of construction from their extended alphabet. They had no fewer than three different modes of proceeding. 1. The letters of the alphabet, in their natural succession, were employed to signify the smaller ordinal numbers. In this way, for instance, the books of Homer's *Iliad* and *Odyssey* are usually marked. But the practice could scarcely be older than the time of Aristotle, who, it is well known, first collected and arranged those immortal poems, in the edition of the *Casket*, for the use of his illustrious pupil Alexander the Great. 2. The first letters of the words for numerals, were adopted as abbreviated symbols. Thus, employing capitals only, I, being retained as before, to denote *one*, the letter Π of ΠΕΝΤΕ marked *five*, the Δ of ΔΕΚΑ denoted *ten*, the H of 'EKATON, anciently written HEKATON, expressed *an hundred*, the X of XIΛIA a *thousand*, and the letter M of the word MYPIA represented *ten thousand*. A simple and ingenious device was used for augmenting the powers of those symbols: a large Π placed over any letter made it signify *five thousand* times more. Thus, |Δ| denoted *fifty thousand*, and |H| *five hundred thousand*. See Plate XXVII. 3. But a mighty stride was afterwards made in numerical notation by the Greeks, when they distributed the twenty-four letters of their alphabet into three classes, corresponding to *units*, *tens*, and *hundreds*. To complete the symbols for the nine digits, an additional character was introduced in each class. The mark ς, called *episêmon*, was inserted among the units immediately after ε, the letter denoting five; and the *koppa* and *sanpi*, represented by Ϟ, ϟ, or ϡ, terminated respectively the range of *tens* and of *hundreds*, or expressed ninety and nine hundred. This arrangement of the symbols, it is obvious, could extend only to the expression of nine hundred and ninety-nine; but, by subscribing an *iota* under any character, the value was augmented a thousand fold, or by writing the letter M, or the mark for a *myriad*, or ten thousand, under it, the effect was increased ten times more. This last modification was sometimes more simply accomplished by placing two dots over the character.

Such is the beautiful system of Greek numerals, so vastly superior in clearness and simplicity to the Roman combination of strokes. It was even tolerably fitted as an instrument of calculation. Hence the Greeks early laid aside the use of the *abacus*; while the Romans, who never showed any taste for science, were confined, by the total inaptitude of their numerical symbols, to the practice of the same laborious manipulation.

It should, however, be remarked, that the Greeks distinguished the Theory from the Practice of Arithmetic, by separate names. The term *Arithmetic* itself was restricted by them to the science which treats of the nature and general properties of numbers; while the appellation *Logistic* was appropriated to the collection of rules framed to direct and facilitate the common operations of calculation. The ancient systems of Arithmetic, accordingly, from the books of Euclid, to the treatise of Böethius and the verses or commentaries of Capella, are merely speculative, and often abound with fanciful analogies. Pythagoras had brought from the East a passion for the mystical properties of numbers, under the veil of which he probably concealed some of his secret or esoteric doctrines. He regarded *Numbers* as of divine origin, the fountain of existence, and the model and archetype of all things. He divided them into a variety of different classes, to each of which were assigned distinct properties. They were prime or composite, perfect or imperfect, redundant or deficient, plane or solid; they were triangular, square, cubic, or pyramidal. *Even* numbers were held by that visionary philosopher as feminine, and allied to earth; but the *odd* numbers were considered by him as endued with masculine virtue, and partaking of the celestial nature. He esteemed the *unit*, or *monad*, as the most eminently sacred, and as the parent of all scientific numbers; he viewed *two*, or the *duad*, as the associate of the *monad*, and the mother of the elements; and he regarded *three*, or the *triad*, as perfect, being the first of the masculine numbers, comprehending the beginning, middle, and end, and hence fitted to regulate

Mystical Properties of Numbers

by its combinations the repetition of prayers and libations. As the *monad* represented the Divinity, or the Creative Power, so the *duad* was the image of Matter; and the *triad*, resulting from their mutual conjunction, became the emblem of Ideal Forms.

But the *tetrad*, or *four*, was the number which Pythagoras affected to venerate the most. It is a square, and contains within itself all the musical proportions, and exhibits by summation all the digits as far as ten, the root of the universal scale of numeration; it marks the seasons, the elements, and the successive ages of man; and it likewise represents the cardinal virtues, and the opposite vices. The ancient division of mathematical science into Arithmetic, Geometry, Astronomy, and Music, was four-fold, and the course was therefore termed a *tetractys*, or *quaternion*. Hence Dr Barrow would explain the oath familiar to the disciples of Pythagoras: "I swear by him who communicated the *Tetractys*."

*Five*, or the *pentad*, being composed of the first male and female numbers, was styled the number of the world. Repeated any how by an odd multiple, it always reappeared; and it marked the animal senses, and the zones of the globe.

*Six*, or the *hextad*, being composed of its several factors, was reckoned perfect and analogical. It was likewise valued, as indicating the sides of the cube, and as entering into the composition of other important numbers.

*Seven*, or the *heptad*, formed from the junction of the *triad* with the *tetrad*, has been celebrated in every age. Being unproductive, it was dedicated to the virgin Minerva, though possessed of a masculine character. It marked the series of the lunar phases, the number of the planets, and seemed to modify and pervade all nature.

*Eight*, or the *octad*, being the first cube that occurred, was dedicated to Cybelè, the mother of the Gods, whose image in the remotest times was only a cubical block of stone.

*Nine*, or the *ennead*, was esteemed as the square of the *triad*. It denotes the number of the Muses, and, being the last of the series of digits, and terminating the tones of music, it was inscribed to Mars.

*Ten*, or the *decad*, from the important office which it performs in numeration, was, however, the most celebrated for its properties. Having completed the cycle and begun a new series of numbers, it was aptly styled *apocatastasic* or periodic, and therefore dedicated to the double-faced Janus.

The cube of the *triad*, or the number *twenty-seven*, expressing the time of the moon's periodic revolution, was supposed to signify the power of the lunar circle. The quaternion of celestial numbers, *one, three, five*, and *seven*, joined to that of the terrestrial numbers, *two, four, six*, and *eight*, compose the number *thirty-six*, the square of the first perfect number *six*, and the symbol of the universe, distinguished by wonderful properties.

But it would be endless to recount all the visions of the Pythagorean school; nor should we descend to notice such fancies, if, by a perpetual descent, the dreams of ancient Philosophers had not, in the actual state of society, still tinctured our language, and mingled with the various institutions of civil life. Not to wander in search of illustration, we see the predeliction for the number *seven* strongly marked in the customary term of apprenticeships, in the period acquired for obtaining academical degrees, and in the legal age of majority.

Numerical Fancies of the Chinese.

The Chinese appear, from the remotest epochs of their empire, to have entertained the same admiration of the mystical properties of numbers that Pythagoras imported from the East. Distinguishing numbers into even and odd, they considered the former as terrestrial, and partaking of the feminine principle *Yang*; while they regarded the latter as of celestial extraction, and endued with the masculine principle *Yn*. The even numbers were represented by small black circles, and the odd ones by similar white circles, variously disposed and connected by straight lines. See Plate XXVII. The sum of the five even numbers, *two, four, six, eight*, and *ten*, being *thirty*, was called the number of the *Earth*; but the sum of the five odd numbers *one, three, five, seven*, and *nine*, or *twenty-five*, being the square of *five*, was styled the number of *Heaven*. The nine digits were likewise grouped in two different ways, termed the *Lo-chou*, and the *Ho-tou*. The former expression signifies the *Book of the river Lo*, or what the Great Yu saw delineated on the back of the mysterious tortoise which rose out of that river: It may be conceived from this arrangement.

| | | |
|---|---|---|
| *Four* | *Nine* | *Two* |
| *Three* | *Five* | *Seven* |
| *Eight* | *One* | *Six* |

*Nine* was reckoned the head, and *one* the tail of the tortoise; *three* and *seven* were considered as its left and right shoulders; and *four* and *two*, *eight* and *six*, were viewed as the fore and the hind feet. The number *five*, which represented the heart, was also the emblem of Heaven. We need scarcely observe, that this group of numbers is nothing but the common *magic-square*, each row of which makes up *fifteen*.

As the *Lo-chou* had the figure of a square, so the *Ho-tou* had that of a cross. It is what the Emperor Fou-hi observed on the body of the horse-dragon, which he saw spring out of the river Ho. The central number was *ten*, which, it is remarked by the commentators, terminates all the operations on numbers.

Figurate Arithmetic.

The Greek system of notation proceeded directly as far as *ten thousand*, comprising four terms of the *Denary Scale;* but by subscribing M, the initial letter of μυρια, it was carried over another similar period, to signify *hundreds of millions.* But the penetrating genius of Archimedes quickly discerned the powers, and unfolded the properties of such progressions. In a curious tract, entitled ψαμμιτης or *Arenarius*, this philosopher amused himself, with showing, that it was possible, assuming the estimation of Aristarchus of Samos, and other Astronomers of that age, to represent the number of particles of sand which would be required to fill the sphere of the universe. He took the limit of the ordinary numeral system, or *ten-thousand* times *ten-thousand*, that is, an *hundred millions*, as the root of a new scale of progression, which therefore advanced eight times faster than the simple denary notation. Archimedes proposed to carry this comprehensive system as far as eight periods, which would therefore correspond to a number expressed in our mode by sixty-four digits. From the nature of a geometrical progression, he demonstrated, that proportional numbers would range at equal distances; and consequently, that the product of any two numbers must have its place determined by the sum of the separate ranks, a principle which involves the theory of logarithms.

Extended Notation proposed by Archimedes:

The fine speculation of the Sicilian philosopher does not, however, appear to have been carried into effect; and without actually performing those calculations, he contents himself by pointing out the process, and stating the approximate results. But Apollonius, the most ingenious and inventive, next to Archimedes, of all the ancient mathematicians, resumed that scheme of numeration, simplified the construction of the scale, and reduced it to a commodious practice, For greater convenience, he preferred the simple myriad as the root of the system, which, therefore, proceeded by successive periods, corresponding to four of our digits. The periods were distinguished by breaks or blanks. That most important office which, in the modern system of notation, the cipher performs, by marking the rank of the digits, was indeed unknown to the earlier Greeks. They were hence obliged, when the lower periods failed, to repeat the letters Μυ. or the contraction for μυρια, *ten thousand.* Thus, to express *thirty-four trillions*, they wrote λδ Μυ. Μυ. Μυ. To signify *units* separately, it was customary with them to prefix the mark M°. or the abbreviation for *monad.*

and by Apollonius.

The procedure of the Greek arithmetician was necessarily slower and more timid than our simple, yet refined mode of calculation. Each step in the multiplication of complex numbers appeared separate and detached; without any concentration which the moderns obtain, by carrying forward the multiples of ten, and blending together the different members of the product. In ancient Greece, the operations of arithmetic, like writing, advanced from left to right; each part of the multiplier was in succession combined with every part of the multiplicand; and the several products were distinctly noted, or, for sake of compactness, grouped and conveniently dispersed, till afterwards collected into one general amount.

Pappus of Alexandria, in his valuable *Mathematical Collections*, has preserved a set of rules which Apollonius had formed, for facilitating arithmetical operations. These are, in the cautious spirit of the ancient Geometry, branched out into no fewer than twenty-seven propositions, though all comprised in the principle formerly stated by Archimedes: *That the product of two integers of different ranks, will occupy a rank corresponding to the sum of the component orders.* Suppose μ were to be multiplied into σ, or *forty* into *two hundred:* Take the lower corresponding characters δ and β, or *four* and *two*, which were called πυθμενες or radicals, the one depressed ten times, and the other an hundred times; and multiply their product η or *eight* successively by the ten and the hundred, or at once by a thousand, and the result is ͵η or *eight thousand.*

Greek mode of Calculation.

We shall take an example in multiplication, affording more variety than such as occur in Eutocius, which generally consist in the mere squaring of numbers. Let it be required to multiply *eight hundred and sixty-two*, by *five hundred* and *twenty-three.* The operation would be performed in this way.

$$
\begin{array}{llllll}
 & & & \omega & \xi & \beta \\
 & & & \phi & \varkappa & \gamma \\
\hline
\ddot{\mu} & \ddot{\gamma} & {}_{,}\alpha & & & \\
 & \ddot{\alpha} & \varsigma & & & \\
 & & {}_{,}\alpha & \sigma & \mu & \\
 & & {}_{,}\beta & \upsilon & & \\
 & & & \rho & \pi & \varsigma \\
\hline
\ddot{\mu} & \ddot{\varepsilon} & & \omega & \varkappa & \varsigma
\end{array}
$$

In the first range, φ multiplied into ω, being the same as the product of *eight* and *five*, augmented ten thousand times, is consequently denoted by $\ddot{\mu}$ or $\overset{\mu}{\mathrm{M}}$; φ multiplied into ξ gives the same result as *five* times *six* increased a thousand fold, and therefore expressed by $\ddot{\gamma}$ or $\overset{\gamma}{\mathrm{M}}$; and φ multiplied into β, evidently makes a thousand or ͵α. In the second range, κ multiplied into ω gives the same product as *eight* repeated *twice*, and then augmented a thousand times, or denoted by $\ddot{\alpha}\varsigma$; κ multipled into ξ is equivalent to *six* repeated *twice*, and afterwards increased an hundred fold, or expressed by ͵α σ; and κ multiplied by β gives forty, the value of μ. In the third range, γ multiplied into ω produces twenty-four hundred, which is denoted by ͵β υ; γ multiplied into ξ makes an hundred and eighty, or ρ π; and

Figurate Arithmetic.

lastly, $\gamma$ multiplied into $\beta$ gives ς, the symbol for *six*. Collecting the scattered members into one sum, the result of the multiplication of *eight hundred and sixty-two* by *five hundred and twenty-three* is $\ddot{\mu}\ \epsilon\ \omega\ \kappa\ \varsigma$ or *four hundred and fifty thousand, eight hundred and fifty-six.*

But the Greek notation was not adapted for the descending scale. To express fractions, two distinct methods were followed. 1. If the numerator happened to be unit, the denominator was indicated by an accent. Thus $\delta'$ signified *one fourth*, and $\kappa\epsilon'$ one *twenty-fifth*; but *one-half* being of most frequent recurrence, was signified by a particular character, varying in its form, C, ∠, C′, or ꓘ. 2. In other cases, it was the practice of the Greeks, to write the denominator, as we do an exponent, a little above the denominator, and towards the right hand: Thus, $\beta^{\iota\alpha}$ intimated *two-elevenths*, and $\pi\alpha^{\rho\kappa\alpha}$ *eighty-one, of an hundred and twenty-one* parts.

As an illustration of the management of fractions, we select an example somewhat complicated from the commentary which Eutocius of Ascalon wrote about the third century of our æra, on the Tract of Archimedes concerning the quadrature of the circle. Let it be required to multiply the mixed number *one thousand* and *thirty-eight*, with *nine-elevenths*, by itself.

Multiplication of Fractions;

$$
\begin{array}{l}
\alpha\ \omega\ \lambda\ \eta\quad \theta^{\iota\alpha} \\
\alpha\ \omega\ \lambda\ \eta\quad \theta^{\iota\alpha} \\
\hline
\underset{M}{\rho}\ \underset{M}{\pi}\ \underset{M}{\gamma}\ \eta\ \omega\ \varsigma\ \eta\quad \beta^{\iota\alpha} \\
\pi\ \underset{M}{\xi\delta}\ \underset{M}{\beta}\ \delta\ \varsigma\ \upsilon\ \chi\ \nu\ \delta\quad \varsigma^{\iota\alpha} \\
\underset{M}{\gamma}\ \underset{M}{\beta}\ \delta\ ϡ\ \sigma\ \mu\ \kappa\ \delta\quad \varsigma^{\iota\alpha} \\
\eta\ \varsigma\ \upsilon\ \sigma\ \mu\ \zeta\ \delta\ \varsigma\quad \varsigma^{\iota\alpha} \\
\omega\ \iota\ \eta\quad \beta^{\iota\alpha} \\
\chi\ \nu\ \delta\quad \varsigma^{\iota\alpha} \\
\kappa\ \delta\quad \varsigma^{\iota\alpha} \\
\varsigma\quad \varsigma^{\iota\alpha} \\
\pi\alpha^{\rho\kappa\alpha} \\
\hline
\tau\ \underset{M}{\lambda}\ \eta\quad \alpha\ \sigma\ \nu\ \alpha\quad \zeta^{\iota\alpha}\ \pi\alpha^{\rho\kappa\alpha} \\
\text{or, } \tau\ \underset{M}{\lambda}\ \eta\quad \alpha\ \sigma\ \nu\ \beta\quad \lambda\zeta^{\rho\kappa\alpha}
\end{array}
$$

It is to be observed, that, to multiply the several integers by the fraction nine-elevenths, amounts to their multiplication by nine, and the subsequent division by eleven. The excesses being *two*, and *six-elevenths*, are denoted by $\beta^{\iota\alpha}$ and $\varsigma^{\iota\alpha}$; while the product of the fraction itself gives *eighty-one* of *an hundred and twenty-one* parts, expressed by $\pi\alpha^{\rho\kappa\alpha}$.

and of Sexagesimals.

But the laborious operations that such complex fractions required, were afterwards superseded by the use of *sexagesimals*, which we have already observed, the astronomers, and especially Ptolemy, had introduced. "The division of the circumference of the circle into three hundred and sixty equal parts or degrees, was no doubt originally founded on the supposed length of the year, which, expressed in round numbers, consists of twelve months, each composed of thirty days. The radius approaching to the sixth part of the circumference, would contain nearly sixty of those degrees; and after its ratio to the circumference was more accurately determined, the radius still continued to be distinguished into the same number of divisions, which likewise bore the same name. As calculation now aimed at greater accuracy, each of these sixty divisions of the radius was, following the uniform progression, again subdivided into sixty equal portions called minutes; and repeating the process of sexagesimal subdivision, seconds and thirds were successively formed. The operations with sexagesimal fractions were performed in the descending scale, on a principle quite similar to that which Archimedes had before laid down. Each period of the multiplier, still proceeding from the left hand, was multiplied into a period of the multiplicand; and this product was then thrown to a rank depressed as much as the descents of both its factors. Thus, minutes multiplied into seconds, produced thirds; and seconds multiplied into thirds, produced fifths." *Edinburgh Review*, xviii. p. 200.

As an exemplification of this process, we shall take the question proposed by Theon, to find the square of the side of a regular decagon inscribed in a circle, or the chord of *thirty-six* degrees, which, according to Ptolemy's computation, measured in sexagesimal parts of the radius, *thirty-seven* degrees, *four* minutes, and *fifty-five* seconds. The multiplication is thus effected:

$$
\begin{array}{lllll}
\lambda\zeta & \delta & \nu\epsilon & & \\
\lambda\zeta & \delta & \nu\epsilon & & \\
\hline
\alpha\tau\xi\theta & \rho\mu\eta & \beta\lambda\epsilon & & \\
 & \rho\mu\eta & \iota\varsigma & \sigma\kappa & \\
 & & \beta\lambda\epsilon & \sigma\kappa & \\
 & & & & \gamma\kappa\epsilon \\
\hline
\alpha\tau o\epsilon & \delta & \iota\delta & \iota & \kappa\epsilon
\end{array}
$$

Here in the first line, λζ multiplied into λζ in the place of units, gives ͵ατξθ or *thirteen hundred and sixty-nine* degrees; λζ into δ on the next bar, gives ρμη or *one hundred and forty-eight* minutes; and λζ into νε, on the lowest bar, gives ͵βλε or *two thousand and thirty-five* seconds. In the second line, δ multiplied into λζ gives the product ρμη as before; δ multiplied into δ, both of them on the bar of minutes, gives ιϛ or *sixteen* seconds; δ into νε, gives σκ, or *two hundred and twenty* thirds. Lastly, in the third line, the νε on the bar of seconds, multiplied successively into λζ and δ, produce, as before, ͵βλε and σκ on the bars of seconds and thirds; and νε, multiplied by itself, gives ͵γκε, or *three thousand and twenty-five* fourths. These several products being reduced and collected together, formed the total amount of ͵ατοε δ ιδ ι κε or *thirteen hundred and seventy-five* degrees, *four* minutes, *fourteen* seconds, *ten* thirds, and *twenty-five* fourths; but all the terms below seconds, were omitted in practice as insignificant.

This calculation is laborious and intricate; yet, with a very few terms, it approaches to a considerable degree of accuracy. One of the most elegant theorems in elementary geometry demonstrates, that the side of a regular decagon, inscribed in a circle, is equal to the segment of the radius, divided in extreme and mean ratio. Wherefore the square now computed, should be equal to the product of *sixty*, or the radius, into *twenty-two* degrees, *fifty-five* minutes, and *five* seconds, the smaller segment; that is, equal to *thirteen hundred* and *seventy-five* degrees, and *five* minutes, from which it differs only by the defect of less than one minute.

The Sexagesimal Arithmetic was, therefore, a most valuable improvement engrafted on the notation of the Greeks. The astronomers of Alexandria and Constantinople continued to employ it in all their calculations, and were afterwards imitated by succeeding observers among the Arabians and Persians. The mode of working sexagesimals had thus become generally known, and reduced to practice; but we owe the first distinct treatise on those fractions to a very extraordinary character,—Barlaam, a Calabrian monk, the friend and Greek preceptor of the famous Petrarch, and a man of learning and vigorous intellect, who laboured by his writings and his missions to reunite the Eastern to the Western church. This adventurous personage, whose wayward conduct and dark features betrayed a lurking ferocity, met with a most singular fate. Being overtaken by a tremendous thunder-storm, while crossing the Adriatic Sea, he lashed himself to the mast of the bark, and was, in this situation, struck dead by a flash of lightning. The event happened in 1348: but Barlaam's tract on sexagesimals, neatly composed in six books, after the strict manner of the Ancients, and entitled generally Λογιστικη or *Computation*, first appeared in a Latin version at Strasburg in 1572, though not published complete with the Greek text, until the year 1600, when it was edited at Paris by Chambers of Eton, from a manuscript procured from the Continent by the zeal of Sir Henry Savile.

To facilitate the operations with sexagesimals, it seemed indispensible to have a more extensive multiplication table, that should include the mutual products of all the numbers from one to sixty. This was actually constructed, about the middle of the sixteenth century, by Philip Lansberg, a Dutch Clergyman; and has been exhibited since, in various forms, by Dr Wallis and others. In the mean time, a material change had been effected in the subdivision of the radius of the circle, from which the sexagesimal system had taken its rise. Purbach, the great restorer of mathematical science, instead of making the radius to consist of 216,000 seconds, as Ptolemy and succeeding Astronomers had done, stopt short at sixty degrees, and distinguished each of these, by a repeated centesimal division, into ten thousand equal parts. Regiomontanus advanced a step farther, and rejecting the sexagesimal admixture, he divided the radius at once into a million of parts, thus following out an arrangement purely decimal. The subdivision into degrees, minutes, and seconds, was henceforth confined to the circumference itself; and when logarithms came afterwards to be adapted to those fractions, they received the appellation, once general, though now restricted, of *Logistic*. But the sexagesimal subdivision had nearly been rejected altogether. Our very meritorious countryman, Mr Briggs, in computing his large canon of logarithms, followed in another branch the example of Purbach, by distinguishing each degree of the circumference into an *hundred* minutes, and each of these again into an *hundred* seconds; and we cannot help regretting, that this easy and obvious improvement had not been generally embraced at the time it was proposed. The French Mathematicians have lately gone farther, and endeavoured to pursue, to its utmost extent, the decimal subdivision first introduced by Regiomontanus. They begin with dividing the quadrant into an *hundred*, instead of ninety, degrees; and then following the plan of Briggs, they successively divide each degree into an *hundred* minutes, and each minute into an *hundred* seconds. But the advantages which might arise from the adoption of this plan, are not sufficient perhaps to outweigh the manifest inconvenience that must attend it in the present advanced state of the science; and, notwithstanding the sanguine dreams of some of its projectors, we cannot indulge the expectation of ever seeing it obtain a general and durable currency.

"The Greek arithmetic, then, as successively moulded by the ingenuity of Archimedes, of Apollonius, and Ptolemy, had attained, on the whole, to a singular degree of perfection, and was capable, notwithstanding its cumbrous structure, of performing operations of very considerable difficulty and magnitude. The great and radical defect of the system consisted in the want of a general mark analogous to our cipher, and which, without having any value itself, should serve to ascertain the rank or power of the other characters, by filling up the vacant places in the scale of numeration. Yet were the Greeks not altogether unacquainted with the use of such a sign; for Ptolemy, in his *Almagest*, employs the small ο, to occupy the accidental blanks which occurred in the notation of sexagesimals. This letter was perhaps chosen by him, because immediately succeeding to ν, which denotes 60, it could not, in the sexagesimal arrangement, occasion any sort of ambiguity. But the advantage thence resulting was entirely confined to that particular case. The letters, being already sig-

Figurate Arithmetic.

nificant, were generally disqualified for the purpose of a mere supplementary notation; and the selection of an alphabetic character to supply the place of the cipher may be considered as an unfortunate circumstance, which appears to have arrested the progress towards a better and more complete system. Had Apollonius classed the numerals by denary triads, instead of tetrads, he would have greatly simplified the arrangement, and avoided the confusion arising from the admixture of the punctuated letters, expressing thousands. It is by this method of proceeding with periods of three figures, or advancing at once by thousands instead of tens, that we are enabled most expeditiously to read off the largest numbers. The extent of the alphabet was favourable to the first attempts at enumeration; since, with the help of three intercalations, it furnished characters for the whole range below a thousand; but that very circumstance, in the end, proved a bar to future improvements. It would have been a most important stride, to have next exchanged those triads into monads, by discarding the letters expressive of tens and hundreds, and retaining only the first class, which, with its inserted *episêmon*, should denote the nine digits. The *iôta*, which signified ten, now losing its force, might have been employed as a convenient substitute for the cipher. By such progressive changes, the arithmetical notation of the Greeks would at last have reached its utmost perfection, and have exactly resembled our own. A wide interval, no doubt, did still remain; yet the genius of that acute people, had it continued unfettered, would in time, we may presume, have triumphantly passed the intervening boundaries. But the death of Ptolemy was succeeded by ages of languor and decline; and the spirit of discovery insensibly evaporated in miserable polemical disputes, till the fair establishment of Alexandria was finally overwhelmed under the irresistible arms of the Arabs, lately roused to victory and conquest by the enthusiasm of a new religion." (*Edinburgh Review*, Vol. XVIII. p. 203.)

History of the Denary Numerals.

The ingenuity and varied resources of the ancient Greeks were the main causes which diverted them from discovering our simple denary system. Having attained a distinct conception of the powers of the geometrical progression, and even advanced so far as to employ their small o to fill the breaks of a period, nothing seemed wanting but to dismiss the punctuated letters and those for tens and for hundreds, and to retain merely the direct symbols for units, that is, the first third part of their alphabet. Here, however, those masters of science were stopt in their career, and the Eastern Empire presents a melancholy picture of the decline and corruption of human nature. Ingenuity had degenerated into polemical subtlety, and the manly virtues which freedom inspires were exchanged for meanness and self-abasement.

Some writers, misled by very superficial views of the subject, have yet ascribed the invention of the modern numeral characters to the Greeks, or even to the Romans. Both these people, for the sake of expedition, occasionally used contractions, especially in representing the numbers and fractions of weights or measures, which, to a credulous peruser of mutilated inscriptions, or ancient blurred manuscripts, might appear to resemble the forms of our ciphers. But this resemblance is merely casual, and very far indeed from indicating the adoption of a regular denary notation. The most contracted of the Roman writings was formed by the marks attributed to Tiro or Seneca, while that of the Greeks was mixed with the symbols called *Siglæ*; both of which have exercised the patience and skill of Antiquaries and Diplomatists. In the latter species of characters, were kept the accounts of the revenues of the Empress Irene at Constantinople. But the modern Greeks appear likewise to have sometimes used a simpler kind of marks, at least for the low numbers. The continuator of Matthew Paris's *History* relates, that "in the year 1251 died John Basingstoke, Archdeacon of Leicester, who brought into England the numeral figures of the Greeks, and explained them to his friends." It is subjoined, that they consisted of a perpendicular stroke, with a short line inserted at different heights and at different angles, signifying units on the left, and tens on the right side. The figures themselves are scrawled on the margin of the text. But they are evidently so different in their form, and so distinct in their nature, from the modern ciphers, that one cannot help feeling surprise, to see an author of any discernment refer the introduction of the latter to Basingstoke.

It cannot be doubted, that we derived our knowledge of the numeral digits from the Arabians, who had themselves obtained this invaluable acquisition from their extended communication with the East. Those deserving people who, under the name of Moors or Saracens, had for many centuries cultivated Spain, were most ready to acknowledge their obligation to the natives of India, who, according to Alsephadi, a learned Arabian doctor, boasted of three very different inventions,—the composition of the *Golaila Wadamna*, or Pilpay's Fables,—the game of chess,—and the nine digital characters. Still much obscurity hangs over the whole subject. Two distinct inquiries naturally present themselves: 1. At what period did the Arabians first become acquainted with those characters; and, 2. What is the precise epoch when the knowledge of them was imparted to the Christian nations of Europe. We shall take a short review of both these questions.

Proofs of their Indian origin.

1. Gatterer, the late ingenious and very learned Professor of History at Göttingen, in his *Elements of Universal Diplomacy*, maintains that our ciphers were only primordial letters, invented by Taaut or Theut, and known to the ancient Egyptians and Phœnicians, being still distinctly observed, as he asserts, in the inscriptions painted on the coverings of the oldest mummies; and that afterwards, along with other branches of science, they passed to the Oriental nations, among whom they were preserved, till the victorious arms of the Mussulmen penetrated to India, and brought back those precious monuments of genius. But we cannot believe that a contrivance so very simple, and so eminently useful as that of the nine digits, if once communicated, could ever again be lost or neglected. Pythagoras and Boethius merely contemplated the properties of numbers, and seem not, in their calculations, to have gone beyond the use of the *Abacus*. An early intercourse had no doubt subsisted between the people of Egypt and of India, and a striking resemblance may be traced in their customs, their

buildings, and their religious rites. But the characters exhibited on the Egyptian monuments bear no indication of the *Denary System*, and are, like the Roman and Chinese numerals, abridged representations of objects, rather than arbitrary signs.

That the occupiers of Hindostan and the nations communicating with them, have for ages been acquainted with the use of the denary notation, cannot be disputed. But was this an original discovery, or at what distant epoch was it first introduced among them? The easy credulity of European visitors encouraged the Brahmins to set up very lofty pretensions respecting the antiquity of their science. Among other treasures, they boasted the possession, from time immemorial, of an elementary treatise on arithmetic and mensuration, composed in Sanscrit, and called *Lilawati*, of such inestimable value as to be ascribed to the immediate inspiration of Heaven. But the researches of our ingenious countrymen in exploring that sacred language of India, have dispelled some illusions, and greatly abated the admiration of the public for such eastern learning. From what we have been able to gather, the *Lilawati* is a very short and meagre performance, loaded with a silly preamble and colloquy of the Gods. It begins with the numeration by nine digits, and the supplementary cipher or small o, in what are called the *Devanagari* characters; and it contains the common rules of arithmetic, and even the extraction of the square root, as far as two places of figures; but the examples are generally very easy, scarcely forming any part of the text, and only written on the margin with red ink. Of fractions, whether decimal or vulgar, it treats not at all.

The Hindus pretend, that this arithmetical treatise was composed about the year 1185 of the Christian era. The date of a manuscript, however, is always very uncertain. We know besides, that the oriental transcriber is accustomed to incorporate without scruple such additions in the text as he thinks fit. Nor will any of the criteria which might ascertain the age of a manuscript apply to the eastern writings, where the composition of the paper, the colour of the ink, and the form of the characters, have for ages continued unchanged.

If the exuberant fancy of the Greeks led them far beyond the denary notation, it seems probable, that the feebler genius of the Hindus might just reach that desirable point, without diverging into an excursive flight. Though now familiar with that system, they are still unacquainted with the use of its descending decimal scale; and their management of fractions, accordingly, is said by intelligent judges to be tedious and embarrassed. In Plate XXVII. on the left hand, and near the bottom, we have given the Sanscrit digits, and have placed over them the numeral elements from which they might be formed. These consist of a succession of simple strokes, variously combined as far as nine. The resemblance to the *Devanagari* characters appears very striking. From these again, the common Hindu, and the vulgar Bengalee digits, are evidently moulded, with only slight alterations of figure. The Birman numerals, which we have copied from Symes' *Embassy to the Kingdom of Ava*, are manifestly of the same origin; only they have a thin, wirey body, being generally written on the palmyra-leaf with the point of a needle.

It appears, from a careful inspection of the manuscripts preserved in the different public libraries of Europe, that the Arabians were not acquainted with the denary numerals, before the middle of the thirteenth century of the Christian æra. They cultivated the mathematical sciences with ardour, but seldom aspired at original efforts, and generally contented themselves with copying their Grecian masters. The alphabet of the Arabians had been employed for expressing numbers exactly in the same way as that of the Greeks. The letters, in their succession, were sometimes applied to signify the lower of the ordinal numbers; but more generally they were distinguished into three classes, each composed of nine characters, corresponding to units, tens, and hundreds. Though, like most of the Oriental nations, the Arabians write from right to left, yet they followed implicitly the Greek mode of ranging the numerals, and performing their calculations. With the same deference, they received the other lessons of their great masters, and very seldom hazarded any improvement, unless where industry and patient observation led them incidentally to extend mensuration, and to rectify and enlarge the basis of Astronomy.

It seems highly probable, therefore, that the Arabians did not adopt the Indian numerals until a late period, and after the torrent of victory had opened an easy communication with Hindostan. They might derive their information through the medium of the Persians, who spoke a dialect of their language, had embraced the same religion, and were, like them, inflamed by the love of science and the spirit of conquest. The Arabic numerals, accordingly, resemble exceedingly the Persic, which are now current over India, and there esteemed the fashionable characters. But the Persians themselves, though no longer the sovereigns of Hindostan, yet display their superiority over the feeble Gentoos, since they generally fill the offices of the revenue, and have the reputation of being the most expert calculators in the East. It should be observed, however, that, according to Gladwin, these accountants have introduced a peculiar contracted mode of registering very large sums, partly by the numeral characters, and partly by means of symbols formed of abbreviated words. Yet Sir John Chardin relates, that the Persians have no proper terms to express numbers beyond a thousand, which they merely repeat, as our young arithmeticians often do, to signify a million or a billion.

The Indian origin of the denary numerals is farther confirmed by the testimony of Maximus Planudes, a monk of Constantinople, who wrote, about the middle of the fourteenth century, a book on practical arithmetic, entitled Λογιςικὴ Ινδικὴ, or Ψηφοφοϱιά κατ Ινδȣς̀, ἡ λεγομενη μεγάλη, that is, "the "great Indian mode of Calculating." In his introduction, he explains concisely the use of the characters in notation. But Planudes appears neither to have received his information directly from India, nor through the medium of the Persians, the nearest neighbours on the eastern confines of the Greek Empire. It is most probable that he was made acquainted with those numerals by his intercourse with

Figurate Arithmetic.

Europe, having twice visited, on a sort of embassy, the Republic of Venice; for, of two manuscripts preserved in the library of St Mark, the one has the characters of the Arabians, and the other has that variety which was first current in Europe, while neither of them shows the original characters used in Hindostan.

Their introduction into Europe.

2. But the most important inquiry is, to ascertain the period at which the knowledge of our present numerals was first spread over Europe. As it certainly had preceded the invention of the art of printing, the difficulty of resolving the question is much increased by the necessity of searching and examining old and often doubtful manuscripts. Some authors would date the introduction of those ciphers as early as the beginning of the eleventh century, while others, with far greater appearance of reason, are disposed to place it two hundred and fifty years later.

While the thickest darkness brooded over the Christian world, the Arabians, reposing after their brilliant conquests, cultivated with assiduity the learning and science of Greece. If they contributed little from their own store of genius, they yet preserved and fanned the holy fire. Nor did they affect any concealment, but would freely communicate to their pupils and visitors that precious knowledge which they had so zealously drawn from different quarters. Some of the more aspiring youth, in England and France, disgusted with the wretched trifling of the schools, resorted for information to Spain; and having the courage to subdue the rooted abhorrence entertained in that age against Infidels, took lessons in Philosophy from the accomplished Moors. Among those pilgrims of science, the most celebrated was Gerbert, a monk, born of obscure parents, at Aurillac, in Auvergne, but promoted by his talents successively to the Bishopricks of Rheims and of Ravenna, and finally raised to the Papal chair, which he filled during the last four years of the tenth century, under the name of Sylvester II. This ardent genius studied Arithmetic, Geometry, and Astronomy, among the Saracens; and on his return to France, charged with various knowledge, he was esteemed a prodigy of learning by his contemporaries. Nor did the malice of rivals fail to represent him as a magician, leagued with the infernal powers. Gerbert wrote largely on Arithmetic and Geometry, and gave rules for shortening the operations of the *Abacus*, which he likewise termed *Algorismus*. In some manuscripts, the numbers are expressed in ciphers; but we are not thence entitled to infer, as many writers have done, that he had actually the merit of introducing those characters into Europe. The context of his discourse will not support such a conclusion. The figures were not, we have seen, still known to the Arabians themselves; and must have long afterwards been inserted in those copies, for the convenience of transcribers.

Figurate Arithmetic.

Nor can we safely refer the introduction of Arabic figures to our famous Roger Bacon, whose various attainments and unwearied research after genuine knowledge, raised him far above the level of his contemporaries, but who, to the disgrace of his age and country, suffered a sharp persecution, and a tedious imprisonment, on the ridiculous charge of practising the redoubted arts of magic. But the writings of Bacon really discover no proofs of his acquaintance with the denary notation; and the fact commonly stated as an irresistible evidence in his favour, bears a very different interpretation. An almanack, now preserved in the Bodleian Library at Oxford, and containing numerals in their earliest forms, has, by the credulity of after-times, been, with all other feats and inventions, ascribed, of course, to the great necromancer. But unluckily this production is marked with the date 1292, the very year on which Bacon, after a lingering illness, expired; and it besides professes to have been calculated for the meridian of Tolouse, and had consequently been imported, without doubt, from France. *

About the same period, John of Halifax, named, in the quaint Latinity then used, *Sacro-Bosco*, who had likewise travelled, wrote his Treatise *De Sphæra*, in some copies of which the numbers are given in ciphers. But it appears from examination, that such abbreviations were introduced by the license of transcribers.

There is little doubt that the Arabic figures were first used by Astronomers, and afterwards circulated in the almanacks over Europe. The learned Gerard Vossius places this epoch about the year 1250; but the judicious and most laborious Du Cange thinks that ciphers were unknown before the fourteenth century; and Father Mabillon, whose diplomatic researches are immense, assures us, that he very rarely found them in the dates of any writings prior to the year 1400. Kircher, with some air of probability, seeks to refer the introduction of our numerals to the astronomical tables which, after vast labour and expence, were published by the famous Alphonso, King of Castile, in 1252, and again, more correctly, four years afterwards. But it is suspected that, in the original work, the numbers were expressed in Roman or Saxon characters. Two letters from that enlightened, but ill-requited prince, to our Edward I., which are preserved in the Tower of London, have the dates 1272 and 1278, still denoted by those ancient characters.

* Nothing appears to be worse founded than the attempts to represent the elder Bacon in the light of an original inventor. Notwithstanding the obscurity of his writings, it needs but a little criticism to dispel the conceits fomented by national partiality. Friar Bacon advances no claim even to the discovery of gunpowder, which has been so gratuitously ascribed to him. On the contrary, he admits that the boys in his time were acquainted with the use of this substance in fire-works; and he merely pretends, in a sort of anagram, to give a receipt for making it stronger and better than ordinary.

After the chief ingredient in the composition of gunpowder, under the mistaken names of *natron* or *nitrum*, and *saltpetre* or *rock-salt*, had been imported from the East, probably through the intervention of the Crusaders, its disposition to explode in the contact of inflammable matters, if not communicated along with it, could not remain for any time a secret. The explosive force was a very different, and a far more important property, which is perhaps rightly attributed to Schwartz, a German monk, who, in the course of his experiments, stumbled on it about the middle of the fourteenth century.

In the tenth volume of the *Archæologia*, the Rev. Mr North has given a short account of an almanack preserved in the library of Bene't College, Cambridge, and containing a table of eclipses for the cycle between 1330 to 1348. There is prefixed to it a very brief explication of the use of numerals, and the principles of the denary notation; from which we may see how imperfectly the practice of those ciphers was then understood. The figures are of the oldest form, but differ not materially from the present, except that the four has a looped shape, and the five and seven are turned about to the left and to the right. The one, two, three, and four, are likewise, perhaps for elucidation, represented by so many dots, thus, . .. ∴ ∷; while five, six, seven, and eight, are signified by a semicircle or inverted ɔ with the addition of corresponding dots—ɔ ɔ· ɔ: ɔ∴ Nine is denoted by o; ten by the same character, with a dash drawn across it; and twenty, thirty, or forty, by this last symbol repeated.

As a farther evidence of the inaccurate conceptions which prevailed respecting the use of the digits in the fourteenth century, we may refer to the mixture of Saxon and Arabic numerals which was copied from some French manuscripts by Mabillon, as exhibited in Plate XXVII. The Saxon 𝔵, signifying ten, is repeatedly combined with the ordinary figures; and 𝔵𝔵𝔵, 𝔵𝔵𝔵𝔦, are immediately followed by 302, and 303, which must have been therefore intended to signify *thirty-two* and *thirty-three*, the force of the cipher not being still rightly understood. It should be observed, that the Greek *episēmon* or *Fau*, for the number *six*, had come to be represented by a character similar to G. The Saxon dates are taken from the Danish and Norwegian registers, preserved in Suhm's *Northern Collections*.

One of the oldest authentic dates in the numeral characters is that of the year 1375, which appears written by the hand of the famous Petrarch on a copy of St Augustine, that had belonged to that distinguished Poet and Philosopher. The use of those characters had now begun to spread in Europe, but was still confined to men of learning. We have seen a short tract in the German language, entitled, *De Algorismo*, and bearing the date 1390, which explained, with great brevity, the digital notation and the elementary rules of arithmetic. What is very remarkable, the characters, in their earliest form, are ranged thus, 0, 9, 8, 7, 6, 5, 4, 3, 2, 1, from right to left, the order which the Arabians would naturally follow. But it was not very easy to comprehend at first the precise force of the *cipher*, which, insignificant by itself, only serves to determine the rank and value of the other digits. The name, derived from an Arabic word signifying *vacuity*, is sufficiently expressive; yet a sort of mystery, which has imprinted its trace on language, seemed to hang over the practice, for we still speak of *deciphering*, and of *writing in cipher*, in allusion to some dark or concealed art. After the digits had come to supply the place of the Roman numerals, a very considerable time probably elapsed before they were generally adopted in calculation. The modern practice of Arithmetic was unknown in England, till about the middle of the sixteenth century. But the lower orders, imitating the clerks of a former age, were still accustomed to reckon with their *counters* or *awgrym stones*. In Shakespear's comedy of the *Winter's Tale*, written at the commencement of the seventeenth century, the clown, staggered with a very simple multiplication, exclaims that he will try it with counters.

Arithmetic was long considered in England as a higher branch of science, and therefore left, like Geometry, to be studied at the University. Most of the public or grammar schools of the South were, on the suppression of the monasteries, erected a little after the Reformation, during the short but auspicious reign of Edward VI. They were accordingly destined by their founders merely for teaching the dead languages; and the too exclusive pursuit of the same system is now one of the greatest defects in the English plan of liberal education.

It cannot be doubted that the kalendars composed in France or Germany, and sent to the different religious houses, were the means of dispersing the knowledge of Arabic numerals over Europe. The library of the University of Edinburgh has a very curious almanack, presented to it, with a number of other valuable tracts, by the celebrated Drummond of Hawthornden, beautifully written on vellum, with most of the figures in vermillion. It is calculated especially for the year 1482, but contains the succession of lunar phases for three cycles, 1475, 1494, and 1513, with the visible eclipses of the sun and moon, from 1482 to 1530 inclusive. The date of this precious manuscript, which had once belonged to St Mary's Abbey at Cupar in Angus, is easily determined, and we have copied from it the oldest numerals exhibited in Plate XXVII. To these we have subjoined *fac similes* from Caxton's *Mirrour of the World*, and a wooden Cut from Shirwood's *Ludus Arithmomachiæ*, given in Dibdin's *Bibliotheca Spenceriana*.

The College accounts in the English Universities were generally kept in the Roman numerals, till the early part of the sixteenth century; nor in the parish registers were the Arabic characters adopted before the year 1600. The oldest date which we have met with in Scotland is that of 1490, which occurs in the rent-roll of the Diocese of St Andrew's, the change from Roman to Arabic numerals occurring, with a corresponding alteration in the form of the writing, near the end of the volume. The old characters in Plate XXVII. are copied from a manuscript history of the Scottish Bishopricks, apparently written about the year 1550, and now in the possession of Thomas Thomson, Esq. Advocate.*

* For want of attending to these facts, some learned Antiquaries have often suffered themselves to be grossly misled. Thus, Mr De Cardonnel, a respectable author, who has given views and short descriptions of the ancient edifices in Scotland, mentions, without marking the smallest doubt or surprise, that the date 1155 appears over the gateway of the ruins of the Castle of St Andrew's. But this front was built subsequent to the murder of the detested Cardinal Beaton, by Archbishop Hamilton, who likewise there affixed his Arms, but who long afterwards, on the capture of Dumbarton Castle, suffered an ignominious death, for his adherence to Queen Mary and the Popish faction. The real date was unquestionably 1555, only the second figure has been almost effaced by time and accident.

Figurate Arithmetic.

Illustrations of the Rules of Figurate Arithmetic.

Having endeavoured to trace the origin and introduction of our numeral characters, it only remains now to explain the *operations of Figurate Arithmetic*. But, on this branch of the subject, we need not dilate; since the common rules, with their various modifications, are given at some length in the *Encyclopædia*. It will be more instructive to derive the practice of numbers from the principles already unfolded, in treating of *Palpable Arithmetic*. The same theory may likewise suggest other methods of varying and abridging the common operations. We shall follow the order observed under the first head, selecting as few examples as may be wanted for illustration. The *Denary* Scale, being the one generally received, will claim our chief attention; but we shall likewise compare its results with those of some other scales, particularly the *Duodenary*, which is partially adopted in commerce, and possesses certain peculiar advantages.

It would, in many cases, facilitate calculation, to have figures corresponding to the open counters. We have, therefore, to transform the ordinary characters into deficient digits, modifying their shape as much as to distinguish without entirely altering or disguising them. By help of such new figures, it will be easy to represent numbers by their defects as well as their excesses. This answers most conveniently in expressing the digits from 5 to 10. Thus 38 may be denoted by $4\bar{2}$, meaning 40 with 2 abated; for the same reason, 829 may be written $1\bar{2}3\bar{1}$, signifying that 1000 is to be diminished by 201.

For the operations with the *Duodenary Scale*, it becomes necessary to devise two additional characters for expressing *ten* and *eleven*. Not to seek far after such objects, we have contented ourselves with condensing the ordinary forms into ϕ and ϕ̸, which are perhaps sufficiently distinct, while they shadow out the figures represented by them.* We now proceed to explain the common operations.

### Addition.

Addition.

From the principle of numerical notation, it follows that addition is performed by collecting the digits of each bar or rank. Each class, whether it be units, hundreds or thousands, is treated in the same way. In adding two figures, it is only requisite to count forwards from one of them, as many steps as are signified by the other. Suppose 5 were to be joined to 8; reckoning onwards, we pass through 9, 10, 11, 12, to 13. This simple process may be more conveniently performed by counting over the fingers. But, for a learner, it is a preferable mode to frame a table of addition, which he may readily commit to memory. The construction and use of such a table are so very simple, as hardly to require any explanation. The one number occupies the horizontal row at the top, and the other the vertical row at the side. Thus, below the column of 7, and opposite to the horizontal range of 6, stands 13, the sum of these numbers. Such tables are found in the more ancient treatises of arithmetic; but they have been most injudiciously, as we think, omitted in the later systems of education.

ADDITION TABLE.

*Denary Scale.*

| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | |
|---|---|---|---|---|---|---|---|---|---|
| 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 1 |
| | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 2 |
| | | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 3 |
| | | | 8 | 9 | 10 | 11 | 12 | 13 | 4 |
| | | | | 10 | 11 | 12 | 13 | 14 | 5 |
| | | | | | 12 | 13 | 14 | 15 | 6 |
| | | | | | | 14 | 15 | 16 | 7 |
| | | | | | | | 16 | 17 | 8 |
| | | | | | | | | 18 | 9 |

Let it be sought to add these four numbers, 3709, 8540, 2618, and 706. Having set them in their ranks, the most natural way would be to write down the sum of each column. The first column on the right hand gives 23, the next 5, the third 25, and the last column 13. The same numbers, collected by a second summation, give for the final result 15573.

```
 3709
 8540
 2618
  706
 ----
   23
  255
 13
-----
15573
```

But the process would be rather shortened, by writing under each column the units of the sum, and below it the tens in a smaller character, which are to be joined to the figures of the next column in adding them. By a little practice, however, this precaution is rendered unnecessary, and the small subscribed figures are retained mentally, and *carried* to the successive higher columns.

```
 3709
 8540
 2618
  706
-----
15573
 1202
```

This operation is somewhat easier with deficient figures. Thus, the numbers may be changed into others with the defects interspersed. In this mode, there being a sort of counterbalance, it will seldom be required to carry any to the higher columns.

$$\begin{array}{r} 4\bar{3}1\bar{1} \\ 1\bar{2}540 \\ 3\bar{4}2\bar{2} \\ 1\bar{3}1\bar{4} \\ \hline 1658\bar{7} \\ \text{or } 15573 \end{array}$$

Suppose those numbers were all transferred to the *Duodenary Scale*; they will stand thus: The figures of the first column give by summation *twenty-one*; that is 19 by the *Duodenary Scale*. The others in succession yield the several sums annexed.

```
2 1 9 1
4 ϕ̸ 3 8
1 6 2 2
  4 ϕ ϕ
-------
    1 9
  2 0
1 ϕ
7
-------
9 0 1 9
```

If the condensed process be followed, the form will be a little different, and more distinct.

```
2 1 9 1
4 ϕ̸ 3 8
1 6 2 2
  4 ϕ ϕ
-------
9 0 1 9
  2 2 1
```

The operation will be somewhat shortened by introducing deficient figures; nor will there be any occasion for any carrying, the accumulated excess of the digits being partly counterbalanced by the intermixed defects.

$$\begin{array}{r} 2\,2\,\bar{3}\,1 \\ 5\,\bar{1}\,4\,\bar{4} \\ 2\,6\,2\,2 \\ 5\,\bar{1}\,\bar{2} \\ \hline 9\,0\,2\,3 \\ \text{or } 9\,0\,1\,9 \end{array}$$

To facilitate the working on the *Duodenary Scale*, it would be expedient to construct an Addition Table. By means of this, we may at once sum up a row of pence, and carry the excess to the place of shillings.

* *These characters are larger, and differently shaped from what was intended; but is too late now to correct the oversight of the artist.*

Figurate Aritametic.

### Addition Table.

*Duodenary Scale.*

| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | ↊ | ↋ | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | ↊ | ↋ | 10 | 1 |
| | 4 | 5 | 6 | 7 | 8 | 9 | ↊ | ↋ | 10 | 11 | 2 |
| | | 6 | 7 | 8 | 9 | ↊ | ↋ | 10 | 11 | 12 | 3 |
| | | | 8 | 9 | ↊ | ↋ | 10 | 11 | 12 | 13 | 4 |
| | | | | ↊ | ↋ | 10 | 11 | 12 | 13 | 14 | 5 |
| | | | | | 10 | 11 | 12 | 13 | 14 | 15 | 6 |
| | | | | | | 12 | 13 | 14 | 15 | 16 | 7 |
| | | | | | | | 14 | 15 | 16 | 17 | 8 |
| | | | | | | | | 16 | 17 | 18 | 9 |
| | | | | | | | | | 18 | 19 | ↊ |
| | | | | | | | | | | 1↊ | ↋ |

It is evident, that the mode of operation will still be the same in the descending terms of any scale. The only thing needed is to preserve the respective ranks of the figures; to secure which, a point may be placed between the units and the fraction. Let the annexed example of integers and decimals be proposed. The fractional part of the sum thus corresponds to *one-fourth*.

| |
|---|
| 602.765625 |
| 370.40625 |
| 81.078125 |
| 1054.250000 |

Suppose deficient figures were employed. The several numbers might assume this form: As generally happens in such cases, no carrying whatever is here wanted.

| |
|---|
| $1\bar{4}03.\bar{2}\bar{4}6\bar{4}25$ |
| $4\bar{3}0.40\bar{4}25$ |
| $1\bar{2}1.1\bar{2}\bar{2}125$ |
| 1154.350000 |
| or 1054.25 |

The same numbers reduced to the *Quaternary Scale* will stand thus: Their addition is extremely simple, and gives of course the same result.

| |
|---|
| 21122.301 |
| 11302.122 |
| 1101.011 |
| 100132.100 |

Subtraction.

Subtraction. This operation having for its object to find the difference between two numbers, is precisely the reverse of addition. The same auxiliary table may hence answer for both. Thus, if 7 joined to 6 makes 13, it is equally clear, that 7 taken away from 13 must leave 6. For the sake of distinction, the greater of the two numbers is called the *Minuend* and the other one the *Subtrahend*.

The method of proceeding will be most clearly perceived from the inspection of an example. Let it be required to take 428053 from 702632. Here, beginning at the right hand, 3 cannot be taken from 2, but the effect will evidently be the same if ten were added to both the minuend and the subtrahend. Ten may therefore be joined to the 2, while one, as equivalent to it, is thrown to 5, which occupies the place higher. This addition of the 10 is called *borrowing*, and the countervailing addition of 1 in the next bar is called *carrying*. Take 3 then from 2, with the junction of 10 borrowed, or 12, and there remains 9. Now 5, with the addition of the unit carried, or 6, is to be taken from 3: To do this, 10 is again borrowed, making the figure of the minuend 13, which leaves 7; and the 1 carried to 0 in the higher place, is taken from 6, and therefore leaves 5. Again, 8 taken from 2 with the addition of 10, leaves 4; and the same addition of 10 is made to the subtrahend, by joining 1 to the 2 which stands a place higher. But 3 taken from 0 increased to 10, gives 7, for the remainder; and 1 carried to the 4, and subtracted from 7, leaves 2, as the last difference.

| |
|---|
| 702632 |
| 428053 |
| 274579 |

Figurate Arithmetic.

Let the same example be worked with deficient digits. In subtracting the lower number, it is only required to change the character of its digits, and then add them. The operation, therefore, needs no farther explanation.

| |
|---|
| $703\bar{4}32$ |
| $43\bar{2}153$ |
| $3\bar{3}558\bar{1}$ |
| or 274579 |

Next, suppose those numbers were converted into the *Duodenary Scale*. The subtraction will be performed thus: It is only to be observed, that when there is occasion for borrowing, *twelve* is joined to the digit of the minuend, and *one* is carried or annexed to the higher digit of the subtrahend.

| |
|---|
| 2 9 ↊ 7 4 8 |
| 1 8 7 8 7 1 |
| 1 1 2 ↊ 9 7 |

Since the terms of a descending scale are treated in the same way, it would, perhaps, be superfluous to take examples of the subtraction of decimal fractions.

### Multiplication.

Multiplication.

This operation, it was observed, is nothing but a repeated addition. The object which it seeks, is to add, for a *Product*, the *Multiplicand*, as often as there are units contained in the *Multiplier*. But such a process would have proved intolerably tedious, if the principle of numerical arrangement had not come to lend its aid. As in the *Denary Scale*, for instance, any digit is augmented tenfold at each shift to a higher place; so its product into the Multiplicand will give a similar increase, in the ascending progression, and must consequently maintain a corresponding value. Suppose it had been required to multiply 57 by 23; the most obvious way of proceeding would be this. First, the 57 is added *three* times, making 171. Next, the same number advanced a place higher, or having a zero annexed to it, is added *twice*, corresponding to the *two* of the multiplier, which, from its situation, has the value of 20. To this sum, or 1140, is joined the other, making in all 1311, for the compound product.

| | |
|---|---|
| 570 | 57 |
| 570 | 57 |
| | 57 |
| 1140 | |
| 171 | 171 |
| 1311 | |

But the operation is shortened by performing mentally this repetition or summation, of each digit in the multiplicand. Thus, resuming the last example: 7 repeated *three* times makes 21, and 5 repeated as often on the advanced bar gives 15; again, 7 repeated *twice*, and moved a place higher, makes 14, and 5 likewise repeated *twice*, and shifted a place still higher, gives 10. The general amount is 1311, the same as before.

| |
|---|
| 57 |
| 23 |
| 21 |
| 15 |
| 14 |
| 10 |
| 1311 |

Such, we have seen, was the method practised by the Greeks; but in many cases this procedure becomes excessively tedious and perplexed. It is much simpler, by *carrying*, as in the process of Addition, to consolidate the figures at once on each bar, before they are written down. Instead of noting the 2 of the first product 21, it is joined immediately to the next product 15, and the sum 17 written down. Again, in the next row, the higher figure of the product 14 is combined at once with the lower figure of the next product 10, making 114.

| |
|---|
| 57 |
| 23 |

Figurate Arithmetic.

This now is the ordinary form of Compound Multiplication, and it seems scarcely to admit of any material improvement. But, to shorten the repeated summation of digits, it is expedient to construct a table, which must be engraved in the memory of the arithmetician. The mechanical method of multiplying digits, which has been already explained, may serve as an useful auxiliary, in fixing the recollection of the series of products. The table itself, though ascribed to Pythagoras, is most easily framed; but, notwithstanding, it has become now so very common, we make no hesitation in copying it, especially as we design to introduce another accommodated to the *Duodenary Scale.*

MULTIPLICATION TABLE.

*Denary Scale.*

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 1 |
| | 4 | 6 | 8 | 10 | 12 | 14 | 16 | 18 | 2 |
| | | 9 | 12 | 15 | 18 | 21 | 24 | 27 | 3 |
| | | | 16 | 20 | 24 | 28 | 32 | 36 | 4 |
| | | | | 25 | 30 | 35 | 40 | 45 | 5 |
| | | | | | 36 | 42 | 48 | 54 | 6 |
| | | | | | | 49 | 56 | 63 | 7 |
| | | | | | | | 64 | 72 | 8 |
| | | | | | | | | 81 | 9 |

It may be observed, that the numbers 1, 4, 9, 16, 25, 36, 49, 64, and 81, which occupy the diagonal, are the second powers or squares of the successive digits. From the inspection of the table, we gather that *one* is the terminating figure in the *three* products 1, 21, and 81; that *two* terminates the *six* products 2, 12, 12, 32, 42, and 72; that *three* occurs as the terminating figure in only the *two* products 3 and 63; that *four* terminates the *four* products, 4, 14, 24, and 54; that *five* terminates likewise the *five* products 5, 15, 25, 35, and 45; that *six* is the terminating figure in the *five* products, 6, 16, 16, 36, and 56; that *seven* terminates only the *two* products 7 and 27; that *eight* terminates the *five* products, 8, 18, 28, and 48; and that *nine* occurs only *twice* as the terminating figure, in 9 and 9. It hence follows, that, out of *thirty-four* chances, there are *six* that any composite number should end in 2; *five* chances that it should end in 5, 6, or 8; *four* chances that it should end in 4; *three* chances that it should end in 1; *two* chances that it should end in 3 or 7; and *two* chances likewise that the terminating figure should be 9. These very different proportions in the recurrence of the several digits at the end of a number, may be remarked in the large tables of products. It likewise appears, that the bulk of the prime numbers must terminate with 9, 3, or 7, and the rest with 1.

It may be instructive, to compare the operation of an example of compound multiplication in the ordinary way, with another performed by deficient figures.

| | |
|---|---|
| 4819 | $5\bar{2}2\bar{1}$ |
| 378 | $4\bar{2}\bar{2}$ |
| 38552 | $\bar{1}04\bar{4}2$ |
| 33733 | $\bar{1}04\bar{4}2$ |
| 14457 | $2088\bar{4}$ |
| 1821582 | $2\bar{1}82\bar{4}\bar{2}2$ |
| | or $19816\bar{2}2$ |
| | and 1821582 |

In this instance, the working is evidently easier with the deficient figures, since lower digits are concerned in the multiplication. But it must be observed, that a deficient figure changes the character of all the digits which it multiplies. The restoration of the ordinary figures is better understood from being made, as here, by successive steps.

The same example treated after the method of the Greeks, where each product of the digits is set down separately, without any previous consolidation by *carrying,* will appear far more complex. This process may be conducted either from right to left, or from left to right, since each step is entirely independent of the rest. We have preferred the former mode, because it approaches nearer to the one generally practised.

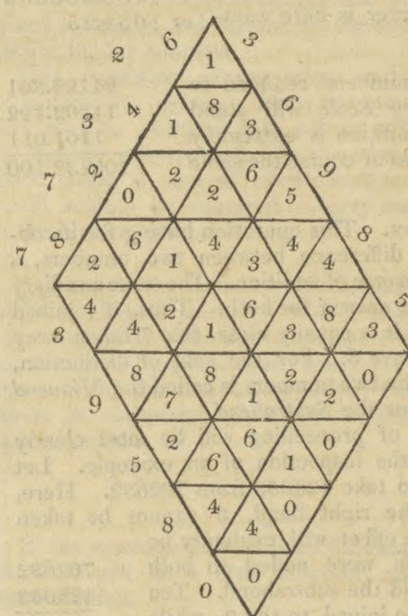
Persian Mode of Multiplication.

The Persians, who probably communicated to the Arabians the knowledge of the Indian numeral characters, but who had likewise carefully studied the astronomy and arithmetic of the Greeks, made a capital step towards the improvement of the ancient mode of calculation. This will be readily understood from an example which we shall borrow from the judicious travels of Sir John Chardin. Suppose it were sought to multiply the number 36985 by 6428. The Persian Arithmeticians, having drawn a rhomboid, would, beginning at the top, write these numbers downwards along the upper sides, and then divide the figure into equilateral triangles, by combining oblique, with horizontal, lines.



```
    36985
     6428
    -----
   18
    36
     54
      48
       40
   12

   24
    48
     72
      64
       40
---------
237739580
```

Now, the multiplication is carried along the rows on the left side of the rhomboid: 6 into 3 gives 18, which is disposed in the uppermost triangle and the one below it; 6 into 6 gives 36, which is deposited in the two next triangles; and the same process is continued through the series. Again, 4 times 3 makes 12, which is placed in the two uppermost triangles of the next row. The rest of the operation of filling the triangles is easily understood. But to collect the products, the figures in each horizontal row, beginning at the bottom, are added up, and the tens carried to the one immediately above it. Thus, the zero at the point of the rhomboid remains unchanged; in the row above this, 4, 4, 0 make 8; in the next row, 2, 6, 6, 1, 0 make 15, and 5 being set

Figurate Arithmetic.

down, the 1 is carried to the higher row, 8, 7, 8, 1, 2, 2, 0, making 29, of which 9 is set down, and 2 carried to the row above it. In this way, the summation is quickly performed, giving 237739580 for the complete product.

To show the advantage of this contrivance, we have exhibited opposite to it the same multiplication after the Greek method. It is easy to perceive, that the straggling figures which there occupy the vertical columns, are precisely the same as those which the Persians, by means of their triangular cells, concentrate in horizontal rows. The oblique direction of the original multiplication might suggest the use of the rhomboid. The process of the Persians requires very little effort or skill; but, as Chardin justly remarks, a European, moderately acquainted with ciphers, would finish the calculation before the Oriental had traced his diagram.

It will be admitted, however, that such artificial helps may prove useful in laborious and protracted multiplications, by sparing the exercise of memory, and preventing the attention from being overstrained. Of this description are the *Rods* or *Bones*, which we owe to the early studies of the great Napier, whose life, devoted to the improvement of the science of calculation, was crowned by the invention of Logarithms, the noblest conquest ever achieved by man. The application of these rods resembles so much the Persian mode of operation, that we are tempted to revert to their construction. The multiplication table being formed into a complete square, and the interior cells parted by diagonal lines running obliquely downwards from right to left, the numbers of each vertical column thus divided are engraved on corresponding slips of ivory or bone, while another slip, called the *index rod*, is marked with the successive digits. Let us resume the former example: The rods, beginning with the several figures of the multiplicand, 36985, are selected and set in the same order, with the index placed before them; then, opposite to the several figures of the multiplier, 6428, on the index, but going backwards, the numbers in each horizontal column are taken, the pair of digits in each rhombus, or double triangle, being always added; and finally, these rows of the products corresponding to each digit of the multiplier, being transcribed and properly disposed, are collected into one sum.

| 1 | 3 | 6 | 9 | 8 | 5 |
|---|---|---|---|---|---|
| 2 | /6 | 1/2 | 1/8 | 1/6 | 1/0 |
| 3 | /9 | 1/8 | 2/7 | 2/4 | 1/5 |
| 4 | 1/2 | 2/4 | 3/6 | 3/2 | 2/0 |
| 5 | 1/5 | 3/0 | 4/5 | 4/0 | 2/5 |
| 6 | 1/8 | 3/6 | 5/4 | 4/8 | 3/0 |
| 7 | 2/1 | 4/2 | 6/3 | 5/6 | 3/5 |
| 8 | 2/4 | 4/8 | 7/2 | 6/4 | 4/0 |
| 9 | 2/7 | 5/4 | 8/1 | 7/2 | 4/5 |

Thus, opposite to 8, the last digit of the multiplier, and proceeding from the right along the horizontal column, there occur these figures: 0, 4, and 4, or 8; 6, and 2, or 8; 7, and 8, or 15; and 1 carried to 4 and 4 makes 9; and lastly, the 2. The other rows are easily formed in the same way. If the horizontal columns opposite to 8, 2, 4, and 6, were supposed to be detached and combined into an oblique group, the similarity to the Persian mode would be very striking.

    73970|2
  147940 |4
 221910  |6
---------
237739580
```

But, without formally adopting either the figurate rods or the rhomboidal cells, it will sometimes be convenient, in very long multiplications, to form, by successive additions, an extemporaneous tablet of the digital products of the multiplicand. The application of this help is easily conceived.

It is evident, from the nature of notation, that, in the descending scale, the products corresponding to each figure of the multiplier, instead of being advanced, should be shifted backwards. Hence the common rule for the multiplication of decimal fractions—to cut off as many decimals as are found in both factors. But, since the remote decimals are of trifling import, a very commodious abbreviation is, to begin the process at the place of units. Passing to the 6 of the multiplier, the last figure 6 of the multiplicand is struck off; but, as it would have given 36, the nearest whole number 4, expressing the tens, is carried to the product of 6 into 3, making 22. The same thing is repeated at each multiplication.

------
 687.4
```

We shall now compare the ordinary method of multiplying numbers with the same process performed by deficient figures. By a little practice, the working with deficient figures would evidently become easier, and more expeditious than the common way.

| | |
|---|---|
| | $4\bar{3}0\bar{2}5$ |
| 36985 | $1\bar{4}43\bar{2}$ |
| 6428 | 86030 |
| 295880 | 129055 |
| 73970 | $15\bar{2}060$ |
| 147940 | $\bar{1}52060$ |
| 221910 | $4\bar{3}0\bar{2}5$ |
| 237739580 | $3\bar{7}8\bar{2}66580$ |
| | or 237739580 |

In farther illustration of the process of multiplication, we shall perform the same examples on the *Duodenary Scale*. It will be convenient, however, though not quite essential, to construct previously a table of products.

MULTIPLICATION TABLE.

*Duodenary Scale.*

| | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | ϕ | ϕ̸ | 1 |
| | 4 | 6 | 8 | ϕ | 10 | 12 | 14 | 16 | 18 | 1ϕ | 2 |
| | | 9 | 10 | 13 | 16 | 19 | 20 | 23 | 26 | 29 | 3 |
| | | | 14 | 18 | 20 | 24 | 28 | 30 | 34 | 38 | 4 |
| | | | | 21 | 26 | 2ϕ̸ | 34 | 39 | 42 | 47 | 5 |
| | | | | | 30 | 36 | 40 | 46 | 50 | 56 | 6 |
| | | | | | | 41 | 48 | 53 | 5ϕ | 65 | 7 |
| | | | | | | | 54 | 60 | 68 | 74 | 8 |
| | | | | | | | | 69 | 76 | 83 | 9 |
| | | | | | | | | | 84 | 92 | ϕ |
| | | | | | | | | | | ϕ01 | ϕ̸ |

Let it be required then to multiply the number 4819 by 378. Transformed into the *Duodenary Scale*, they will stand thus: The same operation is likewise here performed by deficient figures.

```
    2957        3365
     276         356
   -----     -------
    1896      154φ6
  17631     12141
  56φ̸2      9853
  -------   --------
  73φ1φ6    89φ1φ̸6
             73φ1φ6
```

Suppose the large numbers 36985 and 6428 were now converted into the *Duodenary Scale*, their multiplication, in common, and in deficient figures, would proceed in this manner.

```
     194φ1         23521
      3878          4484
   -------      --------
    123288        71884
   1059φ7       129348
  123288        71884
  54263        71884
  --------     ---------
  67750938     758713344
               67750938
```

But this scale is of greater consequence, when viewed in the descending progression, since the duodecimal subdivision has, to a certain extent, obtained currency in the denomination of money, and of weights and measures. A few examples will explain the management of these fractions. Suppose it were sought to multiply L. 6, 15s. 3¾d. by 53, the operation with Duodecimals will be performed thus:

```
     6.923       6.765625
    45.         53.
   --------    ----------
    29.9φ̸3     20.296875
   230.90      338.28125
   --------    ----------
   25φ.6φ̸3    358.578125
```

The product 25φ.6φ̸3 converted again into the *Denary Scale*, gives L. 358, 11s. 6½d. This result is more easily brought out than by Decimals, as appears by the comparison. If the Pound Sterling had been divided into 12 shillings, as the shilling is into 12 pence, the application of Duodecimals to accounts would have been extremely convenient.

Duodecimals are best adapted, however, to mensuration, where feet, inches, and their subordinate parts, enter into play. Thus, if it were required to find the solid contents of a log of timber, 2 feet 7¼ inches square, and 27 feet 5½ inches long. The successive multiplications would be performed in this way, all the figures below the fourth place being excluded, as of little significance. The result is 190 cubic feet, with about 2½ twelfth parts, most inaccurately called, in this case, cubic inches.

```
      2.73
      2.73
     ------
      5.26
      1.629
        799
     -------
      6.9469
     23.56
   ---------
    116.9160
     20.4183
      2.9φφφ̸
       .3483
   ---------
    13φ.2695
```

But these fractions will likewise readily apply to the mensuration of round timber; for the relation of the circle to its circumscribing square, would be expressed in duodecimals by the number .9512. Suppose, for example, a cylinder 4 feet 2¾ in diameter, and 41 feet 10½ long.

The operation is thus performed: Four places of duodecimals only are retained, though in actual practice two places may generally be reckoned more than sufficient. The area of the circular base hence exceeds by a minute fraction 14 square feet, but the solid contents of the cylinder amounts extremely nearly to 700⅔ cubic feet. A similar mode of proceeding could easily be extended to the mensuration of cones and spheres.

```

## Division.

This process, being exactly the reverse of Multiplication, consists in *subtracting* one number repeatedly from another. The former is called the *Divisor*, and the latter the *Dividend*, while the answer, signifying how often the subtraction needs to be made, is termed the *Quotient*. The principle of numerical arrangement suggests the means of abridging this operation. Suppose it were sought to divide 1554 by 37: Let 37 be subtracted in succession from 155, which, standing one place higher than the units, corresponds to tens; the several subtractions are marked by I, II, III, and IV, which belong to the place of tens, and from remainder 7 with 4 annexed to it, the divisor 37 is again subtracted twice. Whence the quotient is 42, or the number of times that 37 is contained in 1554, or must be subtracted before it exhausts this dividend.

```
       1554         74
  I.    37     I.   37
       ---         ---
       118          37
  II.   37     II.  37
       ---         ---
        81           0
  III.  37
       ---
        44
  IV.   37
       ---
         7
```

But such an operation is evidently circuitous. The most obvious improvement is to frame, as in compound multiplication, a small tablet of the digital products of the divisor, and to subtract always the nearest less number from the successive terms of the dividend and the remainder. Let it be required to divide 22028148 by 423. The tablet of products is formed by the successive addition of the divisor 423 and its multiples; of these, the number opposite to 5 comes nearest to the first four terms of the dividend; and the remainder 87, with the next figure annexed to it, is approached the nearest by 846, the next remainder 32 with the annexed 1 is less than the divisor, and, therefore, a zero is put in the quotient to preserve the place, and the following figure 4 is joined. The rest of the operation is easily conceived.

```
  1|  423)22028148(52076
  2|  846  2115
  3| 1269   ----
  4| 1692    878
  5| 2115    846
  6| 2538    ----
  7| 2961    3214
  8| 3384    2961
  9| 3807    ----
              2538
              2538
              ----
                 0
```

This method, however, is more tedious than needful, unless the quotient should consist of several figures. In other cases, a little practice will show how to choose the proper multiples of the divisor. Deficient figures may likewise be sometimes introduced with advantage. An example will explain this: The

Figurate Arithmetic.

dots placed under the figures of the dividend as fast as they are taken down, or annexed for a new division, point out the ranks of the divisor. With the deficient figures, the operation is somewhat easier, though it was unnecessary to make any alteration on the dividend itself.

```
472)1797848(3809      532)18022592(4211
    1416···               1928···
     3818                 1102
     3776                 1064
       4248                1425
       4248                 532
          0                1532
                            532
                              0
```

In the course of working, it will often happen that the product of the divisor, after being written down, will appear greater instead of less than the part of the dividend from which this is to be taken, but without substituting a lower product, the oversight would be rectified by a deficient digit at the next step. Thus, instead of the first two figures 38 of the quotient, we obtain 42, which is equivalent.

Fractions.

But should there be any remainder, it is evident that, by annexing successive ciphers, the division might still be carried on along the descending scale. Hence the process for converting vulgar into decimal fractions. A few examples will elucidate this practice.

```

             52                      567
              80                      730
              78                      729
               20                      *1
               13
               *7
```

In the *first*, a remainder 15, expressed in tenths, hundredths, thousands, &c. is divided by 64, and the quotient .234375 therefore expresses decimally the value of the fraction $\frac{15}{64}$; in the *second* example, it is necessary to annex ciphers before the division begins, and the result .0368 consequently represents the fraction $\frac{23}{625}$.

In both these examples, the operation terminates; but it will oftener happen, in the progress of the division, that the same remainder again emerges, after which the figures in the quotient must evidently maintain a perpetual recurrence. Thus, in the *third* example, the remainders of the division are successively 5, 11, 6, 8, 2, and again 7; from which point the series will recommence. The fraction $\frac{7}{13}$ is therefore, when expanded into decimals, .538461,538461,538461,&c. continued in perpetual circulation. In the *fourth* example, the remainders are 19, 28, 37, 46, 55, 64, 73, and then 1 as at first; here consequently a recurrence takes place, and the value of the fraction $\frac{1}{81}$ is expressed in these circulating decimals .012345679, 012345679, 012345679, &c. In every case, the number of different remainders, and consequently the variety of changes, must obviously be less than the divisor. The last example is extremely remarkable, since it brings out all the digits in their natural succession, except 8. The reason of such a curious result, is that $\frac{1}{81}$, being the square of $\frac{1}{9}$, which, expanded into decimals, is .11111111, &c. will be expressed by this product: The value of the fraction $\frac{1}{81}$, is therefore expressed, by the successive figures 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, &c. continued for ever, through all the descending places of the *Denary Scale*; but, at the junction of every *ten*, the order of the digits is partially disturbed; for the 11 behind the 10 changes it into 11, and this changes the 9 into 10, which again, by its influence, converts the 8 into 9.*

Different Scales of Notation.

Nothing more clearly discloses the properties of numbers, than the transferring of them to different scales of arrangement. Reckoning them, for instance, by successive braces, leashes, warps, &c. they are disposed on the *Binary*, *Ternary*, *Quaternary*, and succeeding scales. This process, requiring only the continued division by *two*, *three*, *four*, &c. is readily performed with figures. To procure greater variety in the results, we shall take a number that is rather large.

Let it be sought to exhibit the number 2138507 on successive scales. Its decomposition will be thus effected:

* The formation of circulating decimals affords a fine illustration of that secret concatenation which binds the succession of physical events, and determines the various though lengthened Cycles of the returning seasons—a principle which the ancient Stoics, and some other Philosophers, have boldly extended to the moral world:

> Alter erit tum Tiphys, et altera quæ vehat Argo
> Delectos heroas: erunt etiam altera bella,
> Atque iterum ad Trojam magnus mittetur Achilles.——See *Monthly Review*, vol. xviii. p. 14—17.

|---|---|
| 178208 | φ |
| 14850 | 8 |
| 1237 | 6 |
| 103 | 1 |
| 8 | 7 |

Hence the same number 2138507 will be thus represented on the different scales:

| | |
|---|---|
| Binary | 1000001010000110001011 |
| Ternary | 11000122110222 |
| Quaternary | 20022012023 |
| Quinary | 1021413012 |
| Senary | 113500255 |
| Septenary | 24114500 |
| Octary | 10120613 |
| Nonary | 4018428 |
| Denary | 2138507 |
| Undenary | 1230768 |
| Duodenary | 87168φ |

The notation may be readily transferred to any higher scale which has, for its index, some power of that of the lower. If the number be distinguished into periods, consisting of two, three, or four places, the amount of these may be condensed into a single figure; and the corresponding index is the second, third, or fourth power of the primary index. Thus, let the expression 10,00,00,10,10,00,01,10,00,10,11 of the *Binary Scale* articulate at every alternate place from the right hand; the value of each period being substituted, or 1 for 01, 2 for 10, and 3 for 11, will transform the whole into this Quaternary arrangement 20022012023. If the same expression be divided into triplets 1,000,001,010,000,110,001,011, and each of these afterwards compressed into a single figure, assuming 1 for 001, 2 for 010, and 4 for 100, it will be changed into the Octary notation 10120613. In like manner, if the representation of the same number on the *Ternary Scale*, 11,00,01,22,11,02,22 be broken at every alternate place, and the values of those periods adopted, 1 being substituted for 01, and 3 for 10, the whole will be converted into the expression of the Nonary Scale, 4018428.

From the principle before investigated, we shall easily find the remainder of the division of the original number, by another number, which is one less than the index of any particular scale. Thus, to begin with the *Ternary Scale*, if the amount of all the figures be divided by two; or, what is the same thing, if every *two* be rejected and the other figures be successively added, retaining only at each step the excess above *two;* and at the end of the operation there will be left *one*. Hence it might be concluded that 2138507 is an odd number; a property indicated also by the character of its last digit. In the *Quaternary Scale*, by adding the figures together, and constantly throwing out the *threes*, there remains *two;* which shows that the division of the original number by *three* would leave *two*. In the *Quinary Scale*, the several figures being collected, omitting the *fours* as they arise, give *three* for the remainder of a division of 2138507 by *four;* which is indeed apparent from the inspection of its two last digits. In the *Senary Scale*, omitting all the *fives*, there is left only *two;* a remainder which might indeed be inferred, from the circumstance that the last digit of the original number was *seven*. In the *Septenary Scale*, collecting the figures, and rejecting the *sixes*, there is an excess of *five;* the same which is left by the division of the original number by *six*. In the *Octary Scale*, when the *sevens* are thrown out, *nothing* remains; which shows that the number was divisible by *seven*. In the *Nonary Scale*, rejecting the *eights*, there is left *three;* but this remainder of the division of the original number by *eight*, might be inferred from the simple inspection of the three last digits 507, since all the rest, being thousands, are evidently divisible by *eight*. In the *Denary Scale*, by adding the figures, and separating the *nines* as fast as they arise, there is still a surplus of *eight;* being the remainder of the division of 2138507 by *nine*. It thus appears, that the common operation of *casting out the nines* is only the application of a general principle to the received system of notation. But to pursue the illustrations,—in the *Undenary Scale*, by casting out the *tens*, there is left *seven* or the digit of the original number, or the remainder of its division by *ten*. Finally, in the *Duodenary Scale*, by rejecting the *elevens* from the collected figures, there remains *eight*, the last figure in the preceding scale, or the residue of the division of the original number by *eleven*. In general, we may perceive the terminating figure of the expression on any scale is the same, as the remainder of the division, by its index, on the next higher scale.

But the quotients of those divisions are, likewise, directly discovered from what was unfolded under Palpable Arithmetic. Not to multiply examples, let us begin with the *Senary Scale*. If the figures

be repeated on all the lower places, their summation will appear thus: The excesses corresponding to the several rows, amount to 22, which leaves 2, and gives 4 to the next column. The sum of this again, with the 4 borrowed, is 21, which contains 6 *three* times, with a remainder of 3. The 3 is then carried to the next column, and the operation repeated; the result is 13100033, which, being transferred from the *Senary* to the *Denary Scale*, gives 427701 for the quotient of the number 2138507 by 5.

| | |
|---|---|
| 1111111 | 1 |
| 111111 | 1 |
| 333333 | 3 |
| 55555 | 5 |
| 22 | 2 |
| 5 | 5 |
| | 5 |
| 1310002 3 | 2 |

The expressions on some of the other scales may be treated more concisely.

OCTARY SCALE.

| | |
|---|---|
| 111111 | 1 |
| 11111 | 1 |
| 2222 | 2 |
| 66 | 6 |
| 1 | 1 |
| | 3 |
| | 0 |
| 1124535 | |

Which, transferred to the *Denary Scale*, gives 305501 for the quotient of the original number by *seven*.

NONARY SCALE.

| | |
|---|---|
| 444444 | 4 |
| 1111 | 1 |
| 888 | 8 |
| 44 | 4 |
| 2 | 2 |
| | 8 |
| 446614 | 3 |

Which, being transferred to the *Denary Scale*, gives 267313 for the quotient of the original number by *eight*.

DENARY SCALE.

| | |
|---|---|
| 222222 | 2 |
| 11111 | 1 |
| 3333 | 3 |
| 888 | 8 |
| 55 | 5 |
| | 7 |
| 237611 | 8 |

Which expresses the quotient of 2138507 by *nine*.

DUODENARY SCALE.

| | |
|---|---|
| 88888 | 8 |
| 7777 | 7 |
| 111 | 1 |
| 66 | 6 |
| 8 | 8 |
| | ⅋ |
| 94609 | 8 |

Which, converted into a Denary expression, is 194409, the quotient of the original number by *eleven*.

But the extension which was made of the same principle to open counters, may be applied to discover the quotient and remainder of any number divided by the index of the next higher scale. Not to dwell on this subject, we shall take only three of the last examples to illustrate the mode of operation. Beginning at the left hand, each figure must be repeated through all the succeeding places, alternately as an excess and a defect, and the balance of addition taken as the result. The same as 720053; which being transformed to the *Denary Scale*, gives 237611, with a remainder of 8 for the quotient of 2138507 by *nine*, the index of the scale augmented by one.

OCTARY SCALE.

| | |
|---|---|
| 111111 | 1 |
| 11111 | 1 |
| 2222 | 2 |
| 62 | 6 |
| 1 | 1 |
| | 3 |
| 1120065 | 8 |

The same as 194409; which is the quotient of the original number by *eleven*, the remainder of the division being 8.

DENARY SCALE.

| | |
|---|---|
| 22222 | 2 |
| 11111 | 1 |
| 3333 | 3 |
| 888 | 8 |
| 55 | 5 |
| | 7 |
| 214411 | 8 |

DUODENARY SCALE.

| | |
|---|---|
| 88888 | 8 |
| 7777 | 7 |
| 111 | 1 |
| 66 | 6 |
| 8 | 8 |
| | ⅋ |
| 81244 | 7 |

This amount is the same as 7⅋244; which, transferred to the *Denary Scale*, makes 164500 for the quotient of the original number by *thirteen*, the remainder of the division being 7.

Casting out Nines, Elevens, &c.

It is of more consequence, however, in such divisions, to discover the remainder than the quotient. If the process be confined to the *Denary Scale*, the number *eleven* will appear to have properties analogous to those of *nine*. But to find the remainder of the division of any number by *eleven*, or, in the vulgar phrase, *to cast out the elevens*, will require attention to the alternate character of the ciphers, fluctuating in succession from excess to defect. The easiest mode is, beginning at the right hand to mark the alternate figures; and, from the amount of these, augmented by eleven, if necessary, take that of the rest, and the difference is the remainder sought. Thus, resuming the original number 2′13′85′07′, the sum of the marked figures is 17, and that of the rest only 9; wherefore, if divided by eleven, it would leave an excess of 8. Again, taking the number 52′90′46′82′, the marked figures together make only 10, while the others amount to 22; the former must consequently be augmented repeatedly by the addition of eleven, till the sum 32 comes to exceed 22. The remainder of this division would therefore be 10.

It hence follows, that, as a number is divided by *nine* when the amount of its figures is any multiple of *nine;* so a number is divisible by *eleven*, when the sums of the alternate figures are either equal or differ by *eleven* or its multiples. This proposition leads to some curious results; but we shall notice only the more striking and simple. It is an obvious consequence, that the *difference* between any number and its reverse is divisible by *nine:* Thus, the number 2138507 being reversed into 7058312, gives the difference 4919805, divisible by 9. The reason is plain, since this number and its reverse are expressed by identical figures, they are both multiples of 9 with the same excess, and consequently their difference must only be some multiple of 9. Again, the *difference* between a number and its reverse is likewise divisible by *eleven*, if it consists of odd figures: Thus, the last difference 4′91′98′05′ is divisible by 11, for the sums of the alternate figures are each 18. But the *sum* of a number and its reverse is divisible by *eleven* when it consists of even figures. Thus, the number 52904682 has 28640925 for its reverse,

and their sum is 81′54′56′07′; which is evidently divisible by 11, for each set of alternate figures amounts to 18. It is not difficult to perceive the reason of these properties of *eleven;* when the number consists of odd figures, they preserve the same character of abundant or defective in its reverse, and consequently the subtraction of the opposite numbers will destroy whatever inequality there had before existed; but when the number proposed consists of even figures, the abundant and defective by reverting change mutual places, and hence the sum of the number and its reverse will extinguish any original inequality between these, balancing any surplus of the one set by the equal deficiency of the other. Thus, in the first example, the number 2′13′85′07′ exceeds by 8 a multiple of 11, and so does its reverse 7′05′83′12′, the marked figures being the same in both; consequently their *difference* is a multiple of 11. In the second example, the number 52′90′46′82′, is greater than a multiple of 11 by 10, and its reverse 28′64′09′25′ is greater than another multiple of 11 by 1, or is less than the next lower multiple by 10: Wherefore these opposite numbers added together will produce a mutual balance accurately divisible by 11.

The *casting out* of the nines and elevens, furnishes a ready, though but a negative proof of the accuracy of arithmetical operations. In addition, for instance, by casting the nines or elevens out of each number, and collecting those excesses, the result of another ejection should be the same as from the sum. This principle applies equally to subtraction; but the mode of proceeding in multiplication and division will require some investigation. By casting the nines out of a number, it is converted into the *Nonary Scale*, of which the excess would occupy the place of units; if another number, therefore, were treated in the same way, and their product represented on that scale, that part of it formed by multiplying the excesses would still retain the rank of units, and exhibit the remainder of the division by nine. The same principle, it is obvious, will extend to the casting out of eleven.

Thus, in the first example of compound multiplication, the nines, being cast out of the multiplier, and multiplicand, 472 and 3809, leave 4 and 2, which produce 8, the remainder of the division of the product 1797848 by 9. In like manner, on casting eleven out of the former numbers, there are left 10 and 3, which being multiplied yield 30, or an excess of 8; but the product 1797848 divided, by 11, leaves also 8. Again in the next example, if nine be cast out of the multiplier and multiplicand, 6428 and 36985, there remains 2 and 4 as formerly, and their product 8 is excess of 237739580 above the nearest multiple of nine. With eleven likewise the remainders are 4 and 3, whose product 12 gives an excess of 1 for the remainder of the division of the result by eleven.

In the *Duodenary Scale*, the corresponding property must belong to the numbers *eleven* and *thirteen*. Thus, in the first example, *casting the elevens* out of 276 and 2957, the excesses are 4, and 1; but their product 73ɸ1ɸ6 being divided by *eleven*, leaves 4. *Casting thirteen* out of the same factors, there remain 1 and 9, and the product, divided by *thirteen*, leaves 9. Again, the second example, *casting out the elevens* from 3878 and 194ɸ1, there are left 4 and 3; which being multiplied give 12, or 1 for the excess of the product 67′75′09′38 above the nearest multiple of *eleven;* but *casting thirteen* out of the same numbers, the remainders are 6 and 9, which give 54 or 10 for the excess of the product.—The agreement in these examples affords a strong presumption of the correctness of the operations; as any discordance would be an absolute proof of inaccuracy.

Transferring of Scales.

To transfer any numeral expression from one scale to another, the most obvious way, is, to decompound it and then dispose it again on the new scale. Suppose it were required to convert the binary expression 1000011001 into another on the *Quinary Scale.*

Beginning at the left hand, and constantly doubling the terms, shifting them every time a place lower, the successive results are 2, 4, 8, 16, 33, 67, 134, 268 and 537. This number again, if decomposed by a series of *pentads*, gives 4122 for its *Quinary* expression. But the conversion might be performed directly with more expedition, by dividing the original expression successively by the root of the new scale.

```
5)537
  107 2
   21 2
    4 1
```

The operation would be conducted thus:

BINARY SCALE.

```
101(           101)        101)   101)100
   )1000011001(1101011(10101(
    101         101        101
    110          110       001
     101         101
      111         111
      101         101
       1000        10
        101
         111
         101
          10
```

The divisor 5 being denoted on the *Binary Scale* by 101, the repeated analysis is pursued on the same scale; the series of inverted remainders is 100, 1, 10, and 10, giving, as before, the final result 4122 on the *Quinary Scale.*

Let it be sought to convert this last expression to the *Ternary Scale*, the division will be performed in this manner:

```
3)4122
  1204 0
   214 2
    34 2
    11 1
     2 0
```

The Ternary expression is hence 201220.

To reduce vulgar fractions to any scale, we have only to multiply the numerator by the root of that scale, and to divide the product by the denominator, and to repeat this process till it either terminates or glides into a circulation. The series of quotients exhibits the value developed on the descending bars. But this decomposition has been already anticipated.

Figurate Arithmetic.

The same method applies likewise to the conversion of mixed fractions. Suppose it were sought to express fifteen shillings and three pence three farthings on the *Denary Scale* of pounds. Multiply this sum repeatedly by ten, and the integral results deferred to the lower bars, must evidently express the same value. The corresponding decimal is hence .765625, as formerly employed.

```
      15   3¾
           10
L.7   13   1½
           10
L.6   11   3
           10
L.5   12   6
           10
   L.6     5
           10
   L.2    10
          10
     L.5
```

This example, however, is better adapted to the *Duodenary Scale*, the multiplication being performed by successive twelves. The duodecimal expression for the same sum is therefore .923, consisting of only three figures.

```
      15   3½
           12
L.9   3    9
           12
   L.2     5
           12
     L.3
```

These reductions might be performed differently, by ascending gradually to the higher denominations; the farthings being changed into parts of a penny, the pence into parts of a shilling, and the shillings into parts of a pound.

DENARY.

```
4)3      12)3.75      20)15.3125

To transfer the expression of a fraction from one scale to another, it should be multiplied successively by the root of this, and the integral results retained. Thus, to convert the decimal fraction 7854, which expresses the relation of the circle to its circumscribing square, to the *Duodenary Scale*: Multiplying the whole by twelve, the product would represent on the next bar of this scale the same value; again, the fractional surplus .4248 being multiplied by twelve, gives another residue for a lower bar; and this process being continued, the fraction proposed is at last changed into the duodecimal .9512, being the number already employed in the mensuration of circular timber.

Again, suppose it were required to transfer the expression .2132032, from the *Quaternary* to the *Ternary Scale*: This operation will be performed by continually multiplying the fractional part by three, and retaining only the integral results. The value of the expression is, therefore, on the *Ternary Scale*, denoted by .12121122, &c.

Figurate Arithmetic.

Extraction of Square Root.

The finding of roots is a branch of Arithmetic, to which the system of numerical arrangement is well adapted. The method of proceeding here, is to approach by successive steps to the final result, descending from the highest to the lowest point of the given scale, by discovering the series of additions required to complete the number sought. The extraction of the square root, is the easiest and the most important. To investigate the principle which should direct this operation, we must examine what takes place in the process of compound multiplication. If a number composed of two parts be multiplied into itself, the result will evidently consist of the squares of those parts, together with twice their mutual product. Now, taking away the square of one of these parts, suppose the greater, there must remain the square of the other, joined to their double product; or, what is the same thing, this residue will be the product of the smaller into a number formed by annexing it to double the greater. Consequently, to discover the secondary or additive portion of the root, we have only, after the square of the principal part has been separated, to divide what is left, by twice its root, annexing always the quotient to this divisor, in closing the process of division. The same operation, descending successively to lower terms, must be repeated, till the number proposed for extraction be entirely exhausted. It is only requisite to observe the rank and number of the figures which the root should contain. But, for this purpose, since every compound number will evidently by squaring have its places of figures doubled, we need only distinguish each pair in the number whose root is sought.

An example will best explain the whole procedure. Suppose it were required to find the square root of 107584. Beginning at the right hand, and marking every second figure, it is divided into three periods; which shows that the root must consist of hundreds, tens, and units. To the first period 10, the nearest square is 9, whose root 3 must occupy the place of hundreds. Subtracting and taking down the next period, the residue 175 comes to be decomposed; doubling, therefore, the root, we have 6 in the place of hundreds, to which the quotient 2, as denoting *twenty*, is annexed, and the product 124 set down for subtraction. The remainder, with the last period, making 5184, is finally to be analysed. Twice the root already found, amounting to 640, with the quotient 8 itself, forms the new divisor, and the product extinguishes what was left of the proposed number. The root is therefore 300, with the successive additions of 20 and of 8.

The same mode of proceeding will obviously extend to the descending terms of any scale, a pair of zeros being annexed to the remainder after each successive division. As an example, we shall select the calculation of the greater segment of a line, divided by extreme and mean ratio, which is denoted by $\sqrt{\frac{5}{4}}-\frac{1}{2}$, the whole being unit. The radical is thus found on three different scales.

It hence appears, that the greater segment of a line, divided by extreme and mean ratio, is expressed in duodecimals by .74φφφ7, or extremely nearly by .75; and, therefore, that it consists of 89 parts, of which the whole contains 144. The very same result is obtained from the recurring series, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, &c. which continually approximates to the required value.

The main advantage of this scale, consists in its fitness to denote fractional parts. Its root has indeed no fewer than four factors — 2, 3, 4, and 6; while *ten* is divisible only by 2 and 5. Several attempts, accordingly, have, at different times, been made to carry the *Duodenary Scale* into actual practice. It is a singular fact, that the famous Charles XII. of Sweden, whose views, though often disturbed by the wildness of heroism, were on the whole beneficent, seriously deliberated on a scheme of introducing this system of numeration into his dominions, a very short time before his death, while lying in the trenches, during the depth of winter, before the towering Norwegian fortress of Fredrickshall.

With respect to square numbers, it may be remarked, that they terminate only in these five digits,—1, 4, 5, 6, and 9,—which lie equally distant on each side of the middle. When a number ends in 1, its square root must end in 1 or 9; when it ends in 4, the root ends 2 or 8; when it ends in 5, the root will likewise end in 5; when it ends in 6, the root will end in 4 or 6; and when it ends in 9, the root will end in 3 or 7. Unless, therefore, in the case of 5, there are always two corresponding terminations of the root, making together the number *ten*.

Cube numbers, or those denoting the third powers, and produced by a triple multiplication, are not affected by such ambiguity. They have for their terminations indiscriminately all the nine digits. If any cube should terminate in one of the fore-mentioned figures, 1, 4, 5, 6, or 9, its root will end in the same figure; but if it terminate in any of the remaining digits, 2, 3, 7, or 8, the corresponding root will end in 8, 7, 3, or 2, that is, in the difference of each from *ten*.

But we have already far exceeded our limits, and must abruptly conclude. Still we should commemorate, though not in the proper place, one of the earliest and ablest writers in England on Arithmetical Science;—Robert Recorde, Fellow of all Souls, Oxford, and Doctor in Physic, published in 1540 a treatise of Arithmetic, in the form of a dialogue. * He afterwards proceeded farther; and, in his *Whetstone of Witte, containing the Extraction of Rootes and Cosike practise*, he introduced the first rudiments of Algebra. But this benefactor of his country, who seems to have devoted himself to the teaching of Mathematics in London, was treated with ingratitude, and, to the disgrace of the age, left to struggle with chilling poverty, and constrained to end his days in the gloom of a prison. (D.)

---

* We subjoin another specimen of the Roman or Saxon numerals till then used: In the accounts of the Scottish Exchequer for the year 1331, the sum of L.6896, 5s. 5d. stated as paid to the King of England, is thus marked, vj$^{m}$. $\overset{c}{\text{viij}}$. $\overset{xx}{\text{iiij}}$. xvj. ŧj. v. š. v. đ. It may be observed, that, in Scotland, the contraction ʒ$^{m}$ for *one thousand*, is still used in the dates of charters, and other legal instruments.

Armagh.

Extent and Boundaries.

ARMAGH is an inland County in Ireland, in the Province of Ulster; it is bounded by the waters of Lough Neagh on the north; by the Counties of Monaghan and Tyrone on the west; by the County of Lowth on the south; and by the County Down on the east. Its figure is that of an irregular oblong; its length, from its northern to its southern extremity, is about 32 English miles; and its breadth, nearly 20 miles. Its area comprises 290,786 acres, or about 454 square English miles. It is divided into five Baronies, and comprises 20 Parishes. The principal Towns are, Armagh, Charlemont, Market-hill, Blackbank, Jonesborough, and Portadown.

Archbishoprics.

Armagh is the metropolitan see of Ireland. The Province of the Archbishop is the largest in the Island, containing ten Dioceses, viz. the Archbishopric of Armagh, and the Bishoprics of Dromore, Down and Connor united, Derry, Raphoe, Clogher, Kilmore, Ardhagh (which, though in this Province, is at present annexed to the Archbishopric of Tuam), and Meath. The Archbishopric extends into five Counties, viz. Armagh, Londonderry, Lowth, Meath, and Tyrone, being 59 miles from north to south, and varying in breadth from 10 to 25 miles. Its annual value is about L. 8000.

Face of the Country.

The face of the country is in general interesting; but in the southern part there is a chain of black and nearly uncultivated mountains called the Fews, thinly inhabited. On the borders of Newry-water, there is also a small range called the Fathom and Newry mountains. Near the banks of Lough Neagh, and along the rivers, the country becomes beautifully champaign, though even here there are extensive mosses. The soil of these mosses is remarkably black, and extends to a great depth.

Rivers.

There are several small streams which rise in the interior of this County, most of which fall into the rivers which wash its confines. The Blackwater, which continues the navigation of the coal canal to Lough Neagh, and divides this County from Tyrone, is enlarged on its entrance into Armagh, by the waters of the Tynan, Tall, and Callen. The Cushier, which rises in the interior, and the Camlough, which issues from Lake Camlough, supply the Newry canal on the eastern boundary of Armagh. In the southern part of the County, the Tara, Newlin, Hamilton, and Fleury waters rise, which, after various windings, enter Lowth County, and fall into the bay of Dundalk. The principal lakes are Lough Neagh, Camlough, and Lough Clay.

Lough Neagh.

Lough Neagh covers a great area in the Province of Ulster, washing parts of the Counties of Antrim, Armagh, Down, Londonderry, and Tyrone. Its extent, however, is ascertained by actual survey, not to be much more than one half of what it was formerly conjectured to be. It is 15 miles in length, and 7 in breadth, and covers 58,200 acres. Seven rivers, and a very great number of smaller streams, run into it, whereas the Ban is the only outlet for its waters. It is by no means a beautiful lake; its banks, for the most part, being low and marshy, and incapable of being drained; and, where bold and abrupt, entirely destitute of wood. There are but two Islands in it: Ram Island, already mentioned in the article Antrim; and another near the shore, in the south-western angle of the lake, called Blackwater Island. A great variety of fish are found in Lough Neagh: salmon, a large kind of trout, bream, perch, and the pollen, which is the same as the *ferra* of the Lake of Geneva, and the *gwyniad* of Bala Lake in North Wales. On some parts of the Antrim shore, its waters possess a petrifying quality, arising either from the water itself, or more probably from some parts of the soil dissolved in the water.

Minerals.

Marble of an excellent quality, and of great beauty, is wrought in Armagh. Its other mineral productions are neither numerous nor important. There are some lead mines, the property of the Earl of Feversham; but they are not at present wrought. In the abrupt stratified banks of the Callen, there are indications of lead, manganese, and other minerals. The lime strata in the vicinity of Armagh approach to what is called *plum-pudding stone*.

Climate.

The climate is mild, considering the latitude, except in the mountainous parts. The mean temperature, in the neighbourhood of the town of Armagh, about 25 miles from the Irish Channel, and elevated about 58 feet above the sea, ascertained by means of a well 6 feet deep, was $47^{0}$ 5.

Landed Property.

Estates in this County are not large; there being only seven or eight proprietors who possess them of the annual value of from L. 6000 to L. 10,000. The farms also are small, being commonly from 5 to 20 acres, and seldom exceeding 40 or 50. From the return of registered freeholds in Ireland, it appears that, in March 1815, there were, in this County, 6053 persons who possessed freeholds of the value of 40s. 120 who possessed freeholds of the value of L. 20, and 144 who possessed freeholds of the value of L. 50.

Agriculture.

Neither the arable nor the pasture husbandry of this County present much that is worthy of notice. Potatoes, flax, and oats, are the chief produce of the arable districts; and those are cultivated in a very rude and inferior manner, in consequence of the ignorance of the farmers, and their want of capital. The quantity of seed used, and the average crop, are nearly the same as those stated in our account of the agriculture of Antrim. But there is a much larger proportion of land under flax in this County; for, in the year 1809, there were 15,000 acres sown with it in Armagh, while there were only 11,000 acres in Antrim. A few acres of hemp were also sown.

Cattle and Sheep.

There are no extensive dairy-farms in Armagh, nor are there any farmers exclusively in this branch of husbandry; nevertheless a considerable quantity of butter is made here. One hundred weight per cow is considered as the average produce. The proportion of milch cows to the size of the farms, is, on small farms under five acres, one cow; on farms exceeding five, and under ten acres, perhaps two cows, seldom more. A considerable number of cattle are reared. From the low country they are sent to the mountain farms, and frequently afterwards sold in the Scotch market. They are in general of a small stunted breed. The native sheep are an awkward breed; the wool coarse, and in small quantity; very little of it is exposed to sale, there being hardly sufficient for domestic use. Goats, swine, and poultry abound. Wild geese, swans, wild ducks, and several

Armagh.

other species of aquatic birds, are indigenous to the lakes and rivers. Formerly bees were much attended to, but at present they are neglected.

Roads.

The roads in general are bad; and, what is extraordinary, the turnpikes are the worst, and the cross roads the best. A canal has been cut from Coal Island to Armagh, but it is little used.

Manufactures.

The principal manufacture is that of linen, which forms the chief employment of the inhabitants; and the annual average value of which is estimated at L. 300,000. This manufacture is very extensively carried on in the vicinity of the city of Armagh. Bleachfields are numerous on the banks of the Callen. Woollen goods are made only for home consumption.

This County returns two representatives to the Imperial Parliament; and the city of Armagh one. It is in the north-east Circuit; the Assizes are generally held in the middle of July.

Population.

The mountainous parts of Armagh are entirely inhabited by Roman Catholics; and it is estimated, that one half of the inhabitants in the other parts are of the same persuasion: so that the Protestants cannot constitute more than one third of the population. Of the other dissenters from the established religion, the Presbyterians and Burghers are the most numerous.

The number of houses, according to the last returns, is 22,900: of which 18,794 have only one hearth; 784 two hearths; 217 three hearths; 105 four hearths; 75 five hearths; 31 six hearths; 28 seven hearths; 21 eight hearths; 15 nine hearths; 8 ten hearths; and 23 more than ten; and four of them forty-four hearths. The population, reckoning $5\frac{1}{2}$ inhabitants to a house, will be about 130,000; which gives 78 people to an Irish square mile. There are rather more than eight Irish acres to a house.

Customs.

In some districts of this County, hunting is a favourite amusement with the weavers; the hounds are not kept in packs, but distributed over the County, one being generally kept in each cabin. On the day appointed for the chace, the looms are deserted. In a County where the land in general is parcelled out into such small divisions, it would not be practicable for the gentlemen to pursue this diversion on horseback; and therefore the game is relinquished to the weavers. The dog they employ on these occasions is a dwarf fox-hound, in a degree similar, either to the English beagle, or the southern slow-hound, still used in the hilly districts of Sussex and Kent. The farmers of Armagh are noted for their fondness for jockeying, in all the arts and tricks of which they are expert to a very criminal degree.

School of Armagh.

The school in the city of Armagh is one of the royal foundations of Charles I., and is very well endowed; for, according to the report of the *Commissioners of the Board of Education*, the lands which belong to it contain 1530 acres, English measure, besides about 100 acres of bog. They are situate in the County, between the towns of Newry and Armagh. In the year 1804 the gross annual rent was L.1144, 10s. $5\frac{1}{2}$d. There are generally upwards of 100 boys educated at it. The school-house was built by Lord Rokeby, better known by the name of Primate Robinson.

Armagh ‖ Arreoys.

The County of Armagh is celebrated both in civil and religious antiquity. In the early annals of Irish history, it is mentioned as the seat of their monarchs. Turgesnis, the first Norwegian Prince that obtained a footing in this kingdom, established his capital here. A tribe of Danes, called Ostmen, for a considerable time afterwards, formed the chief inhabitants of the County. Most of the present inhabitants are descended from the Scotch. See Wakefield's *Ireland*. Barton's *Natural History of Lough Neagh*. *Statistical Survey of Armagh*, by Sir Charles Coote. (c.)

ARMY. See the *Encyclopædia* under that head, and Tactics in this Supplement.

ARNAUD DE RONSIL (George), son of an eminent surgeon, at Paris, and some time Professor of surgery in the College of St Côsme. On account of an accident that occurred while he was practising midwifery, he removed from Paris to London, where he acquired great repute by his operations, and his writings on surgical subjects. Before his time, the treatment of *hernia* had been but imperfectly understood; and the surgeons of this country are indebted to the observations of Arnaud for many of those improvements which have since rendered their practice so successful in this branch of the art. The following is a list of his principal works: 1. *Traité des Hernies ou Descentes*, 2 vols. 12mo. Paris, 1749. 2. *Observations on Aneurysms.* London, 1750. 3. *Instructions on the Diseases of the Bladder and Urethra.* London, 1763. 4. *A Dissertation on Hermaphrodites.* London, 1750. These were afterwards collected, and published, with additions, under the title of *Mémoires de Chirurgie, avec quelques Rémarques sur l'etat de la Medicine, et de la Chirurgie en France, et en Angleterre*, 2 vols. 4to. London, 1768. 5. *Remarks on the Use of the Extract of Lead of Goulard.* London, 1776. Arnaud died in 1774. (E.)

ARRAN. See Arran in the *Encyclopædia*, and Buteshire in this Supplement.

ARREOYS. Among the more singular Secret Societies which mankind have formed, is one in Otaheite and the neighbouring Islands, for the destruction of their own species, called *Arreoy, Arehoe, or Earowie;* and it is not a little remarkable, that it should subsist among tribes distinguished for courteousness and humanity. We read in the older authors, that there is an absolute prohibition against the females of Formosa rearing children before the age of thirty-six, though it does not appear that there is any limitation as to the age at which their espousals may take place. But, in the event of pregnancy, it is necessary that abortion should follow, which is accomplished by the aid of the Priestesses of the Island. Among the Arreoys, however, extirpation of the infant being constitutes the leading feature of their ordinances.

Whether Mendana, Quiros, and the earlier navigators of the South Pacific Ocean, discovered this society, does not appear; it has, at any rate, been reserved for those of later date to unfold its principles and peculiarities; though, indeed, its constitution is still enveloped in much mystery, the members being bound to the strictest secrecy.

Arreoys. The society of Arreoys consists of hundreds or perhaps thousands of both sexes, who engage to destroy their own offspring at the moment of birth. It is chiefly composed of persons distinguished by valour and merit, and hence, one or more individuals of each family of the chiefs are of the number. It has been remarked, that all the men profess themselves warriors, and are in general stout and well made; that the greatest trust and confidence are reposed in them; and it rather appears, that the women consist of the higher ranks only. There are different gradations in this community, which are to be recognised from the mode of tattooing; the more profusely the men are tattooed, the higher is their rank in the society; the first are called *Ava bly areema tutowe; 2. Areema bly; 3. Ahowhoa; 4. Harrotea; 5. Eote ole;* 6. 7. *Po;* and youths training up are designed *Mo;* but the meaning of these names is not explained. By the fundamental laws of the society, the offspring must be destroyed; yet it is not known with certainty by whom or in what particular manner; the murder is always perpetrated in secret, probably by strangulation; all the attendants are excluded; for it is said, were they to witness it, they would be adjudged guilty of participation, and themselves be put to death. Sometimes the mother, animated by natural affection, tries to preserve her infant, and resists the persuasions of her husband, and his brother Arreoys, who wish to consign it to destruction. But in general the enormity of the crime does not appal the females, though they are described to be affectionate and tender. We find a dancing girl pregnant by an Arreoy, expressing herself thus to the English navigators: "Perhaps the *Etooa* or deity of England, might be offended with the practices of the Arreoys, but her own was not displeased with it. However, she promised, if we would come from England for her child, she might perhaps keep it alive, provided we gave her a hatchet, a shirt, and some red feathers." That the rules of the community are very strict, may be inferred from an instance given by Captain Bligh. A chief, a member of the society, married a sister of the king of Otaheite, by whom he had eight children, and the whole were destroyed at their birth! Nor did this enormity seem to originate from any other source, as the parents afterwards adopted a nephew as their heir.

It may here be observed, that there are other practices among these people regarding infanticide, which, though we want materials for positively affirming the fact, may perhaps be connected with the institutions of the Arreoys. When an Otaheitan chief has a child by a woman of the lower orders, it is never suffered to live, and the like seems to take place reciprocally among the higher ranks of females. The King and Queen of Otaheite having ceased to cohabit, he had taken another wife, and she associated with one of her attendants of low rank. When pregnant, the missionaries endeavoured to persuade her to spare her child, which she said she would have done, had it been her husband's, but now it would be base born, and must perish; and she resisted all entreaties to the contrary. Afterwards, having visited them, she excused herself for having put the infant to death; stating that it was the custom of the country to murder all base-born children, and hers being by a low man, she had only complied with the usual practice. Indeed, it is affirmed by the Missionaries who visited that Island in 1797, to be a common proceeding among all ranks, to strangle infants the moment they are born. "A perpetrator of this horrid act," the narrator observes, "was among those whom curiosity attracted to visit us. She was a good-looking woman, and esteemed by the natives a great beauty, which I suppose to be the inducement that tempted her to murder her child; for here the number of women bearing no proportion to the men, those esteemed handsome were courted with great gifts, and got so accustomed to change their husbands, to go with them from place to place, and run after the diversions of the Island, that rather than be debarred those pleasures, they stifle a parent's feelings, and murder their tender children." Thus many hundreds born into the world are never suffered to see the light; and so little criminality in the opinion of the natives is attached to the deed, that many women disclose the number they have put to death, without scruple. It has been calculated, that at least two-thirds of the births on the Island perish in this manner.

Arreoys. The Arreoys enjoy great privileges, and are everywhere united by the reciprocal ties of friendship and hospitality. When they visit different Islands, they receive presents, and are entertained with feasting and dramatic exhibitions; and all this they seem to expect rather as a matter of right than of courtesy. Their clothes are of the finest materials. They pass their time in luxurious idleness, perfuming their hair with fragrant oils, singing and playing on the flute, and passing from one amusement to another. "Wherever they go," says Forster, "the train of sensual pleasure awaits them." They feast on the choicest vegetables; and an abundance of dogs flesh and poultry are liberally provided by the lower classes for their entertainment. They are copiously supplied with *kava,* and for them are performed nocturnal sports of music and lascivious dances, to which no other spectators are admitted. Their presence seems to enliven the whole country; and among the various entertainments to which it gives birth, is one called *hopowpah,* of a dramatic nature, in which they themselves act a part. As soon as one Arreoy visits another, though a stranger, he immediately has his wants supplied and his wishes gratified; he is introduced to other members, who vie with each other in loading him with courtesies and presents. They are of all others the most luxurious and profuse, often consuming the whole provisions of a district. When Captain Cook lay at Huaheine, no less than 70 canoes were observed crossing over to another Island, with 700 Arreoys on board; and thus they keep great meetings at appointed times, and travel in companies from one Island to another. It has been affirmed, but perhaps without sufficient foundation, that a promiscuous inter-

Arreoys. course of the sexes prevails in their society; however, they are permitted great latitude in their amours, except in times of danger, as almost all are fighting men. Sufficient inducements are therefore held out to be admitted into this mysterious community.

Any one may withdraw at pleasure from the society; and an example is given of a chief who had killed his first-born child, but preserved the second, having withdrawn in the interval. A woman who ceases to be an Arreoy, incurs a reproachful name, signifying "bearer of children." Thus, while in most other countries the name of parent confers honour and respect; among the Arreoys of Otaheite, it is used as a term of contempt and reproach. A Chief of some repute, hearing that the King of Great Britain had a numerous offspring, he declared that "he thought himself a much greater man, because he belonged to the Arreoys."

With respect to the origin of this society, Forster was the first to offer any conjectures. "In a country," says he, "which has emerged so lately from barbarism as Otaheite, we cannot suppose that such a community, which is evidently injurious to the rest of the nation, would have maintained itself to the present time, were not its advantages so considerable as to require its continuance." There are two causes, he adds, which favour the existence of the Arreoys: first, the necessity for entertaining a body of warriors, to defend their fellow-citizens from the invasions and depredations of enemies. Secondly, it was necessary by such an association to prevent the too rapid increase of the number of their chiefs. "Perhaps," he remarks, "some intelligent Otaheitan lawgiver might foresee, that the common people would at length groan under the yoke of such petty tyrants, whose number was ever multiplying." The ordinary practice of infanticide is ascribed by Mr Wilson, who visited the South Seas in 1801, merely to the love of pleasure and avarice, which latter passion had gained great ascendancy since the intercourse of the Islanders with Europeans; "being well aware," says he, "that the beauty of females rearing families experiences an earlier decay, it is anxiously preserved for their visitors, by destruction of their offspring, or even by procuring abortion." Before offering any opinion on this point, we shall notice a custom in the North West of India, somewhat analogous, which also is attended with mystery.

Amongst certain tribes called Jarejahs, which are more particularly disseminated in the peninsula of Guzarat, the whole females are devoted to death at the moment of their birth. But this is in consequence of general custom, not of any special association. The immediate death of a daughter is viewed as the inevitable consequence of its birth; and the innocent beings falling a sacrifice to this barbarous ordinance, yearly amount to many thousands. When a woman is delivered of a daughter, the event is communicated to the father by the female attendants, who desires them to do as is customary; an injunction said to be followed by the mother applying a little opium on the nipple of her breast, which is sucked in by the child. More usually it is strangled by herself, or drowned in a basin of milk; but women of rank, who have attendants, never perform the office themselves. However, from the mystery observed, it is, as among the Arreoys, difficult to obtain correct information. In some districts, any of the female attendants may put the infant to death; in others, a kind of domestic Priest becomes the executioner; and the infant being placed naked in a small basket, it is carried out to be interred, for which he receives a trifling fee. Among the Arreoys, those who preserve their children seem to suffer a degree of degradation, and they plead as an apology for their destruction, that it is necessary to preserve the privileges of their tribe. With the Jarejahs, the father is obeyed on signifying his desire for preservation; but if he continue silent on receiving the intelligence, the usual custom must be complied with. The mother is generally averse to the sacrifice, but her scruples to preserve her offspring are seldom attended to; should a short interval elapse, however, before the bloody deed is done, it then becomes unlawful, and the child must be spared.

In India, it is said that mothers who had been long barren, offered their first born as a sacrifice to the gods, either by leaving it in the woods to be devoured by beasts of prey, or by throwing it into a river. But, in progress of time, a commutation took place, by devoting the victim to the service of some temple, from which it might be redeemed. The ancients were profuse of human blood to gratify their Deities, and even without the particular cause just alluded to, children were especially doomed to be offered in sacrifice. In times of public calamity, an only child was deemed the most acceptable sacrifice: as being more precious to its parents, its death was supposed of greater efficacy in purchasing expiation. "And when the king of Moab saw that the battle was too hot for him, he took with him seven hundred men that drew swords, to break through even unto the king of Edom; but they could not. Then he took his eldest son, that should have reigned in his stead, and offered him for a burnt offering upon the wall." Nothing can be more precise than this passage of Scripture, as to the fact of a parent sacrificing his eldest child, in case of a grievous extremity; and there is also another passage, though more obscurely expressed, to the same purport, where the offering is in atonement. "Wherewith shall I come before the Lord, and bow myself before the High God? Shall I come before him with burnt offerings, with calves of a year old? Will the Lord be pleased with thousands of rams, or with ten thousands of rivers of oil? Shall I give my first born for my transgression, the fruit of my body for the sin of my soul?" The barbarities which have been inflicted by mankind to allay their superstitious fears, seem to have no bounds or limitation. It is horrible to reflect, that the most painful death which the mind can figure, burning alive, has been alike the sacrifice of the moderns for erroneous religious tenets, and of the ancients to gain the favour, or to avert the wrath of their Deities. The *Moloch* of the Phenicians, the *Kronus* of the

Arreoys.

Greeks, the *Kali* of the Hindoos, were all sanguinary Deities. Children sacrificed to the two former, were precipitated into the arms of an idol, heated red-hot in a furnace; and thence, by a particular mechanism, fell into the fire. Hamilcar, on receiving sinister intelligence, attended with alarming circumstances, immediately seized on a boy, and sacrificed him to *Kronus*. On another occasion, the enemy being at the gates of Carthage, two hundred children of the first citizens were offered as a public sacrifice to avert the danger. "Yea, they sacrificed their sons and their daughters unto devils, and shed innocent blood, even the blood of their sons and daughters, whom they sacrificed unto the idols of Canaan, and the land was polluted with blood." But farther, we are told, that the mother herself, who offered her child in sacrifice, never uttered a sigh, lest its efficacy might be impaired; and while this innocent blood was flowing from hundreds of victims, their screams were drowned in the noise of clarions and tabors, provided by the priests for the ceremony. "Tell me," says Plutarch, "were the monsters of old, the Typhons, and the Giants, to expel the Gods, and rule the world in their place, would they exact a duty more horrid than such infernal rites?"

Perhaps, therefore, the murderous practices of the Arreoys in the South Sea Islands, may have originated in some religious principle. At the same time, it appears, that, in the ordinary destruction of infants by the Islanders of the South Pacific Ocean, there is nothing of a sacrificial nature; for, though they do not suppose that their displeasure is thereby incurred, they do not pretend that the practice is acceptable to any of their Divinities. Mr Malthus, we may add, ascribes the origin of the Arreoy institutions to a superabundance of population, and the necessity of adopting some forcible expedients to bring it within the limits of subsistence. Of late years, much exertion has been made by the Missionaries to root out this sanguinary practice, but hitherto without producing any material effect. See Forster's *Voyage*, Vol. II.—Cook's *First and Second Voyage*.—Bligh's *Voyage*.—*Missionary Voyage*.—Hamilton's *Account of the Loss of the Pandora*. (s.)

# ARTS, FINE.

Objects of the Article.

In the *Encyclopædia* there is some account, under the head Arts, of the general theory and history of the *Fine Arts*, including Poetry, Eloquence, Painting, Statuary, and Architecture. The term, in its widest application, would also embrace Music, Dancing, Theatrical Exhibition; and in general, all those arts, in which the powers of imitation or invention are exerted, chiefly with a view to the production of pleasure, by the immediate impression which they make on the mind. The phrase has of late, we think, been restricted to a narrower and more technical signification; namely, to Painting, Sculpture, Engraving, and Architecture, which appeal to the eye as the medium of pleasure; and by way of eminence, to the two first of these arts. In the present article, we shall adopt this limited sense of the term; and shall endeavour to develope the principles upon which the great Masters have proceeded, and also to inquire, in a more particular manner, into the present state and probable advancement of these arts in this Country.

Ruling Principle of the Fine Arts.

The great works of art, at present extant, and which may be regarded as models of perfection in their several kinds, are the Greek statues—the pictures of the celebrated Italian Masters—those of the Dutch and Flemish schools—to which we may add the comic productions of our own countryman, Hogarth. These all stand unrivalled in the history of art; and they owe their pre-eminence and perfection to one and the same principle,—*the immediate imitation of nature*. This principle predominated equally in the classical forms of the antique, and in the grotesque figures of Hogarth; the perfection of art in each arose from the truth and identity of the imitation with the reality; the difference was in the subjects; there was none in the mode of imitation. Yet the advocates for the *ideal system of art* would persuade their disciples, that the difference between Hogarth and the antique does not consist in the different forms of nature which they imitated, but in this, that the one is like, and the other unlike nature. This is an error, the most detrimental, perhaps, of all others, both to the theory and practice of art. As, however, the prejudice is very strong and general, and supported by the highest authority, it will be necessary to go somewhat elaborately into the question, in order to produce an impression on the other side.

What has given rise to the common notion of the *ideal*, as something quite distinct from *actual* nature, is probably the perfection of the Greek statues. Not seeing among ourselves, anything to correspond in beauty and grandeur, either with the features or form of the limbs in these exquisite remains of antiquity, it was an obvious, but a superficial conclusion, that they must have been created from the idea existing in the artist's mind, and could not have been copied from anything existing in nature. The contrary, however, is the fact. The general form, both of the face and figure, which we observe in the old statues, is not an ideal abstraction, is not a fanciful invention of the sculptor, but is as completely local and national (though it happens to be more beautiful), as the figures on a Chinese screen, or a copperplate engraving of a negro chieftain in a book of travels. It will not be denied, that there is a difference of physiognomy as well as of complexion in different races of men. The Greek form appears to have been naturally beautiful, and they had, besides, every advantage of climate, of dress, of exercise, and modes of life to improve it. The artist had also every facility afforded him in the study and knowledge of the human form, and their religious and public institutions gave him every encouragement in the prose-

cution of his art. All these causes contributed to the perfection of these noble productions; but we should be inclined principally to attribute the superior symmetry of form common to the Greek statues, in the first place, to the superior symmetry of the models in nature, and in the second, to the more constant opportunities for studying them. If we allow, also, for the superior genius of the people, we shall not be wrong; but this superiority consisted in their peculiar susceptibility to the impressions of what is beautiful and grand in nature. It may be thought an objection to what has just been said, that the antique figures of animals, &c., are as fine, and proceed on the same principles as their statues of gods or men. But all that follows from this seems to be, that their art had been perfected in the study of the human form, the test and proof of power and skill; and was then transferred easily to the general imitation of all other objects, according to their true characters, proportions, and appearances. As a confirmation of these remarks, the antique portraits of individuals were often superior even to the personifications of their gods. We think that no unprejudiced spectator of real taste can hesitate for a moment in preferring the head of the Antinous, for example, to that of the Apollo. And in general, it may be laid down as a rule, that the most perfect of the antiques are the most simple;—those which affect the least action, or violence of passion;—which repose the most on natural beauty of form, and a certain expression of sweetness and dignity, that is, which remain most nearly in that state in which they could be copied from nature without straining the limbs or features of the individual, or racking the invention of the artist. This tendency of Greek art to repose has indeed been reproached with insipidity by those who had not a true feeling of beauty and sentiment. We, however, prefer these models of habitual grace or internal grandeur to the violent distortions of suffering in the Laocoon, or even to the supercilious air of the Apollo. The Niobe, more than any other antique head, combines truth and beauty with deep passion. But here the passion is fixed, intense, habitual;—it is not a sudden or violent gesticulation, but a settled mould of features; the grief it expresses is such as might almost turn the human countenance itself *into marble!*

In general, then, we would be understood to maintain, that the beauty and grandeur so much admired in the Greek statues were not a voluntary fiction of the brain of the artist, but existed substantially in the forms from which they were copied, and by which the artist was surrounded. A striking authority in support of these observations, which has in some measure been lately discovered, is to be found in the *Elgin marbles*, taken from the Acropolis at Athens, and supposed to be the works of the celebrated Phidias. The process of fastidious refinement and indefinite abstraction is certainly not visible there. The figures have all the ease, the simplicity, and variety, of individual nature. Even the details of the subordinate parts, the loose hanging folds in the skin, the veins under the belly, or on the sides of the horses, more or less swelled as the animal is more or less in action, are given with scrupulous exactness. This is true nature and true art. In a word, these invaluable remains of antiquity are precisely like casts taken from life. The *ideal* is not the preference of that which exists only in the mind, to that which exists in nature; but the preference of that which is fine in nature to that which is less so. There is nothing fine in art but what is taken almost immediately, and, as it were, in the mass, from what is finer in nature. Where there have been the finest models in nature, there have been the finest works of art.

As the Greek statues were copied from Greek forms, so Raphael's expressions were taken from Italian faces; and we have heard it remarked, that the women in the streets at Rome seem to have walked out of his pictures in the Vatican.

Sir Joshua Reynolds constantly refers to Raphael as the highest example in modern times (at least with one exception) of the grand or ideal style; and yet he makes the essence of that style to consist in the embodying an abstract or general idea, formed in the mind of the artist by rejecting the peculiarities of individuals, and retaining only what is common to the species. Nothing can be more inconsistent than the style of Raphael with this definition. In his Cartoons and in his groupes in the Vatican, there is hardly a face or figure which is any thing more than fine individual nature finely disposed and copied. The late Mr Barry, who could not be suspected of a prejudice on this side of the question, speaks thus of them: "In Raphael's pictures (at the Vatican) of the *Dispute of the Sacrament*, and the *School of Athens*, one sees all the heads to be entirely copied from particular characters in nature, nearly proper for the persons and situations which he adapts them to; and he seems to me only to add and take away what may answer his purpose in little parts, features, &c.; conceiving, while he had the head before him, ideal characters and expressions, which he adapts these features and peculiarities of face to. This attention to the particulars which distinguish all the different faces, persons, and characters, the one from the other, gives his pictures quite the verity and unaffected dignity of nature, which stamp the distinguishing differences betwixt one man's face and body and another's."

If any thing is wanting to the conclusiveness of this testimony, it is only to look at the pictures themselves; particularly the *Miracle of the Conversion*, and the *Assembly of Saints*, which are little else than a collection of divine portraits, in natural and expressive attitudes, full of the loftiest thought and feeling, and as varied as they are fine. It is this reliance on the power of nature which has produced those masterpieces by the prince of painters, in which expression is all in all;—where one spirit,—that of truth,—pervades every part, brings down Heaven to Earth, mingles Cardinals and Popes with Angels and Apostles,—and yet blends and harmonizes the whole by the true touches and intense feeling of what is beautiful and grand in nature. It is no wonder that Sir Joshua, when he first saw Raphael's pictures in the Vatican, was at a loss to discover any great excellence in them, if he was looking out for

his theory of the *ideal*,—of neutral character and middle forms.

There is more an appearance of abstract grandeur of form in Michael Angelo. He has followed up, has enforced, and expanded, as it were, a preconceived idea, till he sometimes seems to tread on the verge of caricature. His forms, however, are not *middle*, but *extreme* forms, massy, gigantic, supernatural. They convey the idea of the greatest size and strength in the figure, and in all the parts of the figure. Every muscle is swollen and turgid. This tendency to exaggeration would have been avoided, if Michael Angelo had recurred more constantly to nature, and had proceeded less on a scientific knowledge of the structure of the human body; for science gives only the positive form of the different parts, which the imagination may afterwards magnify, as it pleases, but it is nature alone which combines them with perfect truth and delicacy, in all the varieties of motion and expression. It is fortunate that we can refer, in illustration of our doctrine, to the admirable fragment of the Theseus at Lord Elgin's, which shows the possibility of uniting the grand and natural style in the highest degree. The form of the limbs, as affected by pressure or action, and the general sway of the body, are preserved with the most consummate mastery. We should prefer this statue as a model for forming the style of the student to the Apollo, which strikes us as having something of a theatrical appearance, or to the Hercules, in which there is an ostentatious and over-laboured display of anatomy. This last figure is so overloaded with sinews, that it has been suggested as a doubt, whether, if life could be put into it, it would be able to move. Grandeur of conception, truth of nature, and purity of taste, seem to have been at their height when the masterpieces which adorned the temple of Minerva at Athens, of which we have only these imperfect fragments, were produced. Compared with these, the later Greek statues display a more elaborate workmanship, more of the artifices of style. The several parts are more uniformly balanced, made more to tally like modern periods: each muscle is more equally brought out, and more highly finished as a part, but not with the same subordination of each part to the whole. If some of these wonderful productions have a fault, it is the want of that entire and naked simplicity which pervades the whole of the *Elgin marbles*.

Works of the Grecian and Italian Artists.

Having spoken here of the Greek statues, and of the works of Raphael and Michael Angelo, as far as relates to the imitation of nature, we shall attempt to point out, to the best of our ability, and as concisely as possible, what we conceive to be their general and characteristic excellences. The ancients excelled in beauty of form; Michael Angelo in grandeur of conception; Raphael in expression. In Raphael's faces, particularly his women, the expression is very superior to the form; in the ancient statues, the form is the principal thing. The interest which the latter excite, is in a manner external; it depends on a certain grace and lightness of appearance, joined with exquisite symmetry and refined susceptibility to voluptuous emotions; but there is in general a want of pathos. In their looks, we do not read the workings of the heart; by their beauty they seem raised above the sufferings of humanity, by their beauty they are deified. The pathos which they exhibit is rather that of present and physical distress, than of deep internal sentiment. What has been remarked of Leonardo da Vinci, is also true of Raphael, that there is an angelic sweetness and tenderness in his faces, in which human frailty and passion are purified by the sanctity of religion. The ancient statues are finer objects for the eye to contemplate; they represent a more perfect race of physical beings, but we have little sympathy with them. In Raphael, all our natural sensibilities are heightened and refined by the sentiments of faith and hope, pointing mysteriously to the interests of another world. The same intensity of passion appears also to distinguish Raphael from Michael Angelo. Michael Angelo's forms are grander, but they are not so informed with expression. Raphael's, however ordinary in themselves, are full of expression, "even to o'erflowing;" every nerve and muscle is impregnated with feeling,—bursting with meaning. In Michael Angelo, on the contrary, the powers of body and mind appear superior to any events that can happen to them; the capacity of thought and feeling is never full, never strained or tasked to the extremity of what it will bear. All is in a lofty repose and solitary grandeur, which no human interests can shake or disturb. It has been said, that Michael Angelo painted *man*, and Raphael *men*; that the one was an epic, the other a dramatic painter. But the distinction we have stated is, perhaps, truer and more intelligible, *viz.* that the one gave greater dignity of form, and the other greater force and refinement of expression. Michael Angelo, in fact, borrowed his style from sculpture. He represented, in general, only single figures (with subordinate accompaniments), and had not to express the conflicting actions and passions of a multitude of persons. It is therefore a mere truism to say, that his compositions are not dramatic. He is much more picturesque than Raphael. The whole figure of his *Jeremiah* droops and hangs down like a majestic tree surcharged with showers. His drawing of the human form has the characteristic freedom and boldness of Titian's landscapes.

After Michael Angelo and Raphael, there is no doubt that Leonardo da Vinci, and Correggio, are the two painters, in modern times, who have carried historical expression to the highest ideal perfection; and yet it is equally certain that their heads are carefully copied from faces and expressions in nature. Leonardo excelled principally in his women and children. We find, in his female heads, a peculiar charm of expression; a character of natural sweetness and tender playfulness, mixed up with the pride of conscious intellect, and the graceful reserve of personal dignity. He blends purity with voluptuousness; and the expression of his women is equally characteristic of "the mistress or the saint." His pictures are worked up to the height of the idea he had conceived, with an elaborate felicity; but this idea was evidently first suggested, and afterwards religiously compared with nature. This was his excellence. His fault is, that his style of execution is

too mathematical; that is, his pencil does not follow the graceful variety of the details of objects, but substitutes certain refined gradations, both of form and colour, producing equal changes in equal distances, with a mechanical uniformity. Leonardo was a man of profound learning as well as genius, and perhaps transferred too much of the formality of science to his favourite art.

The masterpieces of Correggio have the same identity with nature, the same stamp of truth. He has indeed given to his pictures the utmost softness and refinement of outline and expression; but this idea, at which he constantly aimed, is filled up with all the details and varieties which such heads would have in nature. So far from any thing like a naked abstract idea, or middle form, the *individuality* of his faces has something peculiar in it, even approaching the grotesque. He has endeavoured to impress habitually on the countenance, those undulating outlines which rapture or tenderness leave there, and has chosen for this purpose those forms and proportions which most obviously assisted his design.

As to the colouring of Correggio, it is nature itself. Not only the general tone is perfectly true, but every speck and particle is varied in colour, in relief, in texture, with a care, a felicity, and an effect, which is almost magical. His light and shade are equally admirable. No one else, perhaps, ever gave the same harmony and roundness to his compositions. So true are his shadows,—equally free from coldness, opacity, or false glare;—so clear, so broken, so airy, and yet so deep, that if you hold your hand so as to cast a shadow on any part of the flesh which is in the light, this part, so shaded, will present exactly the same appearance which the painter has given to the shadowed part of the picture. Correggio, indeed, possessed a greater variety of excellences in the different departments of his art, than any other painter; and yet it is remarkable, that the impression which his pictures leave upon the mind of the common spectator, is monotonous and comparatively feeble. His style is in some degree mannered and confined. For instance, he is without the force, passion, and grandeur of Raphael, who, however, possessed his softness of expression, but of expression only; and in colour, in light and shade, and other qualities, was quite inferior to Correggio. We may, perhaps, solve this apparent contradiction by saying, that he applied the power of his mind to a greater variety of objects than others; but that this power was still of the same character; consisting in a certain exquisite sense of the harmonious, the soft and graceful in form, colour, and sentiment, but with a deficiency of strength, and a tendency to effeminacy in all these.

After the names of Raphael and Correggio, we shall mention that of Guido, whose female faces are exceedingly beautiful and ideal, but altogether commonplace and vapid, compared with those of Raphael or Correggio; and they are so, for no other reason but that the general idea they convey is not enriched and strengthened by an intense contemplation of nature. For the same reason, we can conceive nothing more unlike the antique than the figures of Nicholas Poussin, except as to the preservation of the costume; and it is perhaps chiefly owing to the habit of studying his art at second-hand, or by means of scientific rules, that the great merits of that able painter, whose understanding and genius are unquestionable, are confined to his choice of subjects for his pictures, and his manner of telling the story. His landscapes, which he probably took from nature, are superior as paintings to his historical pieces. The faces of Poussin want natural expression, as his figures want grace; but the back-grounds of his historical compositions can scarcely be surpassed. In his plague of Athens, the very buildings seem stiff with horror. His giants, seated on the top of their fabled mountains, and playing on their Pan's pipes, are as familiar and natural as if they were the ordinary inhabitants of the scene. The finest of his landscapes is his picture of the Deluge. The sun is just seen wan and drooping in his course. The sky is bowed down with a weight of waters, and Heaven and earth seem mingling together.

Titian is at the head of the Venetian school. He is the first of all colourists. In delicacy and purity Correggio is equal to him, but his colouring has not the same warmth and gusto in it. Titian's flesh-colour partakes of the glowing nature of the climate, and of the luxuriousness of the manners of his country. He represents objects not through a merely lucid medium, but as if tinged with a golden light. Yet it is wonderful in how low a tone of local colouring his pictures are painted,—how rigidly his means are husbanded. His most gorgeous effects are produced, not less by keeping down, than by heightening his colours; the fineness of his gradations adds to their variety and force; and, with him, truth is the same thing as splendour. Every thing is done by the severity of his eye, by the patience of his touch. He is enabled to keep pace with nature, by never hurrying on before her; and as he forms the broadest masses out of innumerable varying parts and minute strokes of the pencil, so he unites and harmonises the strongest contrasts by the most imperceptible transitions. Every distinction is relieved and broken by some other intermediate distinction, like half notes in music; and yet all this accumulation of endless variety is so managed, as only to produce the majestic simplicity of nature; so that to a common eye there is nothing extraordinary in his pictures, any more than in nature itself. It is, we believe, owing to what has been here stated, that Titian is, of all painters, at once the easiest and the most difficult to copy. He is the most difficult to copy perfectly, for the artifice of his colouring and execution is hid in its apparent simplicity; and yet the knowledge of nature, and the arrangement of the forms and masses in his pictures, is so masterly, that any copy made from them, even the rudest outline or sketch, can hardly fail to have a look of high art. Because he was the greatest colourist in the world, this, which was his most prominent, has, for shortness, been considered as his only excellence; and he has been said to have been ignorant of drawing. What he was, generally speaking, deficient in, was invention or composition, though even this appears to have been more from habit than want of power; but his drawing of actual forms, where they were not to be put into momentary action, or adapted to a particular expression, was as

Fine Arts.

fine as possible. His drawing of the forms of inanimate objects is unrivalled. His trees have a marked character and physiognomy of their own, and exhibit an appearance of strength or flexibility, solidity or lightness, as if they were endued with conscious power and purposes. Character was another excellence which Titian possessed in the highest degree. It is scarcely speaking too highly of his portraits to say, that they have as much expression, that is, convey as fine an idea of intellect and feeling, as the historical heads of Raphael. The chief difference appears to be, that the expression in Raphael is more imaginary and contemplative, and in Titian more personal and constitutional. The heads of the one seem thinking more of some event or subject, those of the other to be thinking more of themselves. In the portraits of Titian, as might be expected, the Italian character always predominates; there is a look of piercing sagacity, of commanding intellect, of acute sensibility, which it would be in vain to seek for in any other portraits. The daring spirit and irritable passions of the age and country, are distinctly stamped upon their countenances, and can be as little mistaken as the costume which they wear. The portraits of Raphael, though full of profound thought and feeling, have more of common humanity about them. Titian's portraits are the most historical that ever were painted; and they are so, for this reason, that they have most consistency of form and expression. His portraits of Hippolito de Medici, and of a young Neapolitan nobleman, lately in the gallery of the Louvre, are a striking contrast in this respect. All the lines of the face in the one, the eye-brows, the nose, the corners of the mouth, the contour of the face, present the same sharp angles, the same acute, edgy, contracted, violent expression. The other portrait has the finest expansion of feature and outline, and conveys the most exquisite idea possible, of mild, thoughtful sentiment. The consistency of the expression constitutes as great a charm in Titian's portraits, as the harmony of the colouring. The similarity sometimes objected to his heads, is partly national, and partly arises from the class of persons whom he painted. He painted only Italians; and in his time it rarely happened, that any but persons of the highest rank, Senators, or Cardinals, sat for their pictures. The similarity of costume of the dress, the beard, &c. also adds to the similarity of their appearance. It adds, at the same time, to their picturesque effect; and the alteration in this respect, is one circumstance among others that has been injurious, not to say fatal, to modern art. This observation is not confined to portrait; for the hired dresses with which our historical painters clothe their figures, sit no more easily on the imagination of the artist, than they do gracefully on the lay-figures over which they are thrown.

Giorgioni, Paul Veronese, Tintoret, and the Bassans, are the remaining great names of the Venetian school. The excellence of all of them consisted in the bold, masterly, and striking imitation of nature. Their want of *ideal form*, and elevated character, is, indeed, a constant subject of reproach against them. Giorgioni takes the first place among them; for he was in some measure the master of Titian, whereas the others were only his disciples. The Carraccis, Domenichino, and the rest of the Bolognese school, formed themselves on a principle of combining the excellences of the Roman and Venetian painters, in which they for a while succeeded to a considerable degree; but they degenerated and dwindled away into absolute insignificance, in proportion as they departed from nature, or the great masters who had copied her, to mould their works on academic rules, and the phantoms of abstract perfection.

Flemish and Dutch Painters.

Rubens is the Prince of the Flemish painters. Of all the great painters, he is perhaps the most artificial,—the one who painted most from his own imagination,—and, what was almost the inevitable consequence, the most of a mannerist. He had neither the Greek forms to study from, nor the Roman expression, nor the high character, picturesque costume, and sun-burnt hues which the Venetian painters had immediately before them. He took, however, what circumstances presented to him,—a fresher and more blooming tone of complexion, arising from moister air, and a colder climate. To this he added the congenial splendour of reflected lights and shadows cast from rich drapery; and he made what amends he could for the want of expression, by the richness of his compositions, and the fantastic variety of his allegorical groups. Both his colouring and his drawing were, however, ideal exaggerations. But both had particular qualities of the highest value. He has given to his flesh greater transparency and freshness, than any other painter; and this excellence he had from nature. One of the finest instances will be found in his *Peasant Family going to Market*, in which the figures have all the bloom of health upon their countenances; and the very air of the surrounding landscape strikes sharp and wholesome on the sense. Rubens had another excellence; he has given all that relates to the expression of motion in his allegorical figures, in his children, his animals, even in his trees, to a degree which no one else has equalled, or indeed approached. His drawing is often deficient in proportion, in knowledge, and in elegance, but it is always picturesque. The drawing of N. Poussin, on the contrary, which has been much cried up, is merely learned and anatomical: he has a knowledge of the structure and measurements of the human body, but very little feeling of the grand, or beautiful, or striking, in form. All Rubens's forms have ease, freedom, and excessive elasticity. In the grotesque style of history,—as in the groups of satyrs, nymphs, bacchanals, and animals, where striking contrasts of form are combined with every kind of rapid and irregular movement, he has not a rival. Witness his Silenus at Blenheim, where the lines seem drunk and staggering; and his procession of Cupids riding on animals at Whitehall, with that adventurous leader of the infantine crew, who, with a spear, is urging a lion, on which he is mounted, over the edge of the world; for beyond we only see a precipice of clouds and sky. Rubens's power of expressing motion perhaps arose from the facility of his pencil, and his habitually trusting a good deal to memory and imagination in his compositions; for this quality can be given in no other way. His portraits are the least

Fine Arts.

valuable productions of his pencil. His landscapes are often delightful, and appear like the work of fairy hands.

It remains to speak of Vandyke and Rembrandt, the one the disciple of Rubens, the other the entire founder of his own school. It is not possible for two painters to be more opposite. The characteristic merits of the former are very happily summed up in a single line of a poetical critic, where he speaks of

"The soft precision of the clear Vandyke."

The general object of this analysis of the works of the great masters, has been to show, that their pre-eminence has constantly depended, not on the creation of a fantastic, abstract excellence, existing nowhere but in their own minds, but in their selecting and embodying some one view of nature, which came immediately under their habitual observation, and which their particular genius led them to study and imitate with success. This is certainly the case with Vandyke. His portraits, mostly of English women, in the collection in the Louvre, have a cool refreshing air about them, a look of simplicity and modesty even in the very tone, which forms a fine contrast to the voluptuous glow and mellow golden lustre of Titian's Italian women. There is a quality of flesh-colour in Vandyke which is to be found in no other painter, and which exactly conveys the idea of the soft, smooth, sliding, continuous, delicately varied surface of the skin. The objects in his pictures have the least possible difference of light and shade, and are presented to the eye without passing through any indirect medium. It is this extreme purity and silvery clearness of tone, together with the facility and precision of his particular forms, and a certain air of fashionable elegance, characteristic of the age in which he flourished, that places Vandyke in the first rank of portrait painters.

If ever there was a man of genius in the art, it was Rembrandt. He might be said to have created a medium of his own, through which he saw all objects. He was the grossest and the least vulgar, that is to say, the least common-place in his grossness, of all men. He was the most downright, the least fastidious of the imitators of nature. He took any object, he cared not what, how mean soever in form, colour, and expression, and from the light and shade which he threw upon it, it came out gorgeous from his hands. As Vandyke made use of the smallest contrasts of light and shade, and painted as if in the open air, Rembrandt used the most violent and abrupt contrasts in this respect, and painted his objects as if in a dungeon. His pictures may be said to be "bright with excessive darkness." His vision had acquired a lynx-eyed sharpness from the artificial obscurity to which he had accustomed himself. "Mystery and silence hung upon his pencil." Yet he could pass rapidly from one extreme to another, and dip his colours with equal success in the gloom of night, or in the blaze of the noon-day sun. In surrounding different objects with a medium of imagination, solemn or dazzling, he was a true poet; in all the rest, he was a mere painter, but a painter of no common stamp. The powers of his hand were equal to those of his eye; and indeed he could not have attempted the subjects he did, without an execution as masterly as his knowledge was profound. His colours are sometimes dropped in lumps on the canvass; at other times they are laid on as smooth as glass; and he not unfrequently painted with the handle of his brush. He had an eye for all objects as far as he had seen them. His history and landscapes are equally fine in their way. His landscapes we could look at for ever, though there is nothing in them. But "they are of the earth, earthy." It seems as if he had dug them out of nature. Every thing is so true, so real, so full of all the feelings and associations which the eye can suggest to the other senses, that we immediately take as strong an affection to them, as if they were our home—the very place where we were brought up. No length of time could add to the intensity of the impression they convey. Rembrandt is the least classical and the most romantic of all painters. His Jacob's Ladder is more like a dream than any other picture that ever was painted. The figure of Jacob himself is thrown in one corner of the picture like a bundle of clothes, while the angels hover above the darkness, in the shape of airy wings.

It would be needless to prove that the generality of the Dutch painters copied from actual objects. They have become almost a bye-word for carrying this principle into its abuse, by copying every thing they saw, and having no choice or preference of one thing to another, unless that they preferred that which was most obvious and common. We forgive them. They perhaps did better in faithfully and skilfully imitating what they had seen, than in imagining what they had not seen. Their pictures at least show, that there is nothing in nature, however mean or trivial, that has not its beauty and some interest belonging to it, if truly represented. We prefer Vangoyen's views on the borders of a canal, the yellow-tufted bank, and passing sail, or Ruysdael's woods and sparkling water falls, to the most classical or epic compositions which they could have invented out of nothing; and we think that Teniers's boors, old women, and children, are very superior to the little carved ivory Venuses in the pictures of Vanderneer; just as we think Hogarth's *Marriage à la Mode* is better than his Sigismunda, or as Mr Wilkie's Card-Players is better than his Alfred. We should not assuredly prefer a *Dutch Fair* by Teniers to a *Cartoon* by Raphael; but we suspect we should prefer a Dutch Fair by Teniers to a Cartoon by the same master; or we should prefer truth and nature in the simplest dress, to affectation and inanity in the most pompous disguise. Whatever is genuine in art, must proceed from the impulse of nature and individual genius.

French and Spanish Painters.

In the French school there are but two names of high and established reputation, N. Poussin and Claude Lorraine. Of the former we have already spoken: of the latter we shall give our opinion when we come to speak of our own Wilson. We ought not to pass over the names of Murillo and Velasquez, those admirable Spanish painters. It is difficult to characterize their peculiar excellences as distinct from those of the Italian and Dutch schools. They may be said to hold a middle rank between

Fine Arts. the painters of mind and body. They express not so much thought and sentiment, nor yet the mere exterior, as the life and spirit of the man. Murillo is probably at the head of that class of painters who have treated subjects of common life. After making the colours on the canvass feel and think, the next best thing is to make them breathe and live. But there is in Murillo's pictures of this kind a look of real life, a cordial flow of native animal spirits, which we find nowhere else. We might here refer particularly to his picture of the *Two Spanish Beggar-boys* in the collection at Dulwich College, which cannot easily be forgotten by those who have ever seen it.

Progress of Art in Britain. We come now to speak of the progress of art in our own Country,—of its present state,—and the means proposed for advancing it to still higher perfection.

Hogarth. We shall speak first of Hogarth, both as he is the first name in the order of time that we have to boast of, and as he is the greatest comic painter of any age or country. His pictures are not imitations of still life, or mere transcripts of incidental scenes or customs; but powerful moral satires, exposing vice and folly in their most ludicrous points of view, and with a profound insight into the weak sides of character and manners, in all their tendencies, combinations, and contrasts. There is not a single picture of his, containing a representation of merely natural or domestic scenery. His object is not so much "to hold the mirror up to nature," as "to show vice her own feature, scorn her own image." Folly is there seen at the height—the moon is at the full—it is the very error of the time. There is a perpetual collision of eccentricities, a tilt and tournament of absurdities, pampered into all sorts of affectation, airy, extravagant, and ostentatious! Yet he is as little a caricaturist as he is a painter of still life. Criticism has not done him justice, though public opinion has. His works have received a sanction which it would be vain to dispute, in the universal delight and admiration with which they have been regarded, from their first appearance, to the present moment. If the quantity of amusement, or of matter for reflection which they have afforded, is that by which we are to judge of precedence among the intellectual benefactors of mankind, there are perhaps few persons who can put in a stronger claim to our gratitude than Hogarth. The wonderful knowledge which he possessed of human life and manners, is only to be surpassed (if it can be) by the powers of invention with which he has arranged his materials, and by the mastery of execution with which he has embodied and made tangible the very thoughts and passing movements of the mind. Some persons object to the style of Hogarth's pictures, or the class to which they belong. First, Hogarth belongs to no class, or, if he belongs to any, it is to the same class as Fielding, Smollett, Vanbrugh, and Moliere. Besides, the merit of his pictures does not depend on the nature of his subjects, but on the knowledge displayed of them, on the number of ideas, on the fund of observation and amusement contained in them. Make what deductions you please for the vulgarity of the subjects—yet in the research, the profundity, the absolute truth and precision of the delineation of character,—in the invention of incident, in wit and humour, in life and motion, in everlasting variety and originality,—they never have, and probably never will be surpassed. They stimulate the faculties, as well as amuse them. "Other pictures we see, Hogarth's we read!" *

There is one error which has been frequently entertained on this subject, and which we wish to correct, namely, that Hogarth's genius was confined to the imitation of the coarse humours and broad farce of the lowest life. But he excelled quite as much in exhibiting the vices, the folly, and frivolity of the fashionable manners of his time. His fine ladies do not yield the palm of ridicule to his waiting-maids, and his lords and his porters are on a very respectable footing of equality. He is quite at home, either in St Giles's or St James's. There is no want, for example, in his *Marriage à la Mode*, or his *Taste in High Life*, of affectation verging into idiotcy, or of languid sensibility that might

"Die of a rose in aromatic pain."

Many of Hogarth's characters would form admirable illustrations of Pope's Satires, who was contemporary with him. In short, Hogarth was a painter of real, not of low life. He was, as we have said, a satirist, and consequently his pencil did not dwell on the grand and beautiful, but it glanced with equal success at the absurdities and peculiarities of high or low life, "of the great vulgar and the small."

To this it must be added, that he was as great a master of passion as of humour. He succeeded in low tragedy, as much as in low or genteel comedy, and had an absolute power in moving the affections and rending the hearts of the spectators, by depicting the effects of the most dreadful calamities of human life, on common minds and common countenances. Of this, the *Rake's Progress*, particularly the Bedlam scene, and many others, are unanswerable proofs. Hogarth's merits, as a mere artist, are not confined to his prints. In general, indeed, this is the case. But when he chose to take pains, he could add the delicacies of execution and colouring in the highest degree to those of character and composition; as is evident in the series of pictures, all equally well painted, of *the Marriage à la Mode*, exhibited lately at the British Institution.

Wilson. We shall next speak of Wilson, whose pictures may be divided into three classes:—his Italian landscapes, or imitations of the manner of Claude,—his copies of English scenery,—and his historical compositions. The first of these are, in our opinion, by much the best; and we appeal, in support of this opinion, to the *Apollo and the Seasons*, and to the *Phaeton*. The figures are of course out of the question (these being as uncouth and slovenly as Claude's are insipid and finical); but the landscape,

* See an admirable Essay on the genius of Hogarth, by Charles Lamb, in a periodical work, called *The Reflector*.

in both pictures, is delightful. In looking at them, we breathe the air which the scene inspires, and feel the genius of the place present to us. In the first, there is the cool freshness of a misty spring morning; the sky, the water, the dim horizon, all convey the same feeling. The fine grey tone, and varying outline of the hills; the graceful form of the retiring lake, broken still more by the hazy shadows of the objects that repose on its bosom; the light trees that expand their branches in the air; and the dark stone figure and mouldering temple, that contrast strongly with the broad clear light of the rising day,—give a charm, a truth, a force and harmony to this composition, which produce the greater pleasure the longer it is dwelt on. The distribution of light and shade resembles the effect of light on a globe. The *Phaeton* has the dazzling fervid appearance of an autumnal evening; the golden radiance streams in solid masses from behind the flickering clouds; every object is baked in the sun;—the brown fore-ground, the thick foliage of the trees, the streams, shrunk and stealing along behind the dark high banks,—combine to produce that richness, and characteristic unity of effect, which is to be found only in nature, or in art derived from the study and imitation of nature. These two pictures, as they have the greatest general effect, are also more carefully finished than any other pictures we have seen of his.

In general, Wilson's views of *English scenery* want almost every thing that ought to recommend them. The subjects he has chosen are not well fitted for the landscape-painter, and there is nothing in the execution to redeem them. Ill-shaped mountains, or great heaps of earth, trees that grow against them without character or elegance, motionless waterfalls, a want of relief, of transparency and distance, without the imposing grandeur of real magnitude (which it is scarcely within the province of art to give),—are the chief features and defects of this class of his pictures. In more confined scenes, the effect must depend almost entirely on the difference in the execution and the details; for the difference of colour alone is not sufficient to give relief to objects placed at a small distance from the eye. But, in Wilson, there are commonly no details,—all is loose and general; and this very circumstance, which might assist him in giving the massy contrasts of light and shade, deprived his pencil of all force and precision within a limited space. In general, air is necessary to the landscape-painter; and, for this reason, the lakes of Cumberland and Westmoreland afford few subjects for landscape-painting. However stupendous the scenery of that country is, and however powerful and lasting the impression which it must always make on the imagination, yet the effect is not produced merely through the medium of the eye, but arises chiefly from collateral and associated feelings. There is the knowledge of the physical magnitude of the objects in the midst of which we are placed,—the slow, improgressive motion, which we make in traversing them;—there is the abrupt precipice, the torrent's roar, the boundless expanse of the prospect from the highest mountains,—the difficulty of their ascent, their loneliness and silence; in short, there is a constant sense and superstitious awe of the collective power of matter, of the gigantic and eternal forms of nature, on which, from the beginning of time, the hand of man has made no impression, and which, by the lofty reflections they excite in us, give a sort of intellectual sublimity even to our sense of physical weakness. But there is little in all these circumstances that can be translated into the *picturesque*, which makes its appeal immediately to the eye.

Wilson's historical landscapes, his *Niobe, Celadon and Amelia*, &c. do not, in our estimation, display either true taste or fine imagination, but are affected and violent exaggerations of clumsy common nature. They are made up mechanically of the same stock of materials,—an over-hanging rock, bare shattered trees, black rolling clouds, and forked lightning. The figures, in the most celebrated of these, are not like the children of Niobe, punished by the Gods, but like a group of rustics, crouching from a hail-storm. We agree with Sir Joshua Reynolds, that Wilson's mind was not, like N. Poussin's, sufficiently imbued with the knowledge of antiquity to transport the imagination three thousand years back, to give natural objects a sympathy with preternatural events, and to inform rocks, and trees, and mountains, with the presence of a God. To sum up his general character, we may observe, that, besides his excellence in aërial perspective, Wilson had great truth, harmony, and depth of local colouring. He had a fine feeling of the proportions and conduct of light and shade, and also an eye for graceful form, as far as regards the bold and varying outlines of indefinite objects; as may be seen in his foregrounds, &c. where the artist is not tied down to an imitation of characteristic and articulate forms. In his figures, trees, cattle, and in everything having a determinate and regular form, his pencil was not only deficient in accuracy of outline, but even in perspective and actual relief. His trees, in particular, frequently seem pasted on the canvass, like botanical specimens. In fine, we cannot subscribe to the opinion of those who assert, that Wilson was superior to Claude as a man of genius; nor can we discern any other grounds for this opinion, than what would lead to the general conclusion,—that the more slovenly the performance the finer the picture, and that that which is imperfect is superior to that which is perfect. It might be said, on the same principle, that the coarsest sign-painting is better than the reflection of a landscape in a mirror; and the objection that is sometimes made to the mere imitation of nature, cannot be made to the landscapes of Claude, for in them the Graces themselves have, with their own hands, assisted in selecting and disposing every object. Is the general effect in *his* pictures injured by the details? Is the truth inconsistent with the beauty of the imitation? Does the perpetual profusion of objects and scenery, all perfect in themselves, interfere with the simple grandeur and comprehensive magnificence of the whole? Does the precision with which a plant is marked in the foreground, take away from the air-drawn distinctions of the blue glimmering horizon? Is there any want of that endless airy space, where the eye wanders at liberty under the open sky, explores distant objects, and returns back as from a de-

lightful journey? There is no comparison between Claude and Wilson. Sir Joshua Reynolds used to say, that there would be another Raphael before there would be another Claude. His landscapes have all that is exquisite and refined in art and nature. Everything is moulded into grace and harmony; and, at the touch of his pencil, shepherds with their flocks, temples and groves, and winding glades, and scattered hamlets, rise up in never-ending succession, under the azure sky and the resplendent sun, while " universal Pan,

> "Knit with the Graces, and the hours in dance,
> Leads on the eternal spring."——

Michael Angelo has left, in one of his sonnets, a fine apostrophe to the earliest poet of Italy:

> " Fain would I, to be what our Dante was,
> Forego the happiest fortunes of mankind."

What landscape-painter does not feel this of Claude?*

Gainsborough.

We have heard an anecdote connected with the reputation of Gainsborough's pictures, which rests on pretty good authority. Sir Joshua Reynolds, at one of the Academy dinners, speaking of Gainsborough, said to a friend,—" He is undoubtedly the best English landscape-painter." " No," said Wilson, who overheard the conversation, " he is not the best landscape-painter, but he is the best portrait painter in England." They were both wrong; but the story is creditable to the versatility of Gainsborough's talents.

Those of his portraits which we have seen are not in the first rank. They are in a good measure imitations of Vandyke; and have more an air of gentility than of nature. His landscapes are of two classes or periods; his early and his later pictures. The former are minute imitations of nature, or of painters who imitated nature, such as Ruysdael, &c. some of which have great truth and clearness. His later pictures are flimsy caricatures of Rubens, who himself carried inattention to the details to the utmost limit that it would bear. Many of Gainsborough's latter landscapes may be compared to bad water-colour drawings, washed in by mechanical movements of the hand, without any communication with the eye. The truth seems to be, that Gainsborough found there was something wanting in his *early manner*, that is, something beyond the literal imitation of the details of natural objects; and he appears to have concluded rather hastily, that the way to arrive at that *something more*, was to discard truth and nature altogether. His fame rests principally, at present, on his fancy-pieces, cottage-children, shepherd-boys, &c. These have often great truth, great sweetness, and the subjects are often chosen with great felicity. We too often find, however, even in his happiest efforts, a consciousness in the turn of the limbs, and a pensive languor in the expression, which is not taken from nature. We think the gloss of art is never so ill bestowed as on such subjects, the essence of which is simplicity. It is perhaps the general fault of Gainsborough, that he presents us with an ideal common life, of which we have had a surfeit in poetry and romance. His subjects are softened, and sentimentalised too much; it is not simple unaffected nature that we see, but nature sitting for her picture. Our artist, we suspect, led the way to that masquerade style, which piques itself on giving the air of an Adonis to the driver of a hay-cart, and models the features of a milk-maid on the principles of the antique. His *Woodman's Head* is admirable. Nor can too much praise be given to his *Shepherd Boy in a Storm*; in which the unconscious simplicity of the boy's expression, looking up with his hands folded and with timid wonder,—the noisy chattering of a magpie perched above,—and the rustling of the coming storm in the branches of the trees, produce a most delightful and romantic impression on the mind.

Gainsborough was to be considered, perhaps, rather as a man of delicate taste, and of an elegant and feeling mind, than as a man of genius; as a lover of the art, rather than an artist. He devoted himself to it, with a view to amuse and soothe his mind, with the ease of a gentleman, not with the severity of a professional student. He wished to make his pictures, like himself, amiable; but a too constant desire to please almost unavoidably leads to affectation and effeminacy. He wanted that vigour of intellect, which perceives the beauty of truth; and thought that painting was to be gained, like other mistresses, by flattery and smiles. It was an error which we are disposed to forgive in one, around whose memory, both as an artist and a man, many fond recollections, many vain regrets, must always linger. †

Sir Joshua Reynolds.

The authority of Sir Joshua Reynolds, both from his example and instructions, has had, and still continues to have, a considerable influence on the state of art in this country. That influence has been on the whole unquestionably beneficial in itself, as well as highly creditable to the rare talents and elegant mind of Sir Joshua; for it has raised the art of painting from the lowest state of degradation,—of dry, meagre, lifeless inanity, to something at least respectable, and bearing an affinity to the rough strength and bold spirit of the national character. Whether the same implicit deference to his authority, which has helped to advance the art thus far, may not, among other causes, limit and retard its future progress? Whether there are not certain ori-

* This painter's book of studies from nature, commonly called *Liber Veritatis*, disproves the truth of the general opinion that his landscapes are mere artificial compositions, for the finished pictures are nearly facsimiles of the original sketches.

† The idea of the necessity of improving upon nature, and giving what was called a *flattering likeness*, was universal in this country fifty years ago; so that Gainsborough is not to be so much blamed for tampering with his subjects.

ginal errors, both in his principles and practice, which, the farther they are proceeded in, the farther they will lead us from the truth? Whether there is not a systematic bias from the right line by which alone we can arrive at the goal of the highest perfection?—are questions well worth considering.

We shall begin with Sir Joshua's merits as an artist. There is one error which we wish to correct at setting out, because we think it important. There is not a greater or more unaccountable mistake than the supposition that Sir Joshua Reynolds owed his success or excellence in his profession, to his having been the first who introduced into this country more general principles of the art, and who raised portrait to the dignity of history from the low drudgery of copying the peculiarities, meannesses, and details of individual nature, which was all that had been attempted by his immediate predecessors. This is so far from being true, that the very reverse is the fact. If Sir Joshua did not give these details and peculiarities so much as might be wished, those who went before him did not give them at all. Those pretended general principles of the art, which, it is said, "alone give value and dignity to it," had been pushed to their extremest absurdity before his time; and it was in getting rid of the mechanical systematic monotony and *middle forms*, by the help of which Lely, Kneller, Hudson, the French painters, and others, carried on their manufactories of history and face-painting, and in returning (as far as he did return) to the truth and force of individual nature, that the secret both of his fame and fortune lay. The pedantic, servile race of artists, whom Reynolds superseded, had carried the abstract principle of improving on nature to such a degree of refinement, that they left it out altogether; and confounded all the varieties and irregularities of form, feature, character, expression or attitude, in the same artificial mould of fancied grace and fashionable insipidity. The portraits of Kneller, for example, seem all to have been turned in a machine; the eye-brows are arched as if by a compass; the mouth curled, and the chin dimpled, the head turned on one side, and the hands placed in the same affected position. The portraits of this mannerist, therefore, are as like one another as the dresses which were then in fashion; and have the same "dignity and value" as the full-bottomed wigs which graced their originals. The superiority of Reynolds consisted in his being varied and natural, instead of being artificial and uniform. The spirit, grace, or dignity which he added to his portraits, he borrowed from nature, and not from the ambiguous quackery of rules. His feeling of truth and nature was too strong to permit him to adopt the unmeaning style of Kneller and Hudson; but his logical acuteness was not such as to enable him to detect the verbal fallacies and speculative absurdities which he had learned from Richardson and Coypel; and, from some defects in his own practice, he was led to confound negligence with grandeur. But of this hereafter.

Sir Joshua Reynolds owed his vast superiority over his contemporaries to incessant practice, and habitual attention to nature, to quick organic sensibility, to considerable power of observation, and still greater taste in perceiving and availing himself of those excellences of others, which lay within his own walk of art. We can by no means look upon Sir Joshua as having a claim to the first rank of genius. He would hardly have been a great painter, if other greater painters had not lived before him. He would not have given a first impulse to the art, nor did he advance any part of it beyond the point where he found it. He did not present any new view of nature, nor is he to be placed in the same class with those who did. Even in colour, his pallet was spread for him by the old Masters, and his eye imbibed its full perception of depth and harmony of tone, from the Dutch and Venetian schools, rather than from nature. His early pictures are poor and flimsy. He indeed learned to see the finer qualities of nature through the works of art, which he, perhaps, might never have discovered in nature itself. He became rich by the accumulation of borrowed wealth, and his genius was the offspring of taste. He combined and applied the materials of others to his own purpose, with admirable success; he was an industrious compiler, or skilful translator, not an original inventor in art. The art would remain, in all its essential elements, just where it is, if Sir Joshua had never lived. He has supplied the industry of future plagiarists with no new materials. But it has been well observed, that the value of every work of art, as well as the genius of the artist, depends, not more on the degree of excellence, than on the degree of originality displayed in it. Sir Joshua, however, was perhaps the most original imitator that ever appeared in the world: and the reason of this, in a great measure, was, that he was compelled to combine what he saw in art, with what he saw in nature, which was constantly before him. The portrait-painter is, in this respect, much less liable than the historical painter, to deviate into the extremes of manner and affectation; for he cannot discard nature altogether, under the excuse that *she only puts him out*. He must meet her, face to face; and if he is not incorrigible, he will see something there that cannot fail to be of service to him. Another circumstance which must have been favourable to Sir Joshua was, that though not the originator *in point of time*, he was the first Englishman who transplanted the higher excellences of his profession into his own country, and had the merit, if not of an inventor, of a reformer of the art. His mode of painting had the graces of novelty in the age and country in which he lived; and he had, therefore, all the stimulus to exertion, which arose from the enthusiastic applause of his contemporaries, and from a desire to expand and refine the taste of the public.

To an eye for colour and for effects of light and shade, Sir Joshua united a strong perception of individual character,—a lively feeling of the quaint and grotesque in expression, and great mastery of execution. He had comparatively little knowledge of drawing, either as it regarded proportion or form. The beauty of some of his female faces and figures arises almost entirely from their softness and fleshiness. His pencil wanted firmness and precision. The expression, even of his best portraits, seldom implies either lofty or impassioned intellect or deli-

cate sensibility. He also wanted grace, if grace requires simplicity. The mere negation of stiffness and formality is not grace; for looseness and distortion are not grace. His favourite attitudes are not easy and natural, but the affectation of ease and nature. They are violent deviations from a right line. Many of the figures in his fancy-pieces are placed in postures in which they could not remain for an instant without extreme difficulty and awkwardness. We might instance the *Girl drawing with a pencil*, and some others. His portraits are his best pictures, and of these his portraits of men are the best; his pictures of children are the next in value. He had fine subjects for the former, from the masculine sense and originality of character of many of the persons whom he painted; and he had also a great advantage (as far as practice went) in painting a number of persons of every rank and description. Some of the finest and most interesting are those of Dr Johnson, Goldsmith (which is, however, too much a mere sketch), Baretti, Dr Burney, John Hunter, and the inimitable portrait of Bishop Newton. The elegant simplicity of character, expression, and drawing, preserved throughout the last picture, even to the attitude and mode of handling, discover the true genius of a painter. We also remember to have seen a print of Thomas Warton, than which nothing could be more characteristic or more natural. These were all Reynolds's intimate acquaintances, and it could not be said of them that they were men of "no mark or likelihood." Their traits had probably sunk deep into the artist's mind; he painted them as pure studies from nature, copying the real image existing before him, with all its known characteristic peculiarities; and, with as much wisdom as good-nature, sacrificing the graces on the altar of friendship. They are downright portraits, and nothing more, and they are valuable in proportion. In his portraits of women, on the contrary (with very few exceptions), Sir Joshua appears to have consulted either the vanity of his employers or his own fanciful theory. They have not the look of individual nature, nor have they, to compensate the want of this, either peculiar elegance of form, refinement of expression, delicacy of complexion, or gracefulness of manner. Vandyke's attitudes have been complained of as stiff and confined. Reynolds, to avoid this defect, has fallen into the contrary extreme of negligence and contortion. His female figures which aim at gentility, are twisted into that serpentine line, the idea of which he ridiculed so much in Hogarth. Indeed Sir Joshua, in his *Discourses* (see his account of Correggio), speaks of grace as if it were nearly allied to affectation. Grace signifies that which is pleasing and natural in the posture and motions of the human form, as Beauty is more properly applied to the form itself. That which is stiff, inanimate, and without motion, cannot, therefore, be graceful; but, to suppose that a figure, to be graceful, need only be put into some languishing or extravagant posture, is to mistake flutter and affectation for ease and elegance.

Sir Joshua's children, as we have said above, are among his *chef d'œuvres.* The faces of children have in general that want of precision of outline, that prominence of relief and strong contrast of colour, which were peculiarly adapted to his style of painting. The arch simplicity of expression, and the grotesque character which he has given to the heads of his children, were, however, borrowed from Correggio. His Puck is the most masterly of all these; and the colouring, execution, and character, alike exquisite. The single figure of the Infant Hercules is also admirable. Many of those to which his friends have suggested historical titles are mere common portraits or casual studies. Thus the Infant Samuel is an innocent little child, saying its prayers at the bed's feet: it has nothing to do with the story of the Hebrew prophet. The same objection will apply to many of his fancy-pieces and historical compositions. There is often no connection between the picture and the subject but the name. Even his celebrated Iphigenia (beautiful as she is, and prodigal of her charms) does not answer to the idea of the story. In drawing the naked figure, Sir Joshua's want of truth and firmness of outline, became more apparent; and his mode of laying on his colours, which, in the face and extremities, was relieved and broken by the abrupt inequalities of surface and variety of tints in each part, produced a degree of heaviness and opacity in the larger masses of flesh-colour, which can indeed only be avoided by extreme delicacy, or extreme lightness of execution.

Shall we speak the truth at once? In our opinion, Sir Joshua did not possess either that high imagination, or those strong feelings, without which no painter can become a poet in his art. His larger historical compositions have been generally allowed to be most liable to objection, in a critical point of view. We shall not attempt to judge them by scientific or technical rules, but make one or two observations on the character and feeling displayed in them. The highest subject which Sir Joshua has attempted was the *Count Ugolino,* and it was, as might be expected from the circumstances, a total failure. He had, it seems, painted a study of an old beggar-man's head: and some person, who must have known as little of painting as of poetry, persuaded the unsuspecting artist, that it was the exact expression of Dante's Count Ugolino, one of the most grand, terrific, and appalling characters in modern fiction. Reynolds, who knew nothing of the matter but what he was told, took his good fortune for granted, and only extended his canvass to admit the rest of the figures. The attitude and expression of Count Ugolino himself, are what the artist intended them to be, till they were pampered into something else by the officious vanity of friends—those of a common mendicant at the corner of a street, waiting patiently for some charitable donation. The imagination of the painter took refuge in a parish work-house, instead of ascending the steps of the Tower of Famine. The hero of Dante is a lofty, high-minded, and unprincipled Italian nobleman, who had betrayed his country to the enemy, and who, as a punishment for his crime, is shut up with his four sons in the dungeon of the citadel, where he shortly finds the doors barred against him, and food withheld. He in vain watches with eager feverish eye the opening of the door at the accustomed hour, and his looks turn to

stone; his children one by one drop down dead at his feet; he is seized with blindness, and, in the agony of his despair, he gropes on his knees after them,

——" Calling each by name
For three days after they were dead."

Even in the other world, he is represented with the same fierce, dauntless, unrelenting character, "gnawing the skull of his adversary, his fell repast." The subject of the *Laocoon* is scarcely equal to that described by Dante. The horror *there* is physical and momentary; in the other, the imagination fills up the long, obscure, dreary void of despair, and joins its unutterable pangs to the loud cries of nature. What is there in the picture to convey the ghastly horrors of the scene, or the mighty energy of soul with which they are borne? * His picture of *Macbeth* is full of wild and grotesque images; and the apparatus of the witches contains a very elaborate and well arranged inventory of dreadful objects. His Cardinal Beaufort is a fine display of rich mellow colouring; and there is something gentlemanly and Shakespearian in the King and the attendant Noblemen. At the same time, we think the expression of the Cardinal himself is too much one of physical horror, a canine gnashing of the teeth, like a man strangled. This is not the best style of history. Mrs Siddons as the *Tragic Muse*, is neither the tragic muse nor Mrs Siddons; and we have still stronger objections to *Garrick between Tragedy and Comedy*.

There is a striking similarity between Sir Joshua Reynolds's theory and his practice; and as each of these has been appealed to in support of the other, it is necessary that we should examine both. Sir Joshua's practice was generally confined to the illustration of that part of his theory, which relates to the more immediate imitation of nature, and it is to what he says on this subject, that we shall chiefly direct our observations at present.

He lays it down as a general and invariable rule, that "*the great style in art, and the most* PERFECT IMITATION OF NATURE, *consists in avoiding the details and peculiarities of particular objects.*" This sweeping principle he applies almost indiscriminately to *Portrait*, *History*, and *Landscape;* and he appears to have been led to the conclusion itself, from supposing the imitation of particulars to be inconsistent with general truth and effect. It appears to us, that the highest perfection of the art depends, not on separating but on uniting general truth and effect with individual distinctness and accuracy.

*First*, it is said, that the great style in painting, as it relates to the immediate imitation of external nature, consists in avoiding the details of particular objects. It consists neither in giving nor avoiding them, but in something quite different from both. Any one may avoid the details. So far, there is no difference between the *Cartoons*, and a common sign-painting. Greatness consists in giving the larger masses and proportions with truth;—this does not prevent giving the smaller ones too. The utmost grandeur of outline, and the broadest masses of light and shade, are perfectly compatible with the utmost minuteness and delicacy of detail, as may be seen in nature. It is not, indeed, common to see both qualities combined in the imitations of nature, any more than the combination of other excellences; nor are we here saying to which the principal attention of the artist should be directed; but we deny, that, considered in themselves, the absence of the one quality is necessary or sufficient to the production of the other.

If, for example, the form of the eye-brow is correctly given, it will be perfectly indifferent to the truth or grandeur of the design, whether it consists of one broad mark, or is composed of a number of hair-lines, arranged in the same order. So, if the lights and shades are disposed in fine and large masses, the *breadth* of the picture, as it is called, cannot possibly be affected by the filling up of those masses with the details, that is, with the subordinate distinctions which appear in nature. The anatomical details in Michael Angelo, the ever-varying outline of Raphael, the perfect execution of the Greek statues, do not destroy their symmetry or dignity of form; and, in the finest specimens of the composition of colour, we may observe the largest masses combined with the greatest variety in the parts of which those masses are composed.

The *gross* style consists in giving no details; the *finical* in giving nothing else. Nature contains both large and small parts, both masses and details; and the same may be said of the most perfect works of art. The union of both kinds of excellence, of strength with delicacy, as far as the limits of human capacity, and the shortness of human life would permit, is that which has established the reputation of the most successful imitators of nature. Farther, their most finished works are their best. The predominance, indeed, of either excellence in the best Masters, has varied according to their opinion of the relative value of these qualities,—the labour they had the time or the patience to bestow on their works,—the skill of the artist,—or the nature and extent of his subject. But, if the rule here objected to (that the careful imitation of the parts injures the effect of the whole), be once admitted, slovenliness would become another name for genius, and the most unfinished performance be the best. That such has been the confused impression left on the mind by the perusal of Sir Joshua Reynolds's Discourses, is evident from the practice, as well as conversation, of many (even eminent) artists. The late Mr Opie proceeded entirely on this principle. He left many admirable studies of portraits, particularly in what relates to the disposition and effect of light and shade; but he never finished any of the parts, thinking them beneath the attention

* Why does not the British Institution, instead of patronising pictures of the battle of Waterloo, of red coats, foolish faces, and labels of victory, offer a prize for a picture of the subject of Ugolino that shall be equal to the group of the Laocoon? *That* would be the way to do something, if there is any thing to be done by such patronage.

of a great artist. He went over the whole head the second day as he had done the first, and therefore made no progress. The picture at last, having neither the lightness of a sketch, nor the accuracy of a finished work, looked coarse, laboured, and heavy. Titian is the most perfect example of high finishing. In him the details are engrafted on the most profound knowledge of effect, and attention to the character of what he represented. His pictures have the exact look of nature, the very tone and texture of flesh. The variety of his tints is blended into the greatest simplicity. There is a proper degree both of solidity and transparency. All the parts hang together; every stroke tells, and adds to the effect of the rest. Sir Joshua seems to deny that Titian finished much; and says that he produced, by two or three strokes of his pencil, effects which the most laborious copyist would in vain attempt to equal. It is true, he availed himself in some degree of what is called *execution*, to facilitate his imitation of the details and peculiarities of nature; but it was to facilitate, not to supersede it. There can be nothing more distinct than execution and daubing. Titian, however, made a very moderate, though a very admirable use of this power; and those who copy his pictures will find that the simplicity is in the results, not in the details. To conclude our observations on this head, we will only add, that, while the artist thinks there is any thing to be done, either to the whole or to the parts of his picture, which can give it still more the look of nature, if he is willing to proceed, we would not advise him to desist. This rule is the more necessary to the young student, for he will relax in his attention as he grows older. And again, with respect to the subordinate parts of a picture, there is no danger that he will bestow a disproportionate degree of labour upon them, because he will not feel the same interest in copying them, and because a much less degree of accuracy will serve every purpose of deception.

*Secondly*, with regard to the imitation of expression, we can hardly agree with Sir Joshua, that "the perfection of portrait-painting consists in giving the general idea or character without the individual peculiarities." No doubt, if we were to choose between the general character, and the peculiarities of feature, we ought to prefer the former. But, they are so far from being incompatible with, that they are not without some difficulty distinguishable from, each other. There is a general look of the face, a predominant expression arising from the correspondence and connection of the different parts, which it is of the first and last importance to give; and without which, no elaboration of detached parts, or marking of the peculiarities of single features, is worth any thing; but which, at the same time, is not destroyed, but assisted by the careful finishing, and still more by giving the exact outline of each part.

It is on this point that the modern French and English schools differ, and (in our opinion) are both wrong. The English seem generally to suppose, that if they only leave out the subordinate parts, they are sure of the general result. The French, on the contrary, as erroneously imagine, that, by attending successively to each separate part, they must infallibly arrive at a correct whole; not considering that, besides the parts, there is their relation to each other, and the general expression stamped upon them by the character of the individual, which to be seen must be felt; for it is demonstrable, that all character and expression, to be adequately represented, must be perceived by the mind, and not by the eye only. The French painters give only lines and precise differences; the English only general masses, and strong effects. Hence the two nations reproach one another with the difference of their styles of art, —the one as dry, hard, and minute,—the other as gross, gothic, and unfinished; and they will probably remain for ever satisfied with each other's defects, as they afford a very tolerable fund of consolation on either side.

Much has been said of *historical portrait;* and we have no objection to this phrase, if properly understood. The giving historical truth to a portrait, means, then, the representing the individual under one consistent, probable, and striking view; or showing the different features, muscles, &c. in one action, and modified by one principle. A portrait thus painted may be said to be *historical;* that is, it carries internal evidence of truth and propriety with it; and the number of individual peculiarities, as long as they are true to nature, cannot lessen, but must add to the strength of the general impression.

It might be shown (if there were room in this place) that Sir Joshua has constructed his theory of the *ideal* in art, upon the same mistaken principle of the negation or abstraction of *particular nature.* The *ideal* is not a negative but a positive thing. The leaving out the details or peculiarities of an individual face, does not make it one jot more ideal. To paint history, is to paint nature as answering to a general, predominant, or preconceived idea in the mind, of strength, beauty, action, passion, thought, &c.; but the way to do this is not to leave out the details, but to incorporate the general idea with the details;—that is, to show the same expression actuating and modifying every movement of the muscles, and the same character preserved consistently through every part of the body. Grandeur does not consist in omitting the parts, but in connecting all the parts into a whole, and in giving their combined and varied action: abstract truth or ideal perfection does not consist in rejecting the peculiarities of form, but in rejecting all those which are not consistent with the character intended to be given; and in following up the same *general idea* of softness, voluptuousness, strength, activity, or any combination of these through every ramification of the frame. But these modifications of form or expression can only be learnt from nature, and therefore the perfection of art must always be sought in nature. The ideal properly applies as much to the *idea* of ugliness, weakness, folly, meanness, vice, as of beauty, strength, wisdom, magnanimity, or virtue. The antique heads of fauns and satyrs, of Pan or Silenus, are quite as ideal as those of the Apollo or Bacchus; and Hogarth adhered to an idea of humour in his faces, as Raphael did to an idea of sentiment. But Raphael found the character of sentiment in nature as much as Hogarth did that of humour; otherwise

Fine Arts.

neither of them would have given one or the other with such perfect truth, purity, force, and keeping. Sir Joshua Reynolds's *ideal*, as consisting in a mere negation of individuality, bears just the same relation to real beauty or grandeur as caricature does to true comic character. *

Present state of British Art.

It is owing either to a mistaken theory of elevated art, or to the want of models in nature, that the English are hitherto without any painter of serious historical subjects, who can be placed in the first rank of genius. Many of the pictures of modern artists have shown a capacity for correct and happy delineation of actual objects and domestic incidents, only inferior to the masterpieces of the Dutch School. We might here mention the names of Wilkie, Collins, Heaphy, and many others. We have portrait-painters, who have attained to a very high degree of excellence in all the branches of their art. In landscape, Turner has shown a knowledge of the effects of air, and of powerful relief in objects, which was never surpassed. But in the highest walk of art—in giving the movements of the finer or loftier passions of the mind, this country has not produced a single painter, who has made even a faint approach to the excellence of the great Italian painters. We have, indeed, a good number of specimens of the clay-figure, the anatomical mechanism, the regular proportions measured by a two-foot rule;—large canvasses, covered with stiff figures, arranged in deliberate order, with the characters and story correctly expressed by uplifted eyes or hands, according to old receipt-books for the passions;—and with all the hardness and inflexibility of figures carved in wood, and painted over in good strong body colours, that look "as if some of nature's journeymen had made them, and not made them well." But we still want a Prometheus to give life to the cumbrous mass, to throw an intellectual light over the opaque image,—to embody the inmost refinements of thought to the outward eye,—to lay bare the very soul of passion. That picture is of little comparative value, which can be completely *translated* into another language,—of which the description in a common catalogue conveys all that is expressed by the picture itself; for it is the excellence of every art to give what can be given by no other, in the same degree. Much less is that picture to be esteemed, which only injures and defaces the idea already existing in the mind's eye,—which does not come up to the conception which the imagination forms of the subject, and substitutes a dull reality for high sentiment; for the art is in this case an encumbrance, not an assistance, and interferes with, instead of adding to, the stock of our pleasurable sensations. But we should be at a loss to point out (we will not say any English picture, but certainly) any English painter, who, in heroic and classical composition, has risen to the height of his subject, and answered the expectation of the well-informed spectator, or excited the same impression by visible means, as had been already excited by words, or by reflection. † That this inferiority in English art is not owing to a deficiency of genius, imagination, or passion, is proved sufficiently by the works of our poets and dramatic writers, which, in loftiness and force, are not surpassed by those of any other nation. But whatever may be the depth of internal thought and feeling in the English character, it seems to be *more internal*; and (whether this is owing to habit, or physical constitution) to have, comparatively, a less immediate and powerful communication with the organic expression of passion,—which exhibits the thoughts and feelings in the countenance, and furnishes matter for the historic muse of painting. The English artist is instantly sensible that the flutter, grimace, and extravagance of the French physiognomy, are incompatible with high history; and we are at no loss to explain in this way, that is, from the defect of living models, how it is that the productions of the French school are marked with all the affectation of national caricature, or sink into tame and lifeless imitations of the antique. May we not account satisfactorily for the general defects of our own historic productions, in a similar way,—from a certain inertness and constitutional phlegm, which does not habitually impress the workings of the mind in correspondent traces on the countenance, and which may also render us less sensible of these outward and visible signs of passion, even when they are so impressed there? The irregularity of proportion, and want of symmetry, in the structure of the national features, though it certainly enhances the difficulty of infusing natural grace and grandeur into the works of art, rather accounts for our not having been able to attain the exquisite refinements of Grecian sculpture, than for our not having rivalled the Italian painters in expression.

Mr West does not form an exception to, but a confirmation of, these general observations. His pictures have all that can be required in what relates to the composition of the subject; to the regular arrangement of the groups; the anatomical proportions of the human body; and the technical knowledge of expression,—as far as expression is reducible to abstract rules, and is merely a vehicle for the telling of a story; so that anger, wonder, sorrow, pity, &c. have each their appropriate and well-known designations. These, however, are but the instrumental parts of the art, the means, not the end; but beyond these, Mr West's pictures do not go. They never "snatch a grace beyond the reach of art." They exhibit the *mask*, not the *soul* of expression. We doubt, whether, in the entire range of Mr West's productions, meritorious and admirable as the design and composition often are, there is to be found one truly fine head. They display a total want of gusto. In Raphael, the same divine spirit breathes through every part; it either agitates the inmost frame, or plays in gentle undulations on the trembling surface. Whether we see his figures bending with all the blandishments of maternal love, or standing in the motionless silence of thought, or hurried into the tumult of action, the

* This subject of the *Ideal* will be resumed, and more particularly enlarged upon, under that head.

† If we were to make any qualification of this censure, it would be in favour of some of Mr Northcote's compositions from early English history.

whole is under the impulse of deep passion. But Mr West sees hardly any thing in the human face but bones and cartilages; or, if he avails himself of the more flexible machinery of nerves and muscles, it is only by rule and method. The effect is not that which the soul of passion impresses on the countenance, and which the soul of genius alone can seize; but such as might, in a good measure, be given to wooden puppets or pasteboard figures, pulled by wires, and taught to open the mouth, or knit the forehead, or raise the eyes in a very scientific manner. In fact, there is no want of art or learning in his pictures, but of nature and feeling.

Means of promoting the Fine Arts.

It is not long ago that an opinion was very general, that all that was wanting to the highest splendour and perfection of the arts in this country might be supplied by Academies and public institutions. We believe the most sanguine promoters of this scheme have at present relaxed in their zeal. There are *three* ways in which Academies and public institutions may be supposed to promote the fine arts; either by furnishing the best models to the student; or by holding out immediate emolument and patronage; or by improving the public taste. We shall bestow a short consideration on the influence of each.

First, a constant reference to the best models of art necessarily tends to enervate the mind, to intercept our view of nature, and to distract the attention by a variety of unattainable excellence. An intimate acquaintance with the works of the celebrated masters may indeed add to the indolent refinements of taste, but will never produce one work of original genius, one great artist. In proof of the general truth of this observation, we might cite the history of the progress and decay of art in all countries where it has flourished. It is a little extraordinary, that if the real sources of perfection are to be sought in Schools, in Models, and Public Institutions, that wherever schools, models, and public institutions have existed, there the arts should regularly disappear,—that the effect should never follow from the cause.

The Greek statues remain to this day unrivalled,—the undisputed standard of the most perfect symmetry of form. In Italy the art of painting has had the same fate. After its long and painful struggles in the time of the earlier artists, Cimabue, Ghirlandaio, Massacio, and others, it burst out with a light almost too dazzling to behold, in the works of Titian, Michael Angelo, Raphael, and Correggio; which was reflected, with diminished lustre, in the productions of their immediate disciples; lingered for a while with the school of the Carraccis, and expired with Guido Reni. From that period, painting sunk to so low a state in Italy as to excite only pity or contempt. There is not a single name to redeem its faded glory from utter oblivion. Yet this has not been owing to any want of Dilettanti and Della Cruscan societies,—of academies of Florence, of Bologna, of Parma, and Pisa,—of honorary members and Foreign Correspondents,—of pupils and teachers, professors and patrons, and the whole busy tribe of critics and connoisseurs.

What is become of the successors of Rubens, Rembrandt, and Vandyke? What have the French Academicians done for the arts; or what will they ever do, but add intolerable affectation and grimace to centos of heads from the antique, and caricature Greek forms by putting them into opera attitudes? Nicholas Poussin is the only example on record, in favour of the contrary theory, and we have already sufficiently noticed his defects. What extraordinary advances have we made in our own country in consequence of the establishment of the Royal Academy? What greater names has the English school to boast than those of Hogarth, Reynolds, and Wilson, who created it? Even the venerable President of the Royal Academy was one of its founders.

Again, we might cite, in support of our assertion, the works of Carlo Maratti, of Raphael Mengs, or of any of the effeminate school of critics and copyists, who have attempted to blend the borrowed beauties of others in a perfect whole. What do they contain, but a negation of every excellence which they pretend to combine? The assiduous imitator, in his attempts to grasp all, loses his hold of that which was placed within his reach, and, from aspiring at universal excellence, sinks into uniform mediocrity. The student who has models of every kind of excellence constantly before him, is not only diverted from that particular walk of art, in which, by patient exertion, he might have obtained ultimate success, but, from having his imagination habitually raised to an overstrained standard of refinement, by the sight of the most exquisite examples in art, he becomes impatient and dissatisfied with his own attempts, determines to reach the same perfection all at once, or throws down his pencil in despair. Thus the young enthusiast, whose genius and energy were to rival the great Masters of antiquity, or create a new æra in the art itself, baffled in his first sanguine expectations, reposes in indolence on what others have done; wonders how such perfection could have been achieved,—grows familiar with the minutest peculiarities of the different schools,—flutters between the splendour of Rubens, and the grace of Raphael, and ends in nothing. Such was not Correggio. He saw and felt for himself; he was of no school, but had his own world of art to create. That image of truth and beauty, which existed in his mind, he was forced to construct for himself, without rules or models. As it had arisen in his mind from the contemplation of nature, so he could only hope to embody it to others, by the imitation of nature. We can conceive the work growing under his hands by slow and patient touches, approaching nearer to prefection, softened into finer grace, gaining strength from delicacy, and at last reflecting the pure image of nature on the canvass. Such is always the true progress of art; such are the necessary means by which the greatest works of every kind have been produced. They have been the effect of power gathering strength from exercise, and warmth from its own impulse—stimulated to fresh efforts by conscious success, and by the surprise and strangeness of a new world of beauty, opening to the delighted imagination. The triumphs of art were victories over the difficulties of art; the prodigies of genius, the result of that strength which had grappled with nature. Titian copied even a plant or a piece of common drapery from the objects

themselves; and Raphael is known to have made elaborate studies of the principal heads in his pictures. All the great painters of this period were thoroughly grounded in the first principles of their art; had learned to copy a face, a hand, or an eye, and had acquired patience to finish a single figure, before they undertook to paint extensive compositions. They knew that though Fame is represented with her head above the clouds, her feet rest upon the earth. Genius can only have its full scope, where, though much may have been done, more remains to do; where models exist chiefly to show the deficiencies of art, and where the perfect idea is left to be filled up in the painter's imagination. When once the stimulus of novelty and of original exertion is wanting, generations repose on what has been done for them by their predecessors, as individuals, after a certain period, rest satisfied with the knowledge they have already acquired.

With regard to the pecuniary advantages arising from the public patronage of the arts;—the plan unfortunately defeats itself; for it multiplies its objects faster than it can satisfy their claims; and raises up a swarm of competitors for the prize of genius from the dregs of idleness and dulness. The real patron is anxious to reward merit, not to encourage gratuitous pretensions to it; to see that the man of genius *takes no detriment*, that another Wilson is not left to perish for want;—not to propagate the breed of embryo candidates for fame. Offers of public and promiscuous patronage can in general be little better than a species of intellectual seduction, administering provocatives to vanity and avarice, and leading astray the youth of the nation by fallacious hopes, which can scarcely ever be realized. At the same time, the good that might be done by private taste and benevolence, is in a great measure defeated. The moment that a few individuals of discernment and liberal spirit become members of a public body, they are no longer any thing more than parts of a machine, which is usually wielded at will by some officious, overweening pretender; their good-sense and good-nature are lost in a mass of ignorance and presumption; their names only serve to reflect credit on proceedings in which they have no share, and which are determined on by a majority of persons who have no interest in the arts but what arises from the importance attached to them by regular organization, and no opinions but what are dictated to them by some self-constituted judge. As far as we have had an opportunity of observing the conduct of such bodies of men, instead of taking the lead of public opinion, of giving a firm, manly, and independent tone to that opinion, they make it their business to watch all its caprices, and follow it in every casual turning. They dare not give their sanction to sterling merit, struggling with difficulties, but take advantage of its success, to reflect credit on their own reputation for sagacity. Their taste is a servile dependant on their vanity, and their patronage has an air of pauperism about it. Perhaps the only public patronage which was ever really useful to the arts, or worthy of them, was that which they received first in Greece, and afterwards in Italy, from the religious institutions of the country; when the artist felt himself, as it were, a servant at the altar; when his hand gave a visible form to Gods or Heroes, Angels or Apostles; and when the enthusiasm of genius was exalted by mingling with the flame of national devotion. The artist was not here degraded, by being made the dependant on the caprice of wealth or fashion, but felt himself at once the servant and the benefactor of the public. He had to embody, by the highest efforts of his art, subjects which were sacred to the imagination and feelings of the spectators; there was a common link, a mutual sympathy between them in their common faith! Every other mode of patronage, but that which arises, either from the general institutions and manners of a people, or from the real unaffected taste of individuals, must, we conceive, be illegitimate, corrupted in its source, and either ineffectual or injurious to its professed object.

Lastly, Academies and Institutions may be supposed to assist the progress of the fine arts, by promoting a wider taste for them.

In general, it must happen in the first stages of the arts, that as none but those who had a natural genius for them, would attempt to practise them,—so none but those who had a natural taste for them, would pretend to judge of or criticise them. This must be an incalculable advantage to the man of true genius; for it is no other than the privilege of being tried by his peers. In an age when connoisseurship had not become a fashion; when religion, war, and intrigue, occupied the time and thoughts of the great, only those minds of superior refinement would be led to notice the works of art, who had a real sense of their excellence; and, in giving way to the powerful bent of his own genius, the painter was most likely to consult the taste of his judges. He had not to deal with pretenders to taste, through vanity, affectation, and idleness. He had to appeal to the higher faculties of the soul,—to that deep and innate sensibility to truth and beauty, which required only fit objects to have its enthusiasm excited,—and to that independent strength of mind, which, in the midst of ignorance and barbarism, hailed and fostered genius, wherever it met with it. Titian was patronised by Charles V. Count Castiglione was the friend of Raphael. These were true patrons and true critics; and, as there were no others (for the world, in general, merely looked on and wondered), there can be little doubt that such a period of dearth of factitious patronage would be most favourable to the full developement of the greatest talents, and to the attainment of the highest excellence.

By means of public institutions, the number of candidates for fame, and pretenders to criticism, is increased beyond all calculation, while the quantity of genius and feeling remain much the same as before; with these disadvantages, that the man of original genius is often lost among the crowd of competitors who would never have become such, but from encouragement and example, and that the voice of the few whom nature intended for judges, is apt to be drowned in the noisy and forward suffrages of shallow smatterers in Taste. ASIA. Under this head in the *Encyclopædia*, there is a general survey of Asia and its Divisions, and of the prevailing manners, religions, and institutions of its chief Communities. We have, in this volume, already treated in a general way of those grand Divisions of our Globe, AFRICA and AMERICA; and notwithstanding the extent of the space devoted to ASIA in the body of the work, the recent acquisitions to our knowledge of that Continent might also, without impropriety, have been made the subject of a supplemental article in this place; but as these additions are more susceptible, than in the case either of AFRICA or AMERICA, of being separately introduced under the names of particular Countries and Islands, we shall, in order to save room for other matters, adopt that course in regard to the recent improvements in Asiatic geography.

It is proper to mention, that the best of the later Geographers have separated a vast number of Islands formerly described as *Asiatic* Islands, from that Continent, and arranged them with a multitude of other Countries and Islands to the south of Asia, and in the Pacific Ocean, under the two new divisions of AUSTRALASIA and POLYNESIA. The grounds of this arrangement, which was first suggested by the learned President des Brosses, are stated with sufficient clearness by Mr Pinkerton, in his introductory observations on the ASIATIC *Islands;* and the reader of this work will also find them explained under our articles on AUSTRALASIA and POLYNESIA.

We may here observe generally, that a great deal yet remains to be done in order to complete the geography of Asia. Its central mountains, perhaps the most stupendous masses on the Globe, present a wholly unexplored field of inquiry; the origin, the course, and progressive increase of some of its greatest rivers, remain still to be ascertained; and scarce any of its internal seas, except the Caspian, has been the subject of actual survey. The interior regions of Siberia require much illustration. The same may be said, and perhaps in a still stronger degree, of the central parts of Tartary, of the northern parts of China, and of those of India. As to the probable *population* of this Continent, it is enough to say, that differences of a hundred millions exist in regard to that of China alone. From all this it appears how very defective our knowledge is of this important Division of the Globe, and what a vast and varied field it still presents to incite the inquiries, and reward the enterprise of future Explorers.

ASPHALTITES, a Lake of Judea, near Jerusalem, so called from the *Bitumen* which floats upon its surface; and equally well known under the name of the *Dead Sea;*—a name associated with many fables, and derived from a long standing belief, that no creature could live in its waters, or within the reach of its pestiferous exhalations.

The reader will find the substance of the ancient accounts, and those of the earlier Travellers in regard to this famous Lake, in the article under its name in the *Encyclopædia;* we shall therefore confine ourselves in this place, to such authentic particulars, as have been furnished by the observations and inquiries of those who have recently visited the *Holy Land.*

This Lake is supposed to be from sixty to seventy miles in length, and from ten to twenty in breadth. It is curved like a bow, and placed between two ranges of mountains, of lofty and majestic appearance. But the grandeur of its features is blended with an air of sadness and desolation, which seems to accord well with the marvellous stories associated with its name.

Some of these fables have an obvious foundation in its physical properties. Its taste is remarkably bitter, saline, and pungent; and hence has arisen the notion of its pestiferous vapours and deadly influence. We are told even by Volney, that its waters are destructive both of animal and vegetable life; but he denies that its vapours have any deadly quality, for swallows, he says, are often seen to skim its surface without injury. M. De Chateaubriand, who visited its shores in 1807, with an imagination abundantly disposed to the marvellous, has given the first decided testimony that it abounds with fish. He reached the Lake when it was already dark, and passed the night among some Arab tents. "About midnight," says he, "I heard a noise upon the Lake, and was told by the Bethlehemites who accompanied me, that it proceeded from *legions of small fish* which come out and leap about on the shore." This interesting Traveller speaks in the following terms of its saline properties: "The first thing I did on alighting was to walk into the Lake up to my knees, and to taste the water. I found it impossible to keep it in my mouth. It far exceeds that of the sea in saltness, and produces upon the lips the effect of a strong solution of alum. Before my boots were completely dry, they were covered with salt: our clothes, our hats, our hands, were in less than three hours impregnated with this mineral."

The common story, that nothing will sink in it, is to be ascribed to the extraordinary density of its waters. Bodies follow the general law, and sink or swim, according to the proportion of their gravity to the gravity of the water of the Lake; but its specific gravity is such, that a man may lie upon its surface motionless, without danger of sinking. This effect was experienced by Pococke, and by a Scottish traveller, Mr Gordon of Clunie, who also bathed in it. This gentleman brought home a phial of its water, and Dr Marcet found its specific gravity to be 1.211; a degree of density, says he, "not to be met with in any other natural water." Dr Marcet was employed to analyse Mr Gordon's specimen, which that gentleman had presented to Sir Joseph Banks in 1807; and the whole process, with its results, is detailed in the *Philosophical Transactions* for that year. It was found that 100 grains of the water contains the following substances, in the under-mentioned proportions:

| | Grains. |
|---|---|
| Muriat of lime . . . . | 3,920 |
| Muriat of magnesia . . . | 10,246 |
| Muriat of soda . . . . | 10,360 |
| Sulphat of lime . . . | 0,054 |
| | 24,580 |

The water of the Dead Sea had been previously analysed by Messrs Macquer, Lavoisier, and Sage, of whose experiments an account was published in the *Mémoires de l'Academie des Sciences* for the year 1778. Their analysis afforded results greatly different from those obtained by Dr Marcet, which that gentleman ascribes to some inaccuracy in their mode of operating. We find, however, that the processes employed by Dr Marcet have been called in question, and the accuracy of his proportions denied by a very skilful Chemist, who subsequently instituted an analysis of the Dead Sea water. We allude to Klaproth, who procured a specimen brought from the East by the Abbé Mariti, and whose analysis offered the following proportions:

| | |
|---|---|
| Muriat of magnesia | 24,20 |
| Muriat of lime | 10,60 |
| Muriat of soda | 7,80 |
| | 42,60 |
| Water | 57,40 |
| | 100. |

Klaproth also found the specific gravity to be 1,245 instead of 1,211; agreeing in this respect more nearly with Macquer and Lavoisier, who stated it at 1,240. The specific gravity of Dr Marcet's specimen may, however, have been less, from its having been taken from the Lake, not far from the influx of the Jordan, on which account it might be somewhat diluted.

Dr Clarke mentions, that the inhabitants of the country still regard the Dead Sea with feelings of terror This may be owing to the tradition that its waters cover the engulphed cities of Sodom and Gomorrah, or to the ideas entertained of the peculiar insalubrity of its exhalations. It is much to be regretted, that this Traveller was prevented by the Arabs, who infested the neighbourhood, from exploring the Lake, which he only saw at some distance; as with his attainments, he could not have failed to gather some interesting information regarding its natural history. Though M. de Chateaubriand, a few years after, succeeded in reaching its banks, he could only, owing to the same cause, remain a few hours; and besides, however capable of interesting his readers, he was not so well qualified for accurate or scientific observation. While some of his facts run counter to the ancient fables, others seem calculated to add to the list; as, when he discovers a resemblance between the noise of its waves, and the stiffled clamours of the people whom they engulphed! The following passage, however, is of the antifabulous kind, and contains some information which cannot but be acceptable to our readers. "There is scarcely any one who has not heard of the famous tree of Sodom; a tree, said to produce an apple pleasing to the eye, but bitter to the taste, and full of ashes. Tacitus, in the fifth book of his *History*, and Josephus, in his *Jewish war*, are, I believe, the two first authors that made mention of the singular fruits of the Dead Sea. Foulcher de Chartres, who travelled in Palestine about the year 1100, saw the deceitful apple, and compared it to the pleasures of the world. Since that period, some writers, as Ceverius de Vera, Baumgarten, de la Vallée, Troilo, and certain Missionaries, confirm Foulcher's statement; others, as Reland, Father Neret, and Maundrell, are inclined to believe that this fruit is but a poetic image of our false joys; while others again, as Pococke and Shaw, absolutely question its existence.

"Amman seemed to remove the difficulty. He gave a description of the tree, which, according to him, resembles the hawthorn. "The fruit," says he, "is a small apple, of a beautiful colour."

"Hasselquist, the Botanist, followed, and he tells a totally different story. The apple of Sodom, as we are informed by him, is not the fruit either of a tree or of a shrub, but the production of the *Solanum melongena* of Linnæus. "It is found in great abundance," says he, "round Jericho, in the valleys near the Jordan, and in the neighbourhood of the Dead Sea. It is true that these apples are sometimes full of *dust;* but this appears only when the fruit is attacked by an insect *(tenthredo)*, which converts the whole of the inside into dust, leaving nothing but the rind entire, without causing it to lose any of its colour."

"Who would not imagine, after this, that the question had been set completely at rest, by the authority of Hasselquist, and the still greater authority of Linnæus, in his *Flora Palæstina?* No such thing. M. Seetzen, also a man of science, and the most modern of all Travellers, since he is still in Arabia, does not agree with Hasselquist in regard to the *Solanum Sodomeum*. "I saw," says he, "during my stay at Karrak, in the house of the Greek clergyman of that town, a species of cotton resembling silk. This cotton, as he told me, grows in the plain of El Gor, near the southern extremity of the Dead Sea, on a tree like a fig-tree, called *Abescha-ez;* it is found in a fruit resembling the pomegranate. It struck me, that this fruit, which has no pulp or flesh in the inside, and is unknown in the rest of Palestine, might be the celebrated apple of Sodom."

"Here I am thrown into an awkward dilemma; for I too have the vanity to imagine that I have discovered the long-sought fruit. The shrub which bears it grows two or three leagues from the mouth of the Jordan: it is thorny, and has small taper leaves. It bears a considerable resemblance to the shrub described by Amman; and its fruit is exactly like the little Egyptian lemon, both in size and colour. Before it is ripe, it is filled with a corrosive and saline juice; when dried it yields a blackish seed, which may be compared to ashes, and which in taste resembles bitter pepper." See Chateaubriand's *Travels in Greece, Palestine, Egypt, and Barbary*.—Dr Clarke's *Travels in Greece, Egypt, and the Holy Land*.—*Philosophical Transactions* of the Royal Society of London for 1807.—Klaproth, *Beiträge zur Chemischen Kenntniss der Mineral Körper*. B. 5. p. 185. Berlin, 1810.

ASSAM, a kingdom of Asia, situated on the north-west of Bengal, between the 25th and 26th degrees

of north latitude, and extending from 94 to 99 degrees of east longitude. The exact limits, however, are not precisely ascertained; for this country is very little known to Europeans, and what respects its extent to the east is at present to be understood as partly conjectural. Assam is an immense valley, about 700 miles in length, by between 60 and 80 in breadth, surrounded by high hills on all sides, and interspersed with numerous eminences in the interior, universally susceptible of cultivation. The whole superficies is calculated at 60,000 square miles, a large portion of which is occupied by woods and rivers, and the remainder consists chiefly of fertile soil; but this calculation is exclusive of any conquered countries, and of the territories that extend in every line beyond the hills. Part of the kingdom is mountainous, particularly what is called Higher or Upper Assam; and part of it is low and level, containing extensive plains, subject to frequent inundations in the rainy seasons. The general position of this great valley, as well as of the mountains and rivers traversing it, is in a direction from north to south. It is bounded on the north by the successive ranges of the mountains of Bootan, Anka, Duffala, and Miree; and, on the south, by the Garrow Mountains, which rise higher as they recede northward, and change their name to Naga at a place called Coliabark. Probably the rivers intersecting Assam are more numerous than those of any other country of equal extent in the universe, from its being completely environed by hills. The rains are collected together, and, pouring down in irresistible torrents, swell the waters below, until the plains are covered by the inundation. The valley is divided throughout, by the Burhampooter, into two parts nearly equal; and many Islands, some of them very large, are formed by it, and by the confluence and mutual intersection of other rivers. They contribute alike to fertilize the ground, and to facilitate the intercourse of the inhabitants, as they are navigable by flat-bottomed boats, capable of transporting them and their property. Of these rivers, not less than sixty-one are known and distinguished by particular names, of which thirty-four flow from the northern, and twenty-four from the southern mountains; but the source of the Burhampooter is scarcely yet ascertained, nor were Europeans acquainted with its course until traced by Major Rennell. However, it seems to rise beyond the confines of Assam. As the rivers change their names at different places, it is sometimes difficult to discover those that are meant in description; and their size may be estimated differently, according as they are examined in the time of inundation, or otherwise. The length of the course, and the sinuosities of many, are remarkable. The Dhekow or Degoo, by the size of which Geographers are accustomed to compare the other rivers, rises very far to the eastward of the Naga mountains, which it traverses for a considerable distance, and then winds 200 miles through the valley from its entrance, until joining the Dehingh, a great branch of the Burhampooter. Another river, the Dekrungh, rises in the Duffala mountains, and, exhibiting a large stream, occupies 100 miles in its windings, before falling into the Burhampooter, though the direct line does not exceed 25. Notwithstanding its depth and rapidity, it is navigable by small boats. The river Pisola, which likewise rises in the Duffala mountains, pursues a winding course of 60 miles, and, during the rainy season, may be ascended to the base of the mountains; but it is not navigable after the inundations subside. The rivers to the south are never so rapid, as the inundations commence from the northern rivers. Both these and the Burhampooter are filled, so that the water has no considerable current until May or June, when the current is rather stronger from the south in the season of the rains, though the increase is not very material, as the large river at this period is always pretty full, and checks the rapidity of all the southern rivers.

Among the numerous Islands of different dimensions, formed by the intersection and confluence of the rivers, is Majuli, or the Great Island, as it is called by pre-eminence, which appears to constitute one of the chief political divisions of the kingdom. This Island extends 100 miles in length, by about 60 in breadth; and is formed by the river Dehingh on the west, and the Looicheh on the north; but independent of these great aquatic boundaries, it is intersected by numerous streams, so that it, in fact, consists of a cluster of lesser Islands, and some Islets, besides, near the banks, which in the principal rivers are dry only while no inundations prevail. The other Islands throughout Assam are of all different dimensions, from the most inconsiderable size to six, ten, or twenty miles and more in length. A correct picture of the country may thus be figured as being an extensive valley, environed by mountains, full of rivers and level plains. While the rivers constitute its defence, and promote the convenience of its inhabitants, as also contribute to fertilize the soil overflowed by their inundations, they interrupt occasional intercourse from their magnitude and rapidity; and it is to be observed, that there is only one stone-bridge in the kingdom, which was erected at Rungpoon by workmen brought from Bengal. Besides the Great Island or Majuli, Assam contains other two political divisions. Ootrecole, Uttarcul, or Ootreparah; Deccancole, Dacshincul, or Deccanparah; the former of which, Ootrecole, denotes the country lying north of the Burhampooter; the latter, Deccancole, that to the south. And it is further to be remarked, that Majuli is formed by great arms of the same river, though passing by different names.

The political subdivisions of Assam are apparently almost as numerous as the more important natural ones; but the province of Camroop in Ootrecole, is one of the largest and the best known by description, at least, to Europeans. It formerly gave name to an extensive kingdom, of which the capital seems to have been Rangmattee, beyond the present western confines of Assam. It now stretches about 100 miles in length, and its breadth, from the banks of the Burhampooter to the foot of the mountains, is 40 miles. There are no strong places within its limits, and its chief town is Cotta. The district Summooria, occupies the southern banks of the Burhampooter; and the district of Nodooaria, which extends to the eastward, is divided into nine shares or districts, held by so many rajahs, though under the rule of only two.

Assam.

Valuable minerals are found in Assam; the whole country produces gold in abundance, insomuch that from 12.000 to 20,000 of the inhabitants are said to have been constantly employed in collecting it. This precious metal is found in all the rivers flowing from the northern mountains, but it is of different quality in purity and colour, and also in malleability. That which is obtained in the Dekrungh is particularly celebrated; and it is distinguished by a higher colour than what is found in the Burhampooter and other rivers. Gold is more abundant in the bed of the Burrowgown than in the channel of most rivers, but is thought of inferior colour and quality. What is procured from the bed of the Burrogown is esteemed as much superior even to the gold of the Dekrungh; the colour is deeper and more vivid, and is compared by the natives to fire; it is likewise deemed of more intrinsic value, and always bears a greater price in Assam. The greatest quantities of gold are found nearest the mountains, which probably indicates that it is carried down from them by the torrents, but it is never sought in the beds of the southern rivers. In the others, as those flowing from the north, it is of paler colour, less pure, and in smaller quantity, according as it is recovered from the mines farther to the east. The persons employed in collecting it, pay a small tribute to the Sovereign in proportion to their success. Besides this precious metal, there are mines of silver, lead, and iron, which all belong to the King, and are wrought for his advantage alone. Rock-salt is dug out of the earth, but it is bitter, and of indifferent quality. The vegetable products of Assam are abundant, and of excellent quality; thick and extensive forests cover a large portion of the country; cultivated fields, especially of rice, the staple grain for subsistence, and the finest fruits, are generally to be seen. A Persian writer, Mahommed Cazim, in describing this country, makes some observations on its general appearance, which, as he was hostile to the inhabitants, may probably merit the greater confidence. He speaks of Majuli as "an Island well inhabited, and in an excellent state of agriculture; it contains a spacious, clear, and pleasant country, extending to the distance of about 100 miles. The cultivated part is bounded by a thick forest, which harbours elephants, and where these animals may be caught, as well as in four or five other forests of Assam. If there be occasion for them, five or six hundred elephants may be procured in a year. Across the Dhonec, which is the side of Ghergong, is a wide agreeable level country, that delights the heart of the beholder. The whole face of it is marked with population and tillage, and it presents, on every side, charming prospects of ploughed fields, harvests, gardens, and groves. From the village of Salagerah to the city of Ghergong, a space of about 100 miles, is filled with such an uninterrupted range of gardens, plentifully stocked with fruit-trees, that it appears as one garden. Within them are the houses of peasants, and a beautiful assemblage of coloured and fragrant herbs, and of garden and wild flowers blowing together. As the country is overflowed in the rainy season, a high and broad causeway has been raised for the convenience of travellers, from Salagerah to Ghergong, which is the only uncultivated ground that is to be seen. Each side of this road is planted with shady bamboos, the tops of which meet and are entwined. Among the fruits which this country produces, are mangoes, plantains, jacks, oranges, citrons, limes, and punialeh, a species of amleh, which has such an excellent flavour, that every person who tastes it, prefers it to the plum. There are also cocoa-nut trees, pepper, vines, areca trees, and the sadij (an aromatic leaf), in great plenty. Sugar-cane excels in softness and sweetness, and is of three colours, black, red, and white; there is ginger free from fibres and betal vines. The strength of vegetation and fertility of the soil is such, that wherever seed is sown, or slips planted, they always thrive. The environs of Ghergong furnish small apricots, yams, and pomegranates, but as these are wild, and not assisted by cultivation and engrafting, they are very indifferent. The principal crop of this country consists in rice and mash. Ades (a kind of pea) is very scarce, and wheat and barley are never sown." This is a favourable picture of the Kingdom, and although the revolutions and convulsions which it has since undergone, may have affected the industry of the inhabitants, the means of renewing it remain.

Elephants, wild buffaloes, hogs, and tigers, haunt the banks of the rivers, which are covered with grass and reeds so as to be impenetrable by men. It has been affirmed that there are neither horses, asses, nor camels here, though two species of the first are natives of a neighbouring territory. The other animals are unknown, but the rivers abound so plentifully with fish as to afford a copious supply to the inhabitants. A particular kind of animal, different from the common silk-worm, according to Turpin, produces silk of another texture, with which beautiful dresses, but of bad quality, are fabricated.

It is not unlikely that some external physical distinctions prevail among the natives, according as they inhabit the high or the low countries, and that their moral qualities are influenced by the same cause. Mahommed Cazim remarks, that the complexion of the mountaineers, like that of the inhabitants of all cold climates, is red and white. They are an active, hardy race, well formed, but the noses of the women are flattish. Both sexes go almost naked; formerly the mountaineers were absolutely so; and, unlike the easterns in general, none of the females, even those of the highest rank, are veiled. They wear a blue bonnet or cap, from which hogs' teeth are suspended, which is perhaps of more recent use, as the Persian just referred to says they had neither turbans, robes, drawers, nor shoes. Their most valuable ornaments, at present, are bracelets of coral or yellow amber, and sometimes tortoise shell or sea shells. They dwell in habitations constructed of wood, bamboos, and straw, and there is only an inconsiderable difference between those of the more wealthy and the poorer classes. With regard to their state of civilization, or their manners and customs, we have very little certain information applicable to the present times. Most probably the mountaineers are more barbarous than the inhabitants of the low country and the plains; and as the kingdom is di-

Assam.

vided into a number of petty States, those may be subordinate to some paramount authority; but the frequent broils of the Rajahs retard the civilization of their subjects. Mahommed Cazim, who entertained a decided aversion to the Assamese, reproaches them with indiscriminately feeding "on all kinds of food, human flesh excepted; they even eat animals that have died a natural death." He divides them into two tribes, Assamians and Cultanians; the latter excelling the former in every thing but warlike operations.

It appears that the government of this Kingdom is monarchical, and that a Sultan or Rajah rules the whole; yet, owing to the incessant contest for power, the course of succession, if it be hereditary, is disturbed, and the most potent Chief, gaining an ascendency, restores the country to peace. The government was wont to be mildly administered: in the words of Turpin, the "king was attentive to the happiness of his subjects, and employed none excepting slaves to labour in the mines. It was the only country where humanity was not crushed under the pressure of despotism." Formerly the Rajah kept a guard of six or seven thousand warlike troops, whose courage was equal to any enterprise.

The religion of these people is supposed by Mr Hamilton to be Brahminical. It is certain that they have many temples erected to their Divinities throughout their territories, although the character and description of these Divinities have never been explained. In the time of Aurengzebe, they are said to have had no settled faith; "they do not adopt any mode of worship, practised either by Heathens or Mahometans. Nor do they concur with any of the known sects which prevail amongst mankind." But it is by no means credible, that all their temples have been erected since that æra. Rafts, covered with human heads, are sometimes seen floating down the Burhampooter through Bengal, which has excited conjectures that they belonged to victims offered to their sanguinary Deities. It is not evident, however, that human sacrifices, unless the destruction of life at funereal obsequies be called such, are publicly offered up in the neighbouring Asiatic territories. This species of barbarity has been widely extended over the world; captives were slaughtered at the pile of the ancients; slaves were buried alive to serve their masters in the world to come; and even the chosen wife of her husband's affections has been doomed to destruction at the same moment that his earthly remains were consigned to oblivion. Such customs have been familiar to mankind from the earliest records of time; and, among the rest, were practised by the natives of Assam. On the decease of a Rajah, or any distinguished person, a capacious pit was prepared, where not only his own body, but many of his women and attendants, were also buried. Of the latter was a torch-bearer, together with a quantity of oil and lamps, as essential to his comfort in a future state; some of his most elegant and useful furniture, carpets and clothes, were, in like manner, included; and even elephants, together with gold and silver, formed part of the promiscuous assemblage. A strong roof, resting on thick timbers, was then constructed over the pit, and the miserable victims, not already slain, were left to perish by a lingering death.

In regard to the present state of the arts, it is to be inferred, that the Assamese are behind many nations in their vicinity: formerly they manufactured excellent silks, chiefly for home consumption; likewise they fabricated velvet, and embroidered it beautifully with flowers. Perhaps the same is continued, as also the extraction of salt from vegetable substances; and their gunpowder was reputed of the best quality. Nay, the Easterns hence ascribed the invention of this destructive substance to their ingenuity, and affirm that it passed from them to Pegu, and thence to China. Their chief exports to Bengal are gold, elephants' teeth, two kinds of lac, which was esteemed the finest in those regions,—a coarse raw silk, and coarse cotton cloths. Brandy is made from grapes, afforded by the numerous vines in Assam. Agriculture is certainly well understood; the populousness of several districts, which have attracted the attention of the Traveller, proves that there is no scarcity of subsistence; and well frequented fairs are spoken of as being held in different places. Assam contains some celebrated Temples, probably of ancient date; and their military causeways, constructed at an early period of their history, are of admirable extent and magnitude. One of these, now in a state of decay, runs from Cooch Bahar in Bengal, through Rangamatty, to the utmost extremity of the eastern limits of the kingdom, serving as a boundary of the Bootan dominions. Another, a work of immense labour, passes the capital; and the banks of the Dhekow is connected with the southern mountains by a lofty rampart, traversing the space of ten or fifteen miles. It is undoubted, that although most authors who have treated of this subject, describe these structures as military causeways only, they have served both as the means of communication among the inhabitants during the season of inundations, and as barriers to the overflowing rivers spreading still farther on the plains. Thus the great causeway, which approaches the capital, was raised to preserve the interior from the inundations of the Dehingh, while in the dry season, the river retires two miles from its base.

A great many towns and villages are scattered over the banks of the rivers of Assam, these having been peculiarly selected by the natives for their habitations; and a certain number seems to be included in a circle, under the same administration. The capital, which is called Ghergong, Kirgana, or perhaps more properly Gurgown, is situated in 25° 35′ north latitude, 93° 10′ east longitude, at a considerable distance above Rungpoor, which is sometimes called the capital, but is only the military station of Ghergong. It stands on the high banks of the river Dhekow, or Degoo, and until recent disasters had overwhelmed it, was a place of great extent. This city, Dr Wade, who resided ten years in Assam, describes to have been ten miles long by five in breadth; and we learn from other authors, that it was fortified and encircled by a fence of bamboos, enclosing villages and fields in its circuit. Like other cities of the East, each house stood separate, amidst a cultivated spot or

garden; each side of the river was lined with dwellings, and the royal palace was situated on its banks. It had four gates, constructed of earth and stone, from each of which the palace was distant four miles and a half, by which means its position was nearly in the centre, and close to the Dhekow. This palace was a spacious edifice, apparently between two and three miles in circuit, surrounded by a causeway, planted on each side by a close bamboo hedge, serving instead of a wall, and beyond them a wet ditch, always full of water. The interior contained many apartments, both for state and convenience, elegantly ornamented. Mahommed affirms it as an undoubted fact, that 3000 carpenters and 12,000 labourers were constantly occupied, during two years, in constructing the palace; but an insurrection, which took place about the year 1790, has proved almost totally destructive of it and the rest of the city. Rungpoor, situated in 25° 47′ north latitude, and 89° 5′ east longitude, stands on the opposite side of the Dhekow, with the river Numdaugh flowing on the south; a rampart, or causeway, to resist the inundations, protects it on the east; and on the west it is secured by a bridge, the only access whereby it can be approached. The circle including it contains several towns, and is about twelve miles in length, by ten in breadth. Goahautee is the capital of Lower Assam, and the residence of a Viceroy; the surrounding territory occupies a hilly country, on both sides of the Burhampooter, the hills on each side forming a spacious amphitheatre, which has been fortified equally by nature and art. The district Goahautee is divided into north and south, including several strong passes among the fortified hills. A great number of other towns might be mentioned by name; but, excepting their position, we are unacquainted with any thing regarding them. Many were greatly injured, and some totally ruined, by the distractions of the country; the cessation of which, for a few years, is now allowing them to recover from their disasters.

The history of this kingdom is involved in great obscurity, arising both from its remote situation, and from a jealousy of strangers, which has almost entirely precluded the access of Europeans; and by a singular fatality, after this difficulty had been conquered, by the admission and residence of an intelligent physician, Dr Wade, some of the most important materials collected by him were lost on being transmitted to Europe. The present race of inhabitants is said to have occupied the country during a thousand years, but not by any means in tranquillity; at least, we know that, since 1638, they have been involved in frequent contests with their neighbours. In these, however, they have, in general, been successful, for unconquerable obstacles are opposed to their enemies. "Whenever an invading army has entered their territories, the Assamese have sheltered themselves in strong posts, and have distressed the enemy by stratagems, surprises, and alarms, and by cutting off their provisions. If these means failed, they have declined a battle in the field, but have carried the peasants into the mountains, burnt the grain, and left the country desert. But when the rainy season has set in upon the advancing enemy, they have watched their opportunity to make excursions, and vent their rage; the famished invaders have either become their prisoners, or been put to death. In this manner, powerful and numerous armies have been sunk in that whirlpool of destruction, and not a soul has escaped." Such dangers were sufficient to intimidate the boldest adventurers, and we have the testimony of eye-witnesses that they are not exaggerated. About the close of the fifteenth century, Husein Shah, King of Bengal, invaded Assam, with a formidable force of cavalry, infantry, and also of boats; and, in the outset, was successful. The Rajah, unable to meet him in the plains, retired to the mountains, whither Husein could not follow him; but returning to Bengal, he left his son with a large army to keep possession of the country; the rainy season commenced, and the roads were shut up by inundations; then the Rajah descended from the mountains, intercepted the supplies of the invaders, harassed them with skirmishes, and cut off the whole in detail. Another Prince of Hindostan attempted the conquest of Assam, with an immense force of cavalry, but, says the author, who records the enterprise, they were all devoted to oblivion in that country of enchantment; and no intelligence or vestige of them remained. The Assamese, however, met with a reverse of fortune in leaving their own confines to sail down the Burhampooter, and assail the inhabitants of Bengal; for in the year 1638, they were repulsed by the troops of Shah Jehaun.

The Rajah of Assam had assumed or preserved the title of Sarjee or Swerg, which signifies celestial, and lived in great pomp and splendour in the reign of Aurengzebe, the Mogul Emperor, who died in 1707. That great Prince, desirous of extending his conquests, sent an army, under an able general, to attempt the subjugation of this Kingdom; partly, it would appear, to humble the pride of the Rajah, who was so vain-glorious as to believe that his ancestors were of divine origin, and that one of them, inclining to visit the earth, descended by a golden ladder; partly to disseminate the principles of the Mahometan faith. The army advanced victoriously, conquering all opposition, and gained possession of the capital. There the imperial general, considering himself firmly established, made many regulations for internal administration, and also proclaimed the Mahometan religion. Measures were taken for keeping the roads open, and for supplying the army with provisions; and as the season was now changing, he resolved, when the inundations subsided, to put his troops in motion to extirpate the Rajah, and those adherents who had escaped. The conquest of Assam extended to a large portion of the country, for all the villages of Decancole submitted to the invaders; and those of Ootrecole followed: Yet it is not to be inferred that this was accomplished without loss, for the panegyrist of the general describes the country as spacious, populous, and hard to be penetrated; that it abounded in dangers; that the paths and roads were beset with difficulties; and that the obstacles to conquest were more than could be expressed. The inhabitants, he says, were enterprising, well armed, and always prepared for

battle: they had lofty forts, numerously garrisoned, and plentifully provided with warlike stores; and the approach to them was opposed by thick and dangerous jungles, and broad and boisterous rivers. Under these circumstances, it was to be considered wonderful that the army had prevailed; "but the Musselman hordes experienced the comfort of fighting for their religion, and the blessings of it reverted to the sovereignty of his just and pious Majesty." But the Assamese were unsubdued: the climate proved destructive to the Moguls, and the general was obliged, first to evacuate the city, and as his troops were harassed by the natives, they were at last compelled to retreat from the country with diminished numbers.

Towards the earlier part of the eighteenth century, it is said that some of the Bramins of Bengal reached Assam, desirous of introducing their religion there, where the inhabitants still had no settled faith. Amidst their exertions for this great object, they persuaded them that it would be gratifying to their Deity, Brama, if they would use salt imported from Bengal in preference to their own, which it greatly excelled. To this the Sovereign consented, on condition that it should be monopolized by himself, and that the vessels conveying it should not penetrate beyond the frontier; and, in consequence, forty vessels, each of from 500 to 600 tons burden, have annually been sent thither.

About the year 1790, the Kingdom was in the most distracted state from a widely extended insurrection, followed by the absolute destruction of many important places; and, in the year 1793, a detachment of British troops was sent to aid the restoration of the Rajah, who seems to have been dethroned by the insurgents. This detachment gained the capital, and completely effected their object, and the Rajah was so sensible of the assistance he had derived, that he immediately concluded a commercial treaty very favourable to the British interests. It was probably on this occasion that Dr Wade visited Assam, and that Mr Wood, of the Engineers, constructed a map of a considerable portion of the country. Either this, or another, was transmitted to Britain, we have understood, to be deposited in the Advocates' Library at Edinburgh; but, after its arrival, it unfortunately never reached the place of its destination, which is much to be regretted, since the geography and history of the country are both so little known. The troops having remained some time in Assam, suffered severely from the pestilential climate, and returned to Bengal with considerable loss. (s.)

ASSAYING, taken generally, implies an examination or analysis of any substance, whose constituent parts are to be chemically determined. The term, however, more particularly relates to the ascertaining the qualities of Gold and Silver in relation to their state of purity; and in the following observations we mean to confine ourselves entirely to this object.

Importance of this Art.

In whatever point of view we consider the art of assaying these metals, it cannot fail to appear of great importance to the welfare and prosperity of the civilized world. Every one must be aware of the importance of a metallic currency agreeing in its standard fineness with the decree which establishes its circulation; and that it is an object of the greatest consequence to a nation, to have the means of ascertaining, with accuracy, the value of the coins issued by the authority of the Monarch. Since the reign of Henry the Eighth, we have had no capricious and unjustifiable changes in the standard fineness of our coins. That monarch, as Dr Henry remarks, "after he had squandered all his father's treasures, the grants he had received from Parliament, and the great sums he had derived from the dissolution of the religious houses, began to diminish his coins both in weight and fineness. This diminution at first was small, in hopes, perhaps, that it would not be perceived; but after he had got into this fatal career, he proceeded by rapid steps to the most pernicious lengths. In the thirty-sixth year of his reign, silver money of all the different kinds was coined, which had only one-half silver and the other half alloy. He did not even stop here; in the last year of his reign, he coined money that had only 4 oz. of silver and 8 oz. of alloy in the pound weight; and the nominal pound of this base money was worth only 9s. 3¾d. of our present money. He began to debase his gold coins at the same time, and proceeded by the same degrees. But it would be tedious to follow him in every step. In this degraded and debased condition Henry the Eighth left the money of his kingdom to his son and successor Edward the Sixth. This shameful debasement of the money of his kingdom, was one of the most imprudent, dishonourable, and pernicious measures of his reign; it was productive of innumerable inconveniencies and great perplexity in business of all kinds, and the restoration of it to its standard purity, was found to be a work of great difficulty." Henry's *History of Great Britain*, Vol. XII. p. 336 and 337.

To possess the art, therefore, by which such dishonourable proceedings as are just detailed, may be speedily detected, is evidently an object of the greatest utility; in as much as the debasement of the coin would require an adjustment of the relative value of commodities to the degraded standard; and the more facility that can be given to this adjustment, the less perplexity and injury will be sustained by the public.

The importance of the art of assaying will farther appear, when we consider the extent of the manufacture of plate, and ornamental articles of gold and silver; the standard value of which is determined by an assay of a few Troy grains only. The nicety and delicacy of the operation must be great, and much practical experience requisite to obtain uniformly a satisfactory result.

Description of Implements.

The principle of assaying gold and silver is very simple; it consists of two operations—the separation of the alloy from the precious metals, and the parting of these latter from each other.

Before proceeding to the detailed description of these processes, we shall describe the furnaces and implements used in the art of assaying.

Plate XXVIII. AAAA, fig. 1. is a front elevation of an assay furnace; *aa*, a view of one of the two iron

rollers on which the furnace rests, and by means of which it is moved forward or backward; *b* the ash-pit, *c c* are the ash-pit dampers, which are moved in a horizontal direction towards each other for regulating the draught of the furnace; *d* the door or opening by which the cupels and assays are introduced into the muffle; *e* a moveable funnel or chimney by which the draught of the furnace is increased.

BBBB, fig. 2. is a perpendicular section of fig. 1.; *aa* end view of the rollers; *b* the ash-pit; *c* one of the ash-pit dampers; *d* the grate; *e* the plate upon which the muffle rests, and which is covered with loom nearly one inch thick; *f* the muffle in section representing the situation of the cupels; *g* the mouth plate, and upon it are laid pieces of charcoal, which during the process are ignited, and heat the air that is allowed to pass over the surface of the cupels, and which will be more fully explained in the sequel; *h* the interior of the furnace, exhibiting the fuel.

The total height of the furnace is 2 feet $6\frac{1}{2}$ inches; from the bottom to the grate 6 inches, the grate, muffle, plate, and bed of loom with which it is covered, 3 inches; from the upper surface of the grate to the commencement of the funnel, *e* fig. 1., $21\frac{1}{2}$ inches; the funnel *e* 6 inches. The square of the furnace which receives the muffle and fuel is $11\frac{5}{8}$ inches, by 15 inches. The external sides of the furnace are made of plates of wrought-iron, and are lined with a 2 inch fire brick.

CCCC, fig. 3. is a horizontal section of the furnace over the grate, showing the width of the mouth-piece or plate of wrought iron, which is 6 inches, and the opening which receives the muffle-plate.

Fig. 4. represents the muffle or pot, which is 12 inches long, 6 inches broad inside; in the clear $6\frac{3}{4}$. In height $4\frac{1}{2}$ inside measure, and nearly $5\frac{1}{2}$ in the clear.

Fig. 5. the muffle-plate, and which is the same size as the bottom of the muffle.

Fig. 6. is a representation of the sliding door of the mouth-plate, as shown at *d* in fig. 1.

Fig. 7. a front view of the mouth-plate or piece, *d* fig. 1.

Fig. 8. representation of the mode of making, or shutting up with pieces of charcoal, the mouth of the furnace.

Fig. 9. a view of the cupel, which is generally one inch by $\frac{7}{8}$ of an inch deep.

Fig. 10. the teaser for cleaning the grate.

Fig. 11. a larger teaser, which is introduced at the top of the furnace, for keeping a complete supply of charcoal around the muffle.

Fig. 12. the tongs used for charging the assays into the cupels.

Fig. 13. represents a board of wood used as a register, and is divided into forty-five equal compartments, upon which the assays are placed previous to their being introduced into the furnace. When the operation is performed, the cupels are placed in the furnace in situations corresponding to these assays on the board; by these means all confusion is avoided, and without this regularity, it would be impossible to preserve the accuracy which the delicate operations of the assayer requires.

The furnace and implements which we have just detailed, are such as are used in the Royal Mint and Goldsmiths' Hall in the city of London.

We shall now proceed to a description of a small assay furnace invented by Messrs Anfrye and D'Arcet of Paris. They term it *le petit Fourneau a Coupelle.* Fig. 14. represents this furnace, and it is composed of a chimney or pipe of wrought-iron, *a*, and of the furnace B. It is $17\frac{1}{2}$ inches high, and $7\frac{1}{4}$ inches wide. The furnace is formed of three pieces; of a dome A; the body of the furnace B; and the ash-pit C, which is used as the base of the furnace, fig. 14. and 15. The principal piece or body of the furnace B, has the form of a hollow tower, or of a hollow cylinder, flattened equally at the two opposite sides, parallel to the axis, in such a manner, that the horizontal section is elliptical. The foot which supports it is a hollow truncated cone, flattened in like manner upon the two opposite sides, and having consequently for its basis two ellipses of different diameters; the smallest ought to be equal to that of the furnace, so that the bottom of the latter may exactly fit it. The dome, which forms an arch above the furnace, has also its base elliptical, whilst that of the superior orifice by which the smoke goes out preserves the cylindrical form. The tube of wrought-iron is 18 inches long, and $2\frac{1}{2}$ inches diameter, having one of its ends a little enlarged and slightly conical, that it may be exactly fitted or jointed upon the upper part of the furnace dome *d*, fig. 14. At the union of the conical and cylindrical part of the tube, there is placed a small gallery of iron *e*, fig. 14. 15. and 16. See also the plan of it, fig. 17. This gallery is both ingenious, useful, and necessary; upon it are placed the cupels, which are properly heated during the ordinary work of the furnace, that they may be introduced into the muffle, when it is brought into its proper degree of heat. A little above this gallery is a door *f*, by which, if thought proper, the charcoal could be introduced into the furnace; and above that there is placed at *g*, a key or valve which is used for regulating the draught of the furnace at pleasure. Messrs Anfrye and D'Arcet say, that, to give the furnace the necessary degree of heat so as to work the assays of gold, the tube must be about 18 inches high above the gallery for annealing or heating the cupels. The circular opening *h*, in the dome fig. 14., and as seen in the section fig. 15., is used to introduce the charcoal into the furnace; it is also used to inspect the interior of the furnace, and to arrange the charcoal round the muffle. This opening is kept shut during the working of the furnace, with the mouth-piece, of which the face is seen at *n*, fig. 15.

The section of the furnace fig. 15. presents several openings; the principal, which is that of the muffle, is placed in *i*; it is shut with the semicircular door *m*, fig. 14., and as seen in the section *m*, fig. 15. In front of this opening is the table or shelf, upon which the door of the muffle is made to advance or recede; the letter *q*, fig. 15., shows the face, side, and cross section of the shelf, which makes part of the furnace. Immediately under the shelf is a horizontal slit *l*, which is pierced at the level of the upper part of the grate, and used for the introduction of the rod of

iron fig. 31., that the grate may be easily kept clean. This opening is shut at pleasure by the wedge represented at *k*, fig. 14. and 15.

Upon the back of the furnace is a horizontal slit *p*, fig. 15., which supports the fire brick S, fig. 15., and upon which the end of the muffle, if necessary, may rest: *u*, fig. 15., is the opening in the furnace, where the muffle is placed.

Fig. 19. is a plan of the grate of the furnace, and fig. 20. a horizontal view of it. These two figures show us the dimensions of the ellipsis, and determines the general form of the furnace, and thickness of the grate. To give strength and solidity to the grate, it is encircled by a bar or hoop of iron. We see at *z* the groove in which the hoop of iron is fixed. The holes of the grate are truncated cones, having the greatest base below, that the ashes may more easily fall into the ash-pit. The letter V, fig. 15., shows the form of these holes. The grate is supported by a small bank or shelf, making part of the furnace, and as seen at *a*, fig. 15.

The ash-pit *c* has an opening *y* in front, fig. 15., and is shut, when necessary, by the mouth-piece *r*, fig. 14. and 15.

To give strength and solidity to the furnace, it is bound with hoops of iron at *b*, *b*, *b*, *b*, fig. 14.

Figs. 21. 22. and 23. are views of the muffle.

Fig. 24. is a view of a crucible for annealing gold.

Figs. 25. 26. and 27. are cupels of various sizes, to be used in the furnace. They are the same as those used by assayers in their ordinary furnaces.

Figs. 28. and 29. are views of the hand-shovels used for filling the furnace with charcoal; they should be made in size and form so as to fit the opening *h* in figs. 14. and 15.

Fig. 30. the smaller pincers or tongs, by which the assays are charged into the cupels, and by which the latter are withdrawn from the furnace.

Fig. 18. the teaser for cleaning the grate of the furnace.

Fig. 16. is a representation of the furnace first constructed by Messrs Anfrye and D'Arcet, and which was worked by means of a pair of bellows, which forced a current of air through the brass tube *b*, entering the ash-pit under the grate at the circular hole *c*, fig. 15. The strength of the blast or current of air can be regulated at pleasure by the stop-cock *d*, fig. 16.

Process of Assaying.

We shall now proceed to a description of the process of assaying, as performed by the assayers of the Royal Mint and Goldsmiths' Hall; and shall then state the facility afforded by the furnace of Messrs Anfrye and D'Arcet in conducting this operation upon a smaller scale and reduced expence.

Some preliminary observations may be requisite in regard to the muffle and cupels, to the proportioning of lead in assaying, &c., before the operation of the assay commences.

In the furnace above described, the number of assays that can be made at one time is 45. The same number of cupels are put into the muffle. The furnace is then filled with charcoal to the top, and upon this are laid a few pieces already ignited. In the course of three hours, a little more or less, according to circumstances, the whole is ignited; during which period the muffle, which is made of fire clay, is gradually heated to redness, and is prevented from cracking, which a less regular or more sudden increase of temperature would not fail to do. The cupels also become properly annealed; all moisture being dispelled, they are in a fit state to receive the piece of silver or gold to be assayed.

The greater care that is exercised in this operation, the less liable is the assayer to accidents from the breaking of the muffle, which it is both expensive and troublesome to fit properly into the furnace.

The cupels used in the assay process are made of the ashes of burnt bones (phosphat of lime). In the Royal Mint, the cores of oxhorn are selected for this purpose, and the ashes produced are about four times the expence of the bone ash used in the process of cupellation upon the large scale. So much depends upon the accuracy of an assay of gold or silver, where a mass of 15 lbs. Troy, in the first, and 60 lbs. Troy in the second instance, is determined by the analysis of a portion not exceeding 20 Troy grains, that every precaution which the longest experience has suggested is used to obtain an accurate result; hence the attention paid to the selection of the most proper materials for making the cupels.

The cupels are formed in a circular mould made of cast steel, very nicely turned, and by which means they are easily freed from the mould when struck. The bone ash is used moistened with a quantity of water sufficient to make the particles adhere firmly together. The circular mould is filled and pressed level with its surface; after which a pestle or rammer, having its end nicely turned, of a globular or convex shape, and its size, equal to the degree of concavity wished to be made in the cupel for the reception of the assay, is placed upon the ashes in the mould, and struck with a hammer until the cupel is properly formed. These cupels are allowed to dry in the air for some time before they are used. If the weather is dry, a fortnight will be sufficient.

The greatest possible attention should be paid to the quality of the lead used in assaying. If it contain silver, it will be easy to perceive a source of material error in the delicate operations of the assayer. Lead revived from litharge contains only about half a grain in the pound weight, and is preferred, on that account, to lead immediately revived from the ore, which usually contains a larger quantity.

The proportion of lead used in an assay of silver varies according as the external character of the silver to be assayed indicates a comparative state of fineness or coarseness to standard metal; of which an expert assayer may pretty accurately determine by the eye; but his opinion will also in some measure be regulated by the comparative ease or difficulty of flattening upon an anvil the piece of silver to be assayed;—if coarse, the metal is harder than standard, and of a brilliant glossy appearance; but, if soft and easily flattened, and of a dead white colour, it will indicate a state approaching to purity. The quantity of lead is then proportioned by the opinion of the assayer, and varies from 10 to 20 times the weight of the silver used. It should be observed, that a cupel is capable of absorbing only its own

weight of litharge, and attention should accordingly be paid to the size of the cupel, when any silver is to be assayed, which requires a great quantity of lead.

As it is always requisite to proportion the lead to the estimated quantity of alloy in the silver before cupellation, the ancient assayers made use of *touch-needles*, which were bars or slips of metal, made with pure silver, alloyed with definite proportions of copper, in a regularly increasing series, from the least to the greatest proportion, which may ever be required. The silver to be assayed was examined in comparison with the touch-needles, in colour, tenacity, and other external characters, and its alloy was estimated by that of the needle, to which it showed the closest resemblance. These needles are seldom or never used now; and the external character of the metal is sufficient to guide an experienced assayer in the proportioning of the lead, to the estimated alloy in the silver, which he has to assay.

In Aikin's *Dictionary of Chemistry and Mineralogy*, under the article ASSAYING (to which we here acknowledge our obligations), there is a table of the proportions of lead to the estimated alloy in fine silver, founded upon the experiments of Messrs Tillet, Hellot, and Macquer, which were the basis of a regulation subsequently adopted by an edict of the late French government. The great uncertainty of the use of the touch-needles, probably suggested these experiments to the French Chemists; and as this table may be extremely useful to unexperienced assayers, we shall insert it here, together with the observations accompanying it in the above work.

"Copper, the usual alloy of the fine metals, when taken singly, is found to require from ten to fourteen times its weight of lead for complete scorification on the cupel. Now, all admixtures of fine metal tend to protect the copper from the action of the litharge, and the more obstinately, the greater the proportion of fine metal. So that copper, with three times its weight of silver (or 9 oz. fine), requires forty times as much lead as copper; with eleven parts of silver it requires seventy-two parts of lead, and the like in an increasing ratio. The following is the table of the proportions of lead required to different alloys of copper; of which a few points are founded on the above mentioned experiments, and the rest filled up according to the estimated ratio of increase (being multiples of the assay integer 24 in arithmetical progression). In the three first columns is shown the absolute increase of the quantity of lead in alloys of decreasing fineness; in the three last columns will be seen the gradual diminution of the protecting power of fine metal against scorification, in proportion to the increase of alloy, shown by the decreasing quantity of lead, required for the same weight of copper, under different mixtures." (Aikin's *Dictionary.*)

TABLE.

| Silver. | Copper. | Copper. | Lead. | Ratio of Increase. | | Copper. | Silver. | Lead. |
|---|---|---|---|---|---|---|---|---|
| 23 with | 1 | requires | 96 | $= 4 \times 24$ | and hence | 1 with | 23 requires | 96 |
| 22 —— | 2 | —— | 144 | $= 6 \times 24$ | —— | 1 —— | 11 —— | 72 |
| 20 —— | 4 | —— | 192 | $= 8 \times 24$ | —— | 1 —— | 5 —— | 48 |
| 18 —— | 6 | —— | 240 | $= 10 \times 24$ | —— | 1 —— | 3 —— | 40 |
| 16 —— | 8 | —— | 288 | $= 12 \times 24$ | —— | 1 —— | 2 —— | 36 |
| 14 —— | 10 | —— | 336 | $= 14 \times 24$ | —— | 1 —— | $1\frac{2}{5}$ —— | 33 |
| 12 —— | 12 | —— | 384 | $= 16 \times 24$ | —— | 1 —— | 1 —— | 32 |
| 10 —— | 14 | —— | 432 | $= 18 \times 24$ | —— | 1 —— | $\frac{5}{7}$ —— | 30 × |
| 8 —— | 16 | —— | 480 | $= 20 \times 24$ | —— | 1 —— | $\frac{1}{2}$ —— | 30 |
| 6 —— | 18 | —— | 528 | $= 22 \times 24$ | —— | 1 —— | $\frac{1}{3}$ —— | 29 × |
| 4 —— | 20 | —— | 576 | $= 24 \times 24$ | —— | 1 —— | $\frac{1}{5}$ —— | 28 × |
| 2 —— | 22 | —— | 624 | $= 26 \times 24$ | —— | 1 —— | $\frac{1}{11}$ —— | 28 × |

In the article just referred to, it is remarked, that many assayers of good authority use proportions of lead to alloy, considerably different from the above table, and that the whole of the numbers here given may be considered as rather high in regard to the quantity of lead. The German assayers, it is added, observe the following rule:

| *Copper.* | *Silver.* | *Lead.* |
|---|---|---|
| 1 with | 30 requires | 128 |
| 1 —— | 15 —— | 96 |
| 1 —— | 7 —— | 64 |
| 1 —— | 4 —— | 56 |
| 1 —— | 3 —— | 40 |
| 1 —— | 1 —— | 30 |
| 1 —— | $\frac{1}{5}$ —— | 20 |
| 1 —— | $\frac{1}{15}$ —— | 17 |

In proportioning the lead to the alloy supposed to exist in the silver to be assayed, care must be taken not unnecessarily to increase the quantity; though it would be all oxidated or absorbed by the cupel sooner or later; which is proved by the cupellation of lead *per se*, in order to ascertain the portion of silver it contains; the latter being always found in a globular shape on the cupel, and in a state of purity.

In the process of cupellation with lead, however, there is always a loss of silver. Mr Tillet found, by experiments which he made with pure silver and lead, whose retent of silver was known, that after the process of cupellation, the button of silver was never precisely of the same weight as before; but was always a portion lighter, even when the heat of the assay furnace was not sufficient to drive off any of the silver. The conclusion was obvious,—a part of the silver was carried into the cupel by the lead;

this was proved by reviving the oxide of lead from the cupel, and cupelling the lead by itself, when the quantity of silver left upon the test was found to be ten times as great as the natural proportion of this metal in the lead, and very nearly corresponded with the loss of silver in the first instance. It will be obvious, then, that the assayer's report of the title or purity of any sample of silver (unless corrected) would make the metal somewhat less pure than it actually is, because all loss is put to the account of alloy. Mr Tillet calculates, when no more lead is used than is necessary for the entire separation of the alloy, that it carries down into the cupel as much silver as, when the whole is again reduced, would make the noble metal $\frac{1}{128}$ of the mass, when the natural admixture of the silver is only about $\frac{1}{1152}$. But if an excess of lead is employed for cupellation, this loss of silver is somewhat greater, though it does not increase in the ratio of the excess of the lead; for 10 parts of lead to a given alloy will not carry down twice as much silver as 5 parts, though the difference of loss will be very sensible.

Assay Weights.

The weights used in assaying gold and silver are peculiar to the profession. In the assaying of silver, a given number of grains are taken, which is called the *assay pound.* This assay pound varies from 14 to 24 grains Troy. This imaginary pound is subdivided into ounces and pennyweights, and the latter into half-pennyweights, which is the lowest term used in reporting assays of silver; so that there are 480 different reports for silver (this being the number of half-pennyweights in the pound); and therefore each nominal half-pennyweight weighs $\frac{1}{20}$ of a Troy grain, when the entire assay pound is 24 grains.

The report of an assay of silver is made according to the proportion of pure metal which it is found to contain. The legal standard of Sterling money of silver is 11 oz. and 2 dwts. fine, and 18 dwts. alloy. If an assay of silver was found to contain 11 oz. only of pure silver, it would be reported *worse* 2 dwts. meaning worse than standard silver by 2 dwts. or 48 grains in the pound Troy. If an assay, on the contrary, contained 11 oz. and 6 dwts. pure silver, it would be reported *better* than standard by 4 dwts. in the pound Troy; because 18 dwts. being the standard proportion of alloy, it was found that it only contained 14 dwts. alloy. When bullion thus assayed and reported is for sale, its value is calculated by reducing the bar or ingot of silver into standard metal.

| | lbs.Troy. | oz. |
|---|---|---|
| In the first example which we have given, if the ingot of silver assayed weighed | 50 | 0 |
| there would be deducted from the weight 2 dwts. per lb. or . . . . | | 5 |
| which 5 oz. is the excess of alloy above the proportion of 18 dwts. to the 11 oz. 2 dwts. of fine metal, and the bar of silver would be, in standard weight, . . | 49 | 7 |

| | lbs. | oz. |
|---|---|---|
| On the contrary, if the ingot weighed | 50 | 0 |
| and the alloy were deficient, which is the case when the metal is reported better than standard by 4 dwts. in the pound Troy, there would be added to the 50 lbs. 4 dwts. per pound, which would be equal to . . . . | 0 | 10 |
| Making the standard weight of the ingot | 50 | 10 |

The gold assay pound, which is from 10 to 20 grains Troy, is subdivided into 24 carats, and each carat into 4 assay grains, and each grain into quarters; so that there are 384 separate reports for gold, each equal to 15 Troy grains, or what is termed a quarter carat grain. An accurate assayer, however, can ascertain, in an assay of gold, to 3 grains Troy; but it is the custom of the trade not to report less than a quarter carat, or 15 grains Troy. A substantial reason is given for this rule, to justify the practice of it. An ingot of gold generally weighs a journey weight, which is 15 lbs. Troy; from a sample cut from the two opposite ends, weighing from 10 to 20 grains, the value of the mass of 15 lbs. is to be determined; if this ingot had been imperfectly melted, the mass would not be homogeneous, and a difference might exist in it of several Troy grains; and the allowance between the quarters given in the assay report is an indemnity to the purchaser. Indeed, so particular are many in the bullion trade, that they will not purchase any foreign gold bullion until it has been remelted by refiners or melters in whose integrity they repose confidence. This, we believe, is generally the case with the Bank of England, in all her purchases of foreign gold bullion.

The assay report of gold is made according as it is better or worse than standard. The standard of our gold coin is 22 carats fine, and 2 carats alloy. If, by assay, an ingot of gold was found to contain 21 carats fine gold, it would be reported *worse* 1 carat, the mass containing a carat of alloy more than the proportion of 2 carats to 22 carats fine. If the ingot weighed 15 lbs. Troy, there would be deducted from the gross weight 1 carat, or 240 grains Troy, reducing the standard of the mass to 14 lbs. 11 oz. 10 dwts. If, on the contrary, the mass was found to contain 23 carats fine gold, it would be reported 1 carat *better* than standard; and this carat would be added to the gross weight of the ingot, which we have supposed to weigh 15 lbs. Troy, and would be called 15 lbs. 0. oz. 10 dwts. of standard gold. When the gold assay pound or integer is only 12 grains, the quarter assay grain weighs only $\frac{1}{32}$ part of a Troy grain. This will show how delicate the scales must be by which the assayer works in order to obtain accuracy. In the Royal Mint, the scales of the assayers will be sensibly affected even with the $\frac{1}{1000}$th part of a Troy grain. When the Emperor of Russia lately visited the Mint, he was particularly struck with the extreme delicacy of the assay scales of Mr Bingley, the King's Assay-Master. That gentleman requested the favour of his Imperial Majesty to put one of the hairs of his head into the scale, which he did, and, to the great satisfaction of his Majesty, it very sensibly affected the equilibrium of the beam.

When the assay pound is subdivided, as for silver, in the same manner as the Troy pound, it is obvious

that all the lower denominations bear the same relation to each other; which is some little advantage in transferring the assay reports to real mixtures for use. On the contrary, the carat subdivision for gold is confined to assaying, but its fractions being aliquot parts of the pound Troy, the calculation for real use is very easy. As the pound Troy contains 5760 grains, the carat corresponds with 240 grains or 10 dwts; the assay grain, or fourth part of a carat, with 60 Troy grains; and the assay quarter-grain with 15 Troy grains; to which report, when the assayer has separated the gold (4 oz. for example), he adds 4 *oz. gold in a pound Troy*. Whereas in gold parting he takes two equal pieces, treats one as a silver assay, and the other as a gold assay, to find the absolute quantity of each metal, after which the report is made on gold singly, to which is added the report of the silver separately. Thus, if he finds 4 oz. of gold, and 3 oz. of silver, he reports *worse* 14 *carats* (2 carats being equivalent to an assay ounce, and consequently the 4 oz. of gold equal to 8 carats, which subtracted from 22 carats, the gold standard, leaves 14), to which report *he adds, fine silver 3 oz.* But when the mixed metal contains more than half alloy, it is called *metal for gold and silver*, and the absolute quantity of each reported separately. (Aikin's *Dictionary*.)

Having made the reader acquainted with these details, we shall now proceed to explain the process of assaying silver, commonly known by the name of *cupellation*.

Assay of Silver.

When we have an assay of silver to make, we flat the portion of metal upon a polished anvil; the face of the flatting hammer is also highly polished; that the metal may receive no extraneous matter whatever. The piece of metal is flatted to about the thinness of a sixpence, and an assay pound is cut from it, and most accurately weighed in such scales as we have already noticed. This assay pound is then enveloped in a sheet of lead, which is flattened from a lead bullet, and circular, but made into a funnel shape, in order to contain the silver; and the more nicely to prevent any portion of the silver from being lost, the corners of this leaden funnel are closely and firmly folded down. If the Assay-Master has 45, or, indeed, any number short of 45, they are ranged according to their number upon the table, fig. 13. When the furnace and cupels have been prepared according to the number of assays to be made, and when the proper degree of heat has been attained, the assays are charged into the cupels; and the following method is followed in this part of the process: In the first instance, a ball of lead is charged into each cupel, with the charging tongs (fig. 12.), and its weight is according to the quality of the silver to be assayed; the assayer keeping a stock of leaden bullets of different weights for the purpose. As soon as this lead is melted, which is instantaneous, the assays of silver enveloped in lead are also charged into the cupels. The mass is very soon in complete fusion. The mouth of the muffle, which had before been partially closed with cylinders of charcoal about 6 or 7 inches long, and of different diameters suitable to the convenience of the assayers, as represented in fig. 8., is now nearly closed by smaller cylinders of charcoal. The object of this precaution is, that the stream of air admitted to pass over the surface of the cupels, and which is indispensably necessary for the oxidation of the lead in the process of cupellation, may not chill the muffle, and retard the progress of the assay. The oxidation of the metal will proceed with more or less rapidity, according as the stream of air admitted is great or small, and which the assayer has it always in his power to regulate at pleasure. The work already referred to in this article, has so beautifully and accurately described the progressive appearance of the assay process of silver, that we cannot do better than quote the description: "The melted metal begins to send off dense fumes, and a minute stream of red fused matter is seen perpetually flowing from the top of the globule down its sides to the surface of the cupel, through which it sinks and is lost to view. This fume and the stream of melted matter consists of the lead oxidated by the heat and air, in one case volatilized, in the other vitrified; and in sinking through the cupel it carries down with it the copper or other alloy of the silver. In proportion to the violence of the heat, is the density of the fume, the violence with which it is given off, the convexity of the surface of the globule of melted matter, and the rapidity with which the vitrified oxide *circulates* (as it is termed), or falls down the sides of the metal. As the cupellation advances, the melted button becomes rounder, its surface becomes streaky with large bright points of the fused oxide, which moves with increased rapidity, till at last the globule, being now freed from all the lead and other alloy, suddenly *lightens*; the last portions of litharge on the surface disappear with great rapidity; showing the melted metal bright with irridescent colours, which directly after becomes opaque, and suddenly appears brilliant, clean, and white, as if a curtain had been withdrawn from it. The operation being now finished, and the silver left pure, the cupel is allowed to cool gradually, till the globule of silver is fixed, after which it is taken out of the cupel while still hot, and when cold weighed with as much accuracy as at first. The difference between the globule and the silver at first put in, shows the quantity of alloy, the globule being now perfectly pure silver, if the operation has been well performed. The reason of cooling the globule or button gradually is, that pure silver, when congealing, assumes a crystalline texture, and if the outer surface is too suddenly fixed, it forcibly contracts on the still fluid part in the centre, causing it to spurt out in arborescent shoots, by which some minute portions are often thrown out of the cupel, and the assay spoiled." (Aikin's *Dictionary*.)

Assay of Gold.

The assaying of gold, preparatory to the parting process, which we are about to describe, is exactly the same as in the case of silver; the object in the process of cupellation being to destroy the base metal or alloy contained in the gold. If gold contained only copper as alloy, the assaying of gold would be as simple and expeditious as that of silver; but all gold contains a portion of silver, which, though reckoned as alloy, cannot, as we have already seen, be destroyed

by cupellation. Recourse is had to the process, commonly called the parting process, to get rid of the silver contained in the gold. This is done by means of nitric acid, which entirely dissolves the silver, and leaves the gold perfectly pure. The quantity of silver which gold generally contains, is too small to allow the nitric acid to act upon it without addition; and the general allowance by assayers is two or three parts of silver to one of gold. If the quantity of silver greatly exceeded these proportions, the operation would not succeed so well; the fine gold would be obtained in the state of brown powder, the particles having been too minutely divided by the excess of silver.

When assays of gold have passed the test, by which all the alloy, excepting silver, has been destroyed, it is in this process that the additional quantity of silver is added. Suppose, for example, that a gold assay is made from the integer, or pound, weighing 12 grains Troy, an addition of from 24 to 36 grains of pure silver is made in addition to the small portion already supposed to exist in the mass. This becomes thoroughly incorporated with the gold in the process of cupellation. The globule, or button, as soon as it is taken from the furnace, is passed between a pair of polished steel rollers, and drawn out into a thin lamina, or plate, of the thickness of a sixpence, and returned into the furnace to be annealed. After being kept in a red heat for some time, it is taken out, and suffered to cool. It is then wound up into a cornet. This is put into a glass matrass, of the shape of an inverted cone, and with about twice or thrice its weight of very pure nitric acid. M. Vauquelin recommends it to be 1.25 specific gravity. But the true test of its strength is in the working of the process. The assayer's attention being directed to the point of strength that will maintain the gold when the silver is extracted in the spiral form, if the acid were too strong, or the silver in too great excess, the gold, as we have already mentioned, would be reduced to powder, and considerable danger exists that it would not be accurately collected, by which an imperfect result would be obtained. The glass matrass is placed upon a sand-heat, or bath, which is generally a square or oblong pan of copper, with from one to two inches of dry sand in the bottom. The pan is placed over a small square furnace, in which is burning charcoal or coke. As soon as the acid is warm, it begins to act upon the silver, and a dense stream of nitrous gas is disengaged. As long as the acid continues to act, the metal appears everywhere to be studded with very minute bubbles, which issue in jetts. The disappearance of these, or their uniting into a few large ones, is a sign or mark that the acid has ceased to act. The disappearance also of the nitrous fumes is an indication that the acid has no silver to act upon. In the course of fifteen or twenty minutes, the process is finished. But, in order to extend the last portions of silver which the mixture may contain, a small quantity of highly concentrated acid is poured upon the cornet, and boiled, by which the last portions of the silver are extracted. The cornets of gold are thoroughly corroded, but retain the same form, having lost all the silver, to two thirds or three fourths of their weight; they are slender and brittle, as we observed before. It is an object of considerable importance to prevent the cornets from being broken, the result being more likely to be accurate than having the gold in fragments; and to prevent this, the quantity of silver used is no more than is absolutely necessary, it being obvious that the less the quantity of gold, compared to the silver, used in the assay, the more likely is the gold to be broken into pieces.

The hot acid is poured very carefully from the matrass, and warm water is added to wash any remain of silver from the gold, and the addition repeated until the water comes off perfectly clear. The cornets of gold, which are of a dull brown colour, and unmetallic appearance, are then put according to their numbers into small clay crucibles, into which they are allowed gently to fall by inverting the matrass, with a portion of water in it, which breaks their fall, and also collects any grains of gold that may be in the matrass. The water is then poured off, and they are put into the furnace, and annealed under a bright cherry heat. When cooled, the pieces of gold have regained their beautiful metallic lustre, and possess all the softness and flexibility of this truly noble metal.

The pieces of gold, thus thoroughly purified, are carefully and accurately weighed, the absolute loss in weight indicating the purity of the metal assayed.

It is a matter of the greatest importance, that the silver used in this process should contain no gold, otherwise a source of very material error would arise in the delicate operations of the assayer. Silver generally contains a small portion of gold. Spanish dollars, for example, are found to contain about 4 Troy grains in the pound, and are generally preferred in the parting process upon the large scale; but assayers in general use silver revived from a precipitation of the nitrate of silver, which they are sure contains no gold.

The nitrate of silver is precipitated by immersing in it plates of copper, which throw down the silver in the metallic state. It may also be recovered by a solution of common salt, which converts the silver into luna cornea, of which, when washed and well dried, 100 parts contain 75 silver. The accuracy of the assay may also be proved by this process. The luna cornea, however, is more difficult to reduce to the metallic state, and the mode of recovery by plates of copper is always preferred.

New Process of Assaying.

It remains for us now briefly to mention the process of assaying by the *Petit Fourneau à Coupelle* of Messrs Anfrye and D'Arcey. This process is the same in principle, in all respects, as that which we have been detailing. The only difference consists in the greater facility of the process, and the comparative diminution in the fuel used. The furnace first used by these gentlemen had a small pair of bellows attached to it; see fig. 16.; and after the furnace was brought to a proper degree of heat, which required two hours and a half, the following was the result of the experiments made:

| Numérôs. | Argent Employé. | Plomb Employé. | Durée de L'Essai. | Titres. | Charbon Employé. |
|---|---|---|---|---|---|
| 1 | 1 Gram. | 4 Gram. | 12 Min. | 947 Mill. | 173 Gram. |
| 2 | .. | .. | 11 .. | 950 .. | 86 .. |
| 3 | .. | .. | 13 .. | 949 .. | 93 .. |
| 4 | .. | .. | 10 .. | 949 .. | 60 .. |
| Termes Moyens. | 1 Gram. | 4 Gram. | 11 M. 5. | 948 M. 75. | 103 Gram. |

So that each assay, on an average, was performed in $11\frac{1}{2}$ minutes, and the charcoal used did not much exceed $\frac{1}{4}$th of a pound weight. The standard of the silver used in these experiments was proved by an assay in the ordinary furnace to be 949 milliémes, and the average result by the new furnace was 948 mil. 75. a difference not more than occurs in the use of the large furnace, and an object of no importance in point of accuracy.

Experiments were also tried with this small furnace, to prove the highest degree of heat that could be produced; and two balls of Wedgwood's pyrometer were put into the furnace, which, when cold, indicated the one 35, the other 30 degrees, and is fully equal to the heat of the ordinary assay furnace.

When Messrs Anfrye and D'Arcet had improved their furnace, by adopting a tube of iron in place of the bellows, they could raise the proper degree of heat in the furnace in half-an-hour, which required by the original construction two hours and a half.

The following experiments were made upon some five franc pieces, the standard of which, according to law, should have been from 897 to 903 milimétres:

| Numérôs. | Argent Employé. | Plomb Employé. | Durée de L'Essai. | Titres. | Charbon Employé. |
|---|---|---|---|---|---|
| 1 | 1 Gram. | 7 Gram. | 15 Min. | 900 Mill. | 120 Gram. |
| 2 | 1 .. | 7 .. | 14 .. | 902 .. | 123 .. |
| 3 | 1 .. | 7 .. | 14 .. | 901 .. | 175 .. |
| Termes Moyens. | 1 Gram. | 7 Gram. | 14.33 | 901 Mill. | 139.33 qrs. |

These experiments differ very little from those we have already stated; a trifling increase in the duration of the assay, and in the charcoal consumed, being the only difference; and the greater facility which this furnace has of being raised to the necessary degree of heat, before the assays are charged into the cupels, more than compensate for the increased duration of the assay and charcoal consumed.

This small furnace is particularly recommended for the service of the *Bureaux de Garantie de Province*, where a limited number of assays are from time to time made; and, in point of economy, presents many advantages to recommend it to a place in the chemical laboratory.

This furnace may also be used for a melting furnace; and to convert it to this purpose, the muffle is taken out, and the various apertures, which are open when the assays are making, closed by their respective stoppers: a stand may then be put upon the grate, and a crucible of such size as the furnace will admit, placed upon it, and which can very readily and conveniently be done from the opening *h*, fig. 15. In this use of the furnace, coke may be employed instead of the charcoal, the heat being greater and more steady with the former than the latter. (AA.)

ASSURANCE. See the article INSURANCE in the *Encyclopædia*. The subject of *Life Assurances*, partly treated there, requires some correction, and a more detailed explanation in this place. Assurance on lives, is the *assurance of a certain sum of money to be paid in the event of a person named being alive at a certain time, or dying within a certain time, or to be paid within a certain time after the death of a person named, whenever that may happen.* The party agreeing to pay this sum, is called the *Assurer*, and the sum he receives in compensation for what he is to pay, is called the *Premium* of assurance. The instrument by which the party is bound to pay the sum assured, is called a *Policy* of assurance. Nature of the Contract.

Policies of this kind are granted either by individuals or by companies, more generally by companies, on account of the greater security there is in large bodies of men, and which cannot easily be attained by an individual, when the policy may be of long continuance.

The policies to be paid on the death of a person or persons named, are also absolute or contingent; *absolute*, when the sum assured is payable on the death of a party assured; contingent, when the payment of this sum depends on some other event; as, for example, the existence or antecedent death of some other person or persons.

The premium of assurance is either a gross sum paid down at once, or a sum paid down on the day that the contract is made, with an obligation to pay the same sum annually, during the existence of the policy. The latter is the more general mode of assurance.

Mode of effecting an Assurance.

As policies on lives are much more frequently conducted by companies than individuals, the mode generally adopted by those companies shall be first explained. The party desirous of effecting an assurance, receives from the office of the company a printed paper called a declaration, which he fills up with the name of the party to be assured, his age, the place and time of his birth, and place of his present residence, with certain particulars as to his health. This declaration is then duly signed; and it contains a clause, stating, that any falsehood in the declaration invalidates the policy. To corroborate the statement, references are given to two persons well acquainted with the party on whom the assurance is made, one of whom is to be a medical person, and sometimes more references are required. The reasons for these precautions are obvious.

When the declaration has been thus completed, the person by whom the assurance is made makes his appearance before the directors of the company, who inquire into the general state of his health, and a minute is entered in their books accordingly. The letter of the referrees, with the declaration, are subsequently laid before the court, which from these documents, and information frequently derived from other sources, forms its decision; and this is entered on the minutes of the court, and communicated to the applicant. A certain time is allowed for the payment of the premium; and if it is not paid within that time, the assurance cannot be effected, but by a fresh application to the court, according to the forms above mentioned. On the payment of the premium a receipt is given, containing the number of the policy, which is then made out according to the declaration, inspected by the court, signed by a certain number of directors, and delivered to the other party interested in it.

If the person, on whose life the assurance is made, cannot appear before the directors, or any one appointed by them for that purpose, an additional sum is charged for non-appearance. There is also a duty to be paid to government on each policy, and this, with a small entrance fee, makes an addition to the first year's premium. But the premium itself is only named in the policy, as on the future payment of this sum its existence depends.

Assurances are assignable.

A policy is assignable, and frequently forms a security for sums advanced, and not unfrequently becomes an object of sale. In these cases the holder of the policy pays the future premiums, and the advantage of a purchaser consists in holding a policy at a less premium than he must have paid at the present age of the party, on whose life the assurance was made. Thus, supposing a policy to have been granted for the payment of a thousand pounds, at the death of a party aged between 37 and 38, when the policy was made; suppose it is sold when the party is between 50 and 51; the purchaser will have to pay L.32, 5s. annually, during the existence of the policy: whereas, if he had taken out a policy at the present age of the party, his premium would be L. 46, 15s. For the difference between these two sums, namely L. 14, 10s., a price is fixed on; but it is to be observed, that, in the sale of a policy in the market, this disadvantage attends it,—that the bidders, not being acquainted with the person on whose life the policy is made, and being liable to trouble and expence, to ascertain that he is alive at each payment of the premium, must make a deduction on this account, from what they might otherwise presume to be a compensation for the difference between the two premiums. Policies are in consequence sold at very disproportionate prices; and it is evident, that a policy must be most valuable to the party assured himself, and less so to others, according to their convenience of paying the premiums, and receiving proper information respecting the party in whose life and death they are interested.

On the death of the party on whom the claim depends, certain documents are required, such as the register of the burial of the deceased; and references to the medical persons or others who attended him in his last illness; and, if he effected the policy himself, the probate of his will, or, if it has been assigned to another, the copy of the assignment. The grounds of these precautions are, with respect to the receiver of the sum assured, obvious; and the nature of the death must be ascertained; as, in case of suicide, or dying by the hands of justice, or on the high seas, without licence from the company, except, in general, in going from one part in the united kingdom to another, the policy is vitiated. In the interval between the notice of the party's death, and the time assigned for the payment of the claim, due investigation is made; and, every thing having been found satisfactory, the claimant brings with him the policy and a receipt for the sum claimed, which is immediately paid to him; the seals are torn from the policy, and the contract is at an end. In the case that a claim is payable, in the event of a person being alive at a certain time, his appearance before the court is requisite, or sufficient proof must be given that he was alive at the time defined by the policy.

Policies depending on a person being alive at a certain time, are very rare, and chiefly confined to endowments for children, in which case the payment of a gross sum down, or of an annual payment till the child attains the age of 21, secures to that child, at that age, the sum named in the policy. This mode of assurance has led some offices to compose a table of rates, according to which, a person at the age of 20 is required to pay a premium, which would produce at legal interest more than he would receive at the expiration of the year, from the company; and thus a person, if any such could be found, to effect an assurance of this kind, would run the risk of losing the sum assured, and receive, if successful, not so much as he could have attained without any risk at all.

Tables of Rates.

For adjusting the premium to be paid according to the age of the party on whom the assurance is made, tables of rates have been formed, and those derived from the register of mortality at Northampton are in general adopted. Tables of the duration of human life have also been made from observations in various other places; amongst which the most distinguished are those of De Parcieux, Kerseboom, Gorsuch, Aikin, and the registers of Sweden, Finland, and London. The hypothesis of De

Moivre presumes that, if eighty-six persons were born at the same time, one would die in each year till the whole number ceases to exist. This hypothesis has been abandoned, but an easy rule is derived from it, for estimating the expectation of life at any age. Subtract the age from eighty-six, and dividing the quotient by two, the remainder gives the expectation nearly. Thus, let the age be 30, then $\frac{86-30}{2}$ is 28, which differs from the Northampton table by only 27. At the age of fifty, the error is trifling, the Northampton table giving 17·99, De Moivre's, 18. But, in the higher ages, the error becomes considerable.

In the formation of these tables, a vulgar error is entertained, that they are dependant on chance; for life, being uncertain, every attempt to regulate premiums is of no avail. It is true that life cannot be reduced to a certain scale; *i. e.* if a thousand persons are named, it is impossible to state how many will die in each year, till the whole cease to exist. But though a fixed rule cannot be laid down for any given number of persons, yet an approximation may be made to the general course of life, which will sufficiently suit the purpose for which the tables are framed.

After a scale of life has been adopted, a table of premiums is derived from it by strict mathematical calculation, and in a very ingenious manner. Suppose the premium for a person of a certain age to be known; then the premium for a person of one year younger, being compounded of the premium for one year and the present value of the above premium, is easily calculated from the table of lives, thus: Multiply the premium on the oldest life into the number of persons alive in the tables at that age, and divide by the number of persons of the younger age alive in the tables. This sum, discounted for a year, gives the premium for assuring the desired sum at the end of the year. Then multiply the sum to be assured into the number of persons of the younger age, that die according to the tables in a year, and divide by the number of persons alive at that age, and this sum discounted for a year is the assurance of the sum for the first year, and consequently, the two sums added together, give the desired premium. Now, as the oldest person in the scale of life, dies in the ensuing year, the premium on him is evidently the sum to be paid discounted for one year, and thence the premium for the age below is ascertained by the above rule; and so of every age in succession. No errors can be committed without detection, as every step is checked by a similar table drawn out for the value of an annuity at each age.

In a similar manner, tables are formed for the assurance of a sum payable at the death of one out of two persons, or at the death of the survivor of two persons, or at the death of one on the contingency of his surviving another, and so on. The tables generally adopted by the companies, on the contingency of one person surviving another, being calculated by an approximation, founded on the expectation of their lives, does not partake of the mathematical accuracy of the other tables; but the companies, in this case, grant assurances at times to their own disadvantage; for if they take rather too much upon one life, they lose that sum upon the other; the premium payable on the death of one of two parties, being divided by the above-mentioned rule of approximation into two premiums, to be paid by the two parties on the contingency of one surviving the other.

The above rules give tables of rates for the payment of a gross premium: but as it is generally more convenient to pay an annual sum equivalent to it, a table of rates is made for this case, and it is formed by dividing the gross premium by the value of an annuity upon each age added to unity. If the annual premium were paid at the end of the year, the addition of unity would be unnecessary; but a policy is not granted till one premium is paid, and hence the necessity of the addition is obvious.

As premiums are settled from a fixed table of observations on life, it is evident, that, unless the deaths happen exactly in the order prescribed by the tables, there will be a surplus or deficiency of capital for the payment of the sums assured. For the latter case, a call is to be made on the proprietors to make up the deficiency: the management of the surplus or apprehended surplus, is different in different companies. Either the company appropriates the whole of the surplus to itself, or makes a compensation to the assured for it. In the former case, the company pays the sum specified in the policy, and no more. Consequently, a party may pay to the office a sum far greater than his executors or assigns receive in return. Thus, if an assurance is effected on a person aged between sixteen and seventeen for L. 100, receivable at his death, the annual premium is L. 2, 0s. 8d; and if he lives forty-nine years, he will have paid more than the whole sum to be received, without computing interest on these payments. The surplus of the accumulation of premiums above the claims, may be great from two causes: 1st, the increased interest obtained by the company above that by which the table of rates was computed; and 2d, a longer duration of life in the earlier years than is assigned by the table; and here, great circumspection on the part of the company is requisite to preserve it from imposition, and to secure the best lives that circumstances admit. In the companies where only the sum specified in the policy is paid, the surplus does not go entirely to the company; for it is common in these offices to allow a per centage on the premium to the party who brings an assurance to them, generally a solicitor, who, thus participating in the gains of the company, has an interest in increasing its concerns, though to the evident disadvantage of his client.

In companies where the surplus is made advantageous to the assured, two methods are adopted; the one is, to add, at certain periods, a sum to each policy; the other, to diminish the premium. In both cases, a valuation is made of all the annual premiums, with the past and future expected accumulations, and also of the claims upon every policy. If the former exceeds the latter to a sufficient amount, then an addition is made to each policy, or the premium is diminished. It is requisite, however, that the utmost care should be taken to secure to each policy the sum named in it, with every addition made to it; and hence a third part of the surplus is constantly retained to guard against possible contingencies. This reservation has

occasioned a singular anomaly in one of the most distinguished companies for life assurance. In that company all are partners, being mutually guarantees to each other for the payment of their respective claims. The surplus arising from the excess of premiums, with their accumulations above the claims, evidently belongs to the whole of the company, and consequently each partner is entitled to a portion of it. But of this surplus, a third being constantly reserved, and each person at his death ceasing to be a partner, every person leaves behind him a portion for his successors. This third is therefore, we may say, without an owner, for a partner has not a right to it during his life, and his heirs or assigns have not a claim upon it after his death.

This anomaly led to the formation of a plan, which is adopted by another company that vests this third in determinate hands. To do this, the company consists of a number of proprietors, each of whom is bound to keep up an assurance with it, and whose interest in these assurances is greater than that derived from the profit of assurances granted to non-proprietors. The company takes upon itself the whole risk of policies made with it, being bound to pay to each party assured the sum specified in his policy; and additions are made to each policy in the manner above-mentioned. But the third reserved is joined to, and makes part of the subscription capital stock; and the interest upon it is annually divided among the proprietors. Thus the third reserved belongs to, and continues to add to the security of the company, and the non-proprietor, secured from all risk, participates in the two thirds divisible at every period.

Another mode is adopted by a company, that prevents accumulations, by diminishing, at certain periods, the premiums paid on each assurance; and in this case the sum specified in the policy is paid, though the party assured may have paid a much less sum than in the companies above mentioned. The diminution of premium depends on the excess of capital in hand, with the present value of future premiums, above the claims that are or may be made upon it, and consequently the same care is necessary to reserve a part of the surplus for fear of future contingencies. The public have thus a choice either to receive a fixed or an increasing sum; the fixed sum by means of a definite or a probably decreasing premium, and an increasing sum by means of a definite premium. In all cases it is obvious, that it is most for the advantage of the public that the proprietors of the company should be assurers of each other, as well as of the non-proprietors.

Besides the companies for assurance in general, there are peculiar societies for a particular object,—those of clergymen, schoolmasters, officers in the army, and the like, for annuities to their widows, or sums to be paid to their assigns. In all these associations, calculations are made according to a general table of life, modified by the peculiar circumstances of the profession, which combines in assuring to each other certain advantages. In some of these, the premium annually paid remains the same, but the sum assured increases with the number of years that it has been paid. In all these societies, care should be taken to ascertain, at certain periods, the state of their concerns; and, in the formation of them this is peculiarly necessary, as the errors committed by persons unused to the calculations requisite in the particular modes of assurance, lead to very dangerous consequences.

Policies of assurance are generally confined to the limits of Europe, but they are capable of being extended to all parts of the world. In such cases, an addition is made to the premium, according to the supposed addition to the risk from unhealthiness of climate, and danger of the seas. An addition is in like manner made to the premium on account of the profession,—as of the army, in which the assured is engaged; and also an account of the diseases,—as of gout, by which he is occasionally afflicted; or of diseases,—as of small-pox and measles, to which he is liable.

Assurances granted by Individuals.

A policy granted by an individual is generally of short continuance, and the granter takes all the precautions he can to ascertain that the person is a fit subject for assurance: or, in other words, whose state of health is not worse than that of the average of persons of the same age in the tables. If the person is at a distance, a guarantee of health is required. The premiums required are generally higher than those of companies, and a policy is effected to greater amount than would be granted by a company, in consequence of the risk being divided between a number of individuals, who are only answerable for the sums assured in each name. The sum assured by policics granted by individuals, bears, however, a very small proportion to that granted by the companies.

Advantages of Life Assurances.

Assurances upon lives are of modern invention, and are very little known in foreign nations. They are suited only to those countries where property is amply secured, and public credit is fixed on a solid basis. The large capitals created by companies for assurance would be too great a temptation for the rapacity of a tyrant; and no one would be found to advance annual premiums, when his intention might be frustrated by the seizure of the whole, or a great part of his deposits. Assurances cannot be too much fostered in countries where due attention is paid to the morality, economy, and general welfare of the subject; yet, even in England, where these institutions have been raised by the people, and in a variety of ways, are of utility to the government, they have not escaped its grasp, and policies are made subject to a duty. The sum accruing to government is, in a national point of view, very trifling: but a policy being a contract, is thought a proper object for a stamp. It would, perhaps, be wiser in the nation to grant a bounty to these policies, than to make them an object of revenue.

The benefit of these institutions is far more extensive than is generally imagined. It is obvious, that persons whose incomes depend on their lives, such as clergymen, officers under government, physicians, &c. are peculiarly interested in them. By setting apart a portion of their income, they secure such a provision to their families at their death, as they

could not in any case have realised by their own exertions; and this is done with scarcely any trouble to themselves, whilst they have the confidence that, at whatever time the fatal stroke arrives, a provision is secured for those who are most dear to them. Physicians, as they rise in practice, are accustomed to increase their assurances; and facilities are given to those in inferior stations by the small sums that may be assured by each policy. A large class of persons, possessed of very considerable incomes, find their benefit in these institutions; for if their estates are entailed on their eldest sons, death may prevent them from making the provision they desire for their younger children, unless they secure it by an assurance. Persons engaged in trade have similar advantages; for, at marriage, part of the fortune of the wife, which is frequently tied up by marriage-settlements, may be realised to the husband, on appropriating a certain part of the interest of the part tied up to the payment of the premium of such a sum, as shall, with the part tied up, be equal, at his decease, to the original fortune of the wife. Short period policies are found beneficial also, in numerous instances. For example, a legacy is to be received at a certain time, if the legatee is alive at that time; it may be a few months or a few years; in either case the sum may be secured to him, for he may have it either from the office or under the will. A person takes a voyage, which will be completed within the year, and on his performance of it, depends certain advantages; these are secured in the same manner by means of the office. A debt has been contracted, which the debtor will pay at a certain time, if he is alive; the creditor secures it by assuring the life for that time. Similar cases will occur to the mind of the reader; but it is to be observed, that the legislature has very properly interfered in preventing policies being granted *ad libitum*; for otherwise they might be made the vehicles of gaming transactions. It is declared unlawful for a policy to be granted, unless the person effecting the assurance has a legal interest in the life of the party on whom it is effected, *i. e.* unless the cessation of life of that party is detrimental to him in a pecuniary way. Before the passing of the act to this purpose, persons were used to hunt out for infirm or diseased subjects, on whom to effect assurances, to the detriment of the office, or individuals they had to deal with; and even parents have effected policies on their children whose deaths, in consequence, they are said to have accelerated.

Principal Assurance Societies.

The societies for assurances on lives in London are now numerous. The oldest of them is the *Amicable Society*, instituted by charter in the year 1706. The history of this society proves the little knowledge there was on the subject at that time; for the same contribution was required from every member, whatever his age might be, and the sums received at the death of members were variable, depending on the number of persons that died in the same year. Subsequent alterations were made in this company by successive charters. At present, the several interests of the members are divided into shares, each share being now warranted to produce L. 200 at the death of the insured, together with such additions as may arise from the circumstances of the year in which the death happens; and any number of shares, and half shares, not exceeding sixty-five shares, may be granted on one and the same life, by which assurances may be effected from L. 200 to L. 5000, and participate in the benefits of the Society.

The *Royal Exchange Assurance Company* received its charter in 1720, and is chiefly engaged in insuring ships and goods at sea, and of houses and goods from fire, but it also grants annuities and assurances on life. In the latter, it confines itself to the payment of the sum assured.

The *Equitable* is the most considerable in point of numbers of the societies for the assurance of lives, to which object it is chiefly confined. In this society all are partners, and mutually assurers of each other. It arose from small beginnings, and has made considerable alterations from the rate of its first premiums, till it settled in the table annexed to this article, which is that generally adopted by these associations. At certain periods, additions have been made to the policies; and, in this manner, its affairs were conducted till December 7, 1809, when a change took place respecting the members then assured, namely, that instead of waiting till the end of the next interval, for assigning a sum out of the accumulations to each policy, every member should have two *per cent.* annually assigned to his policy, during the years of this period. Consequently, all holders of policies, prior to the year 1810, will leave to their heirs the sum assured by the policy, together with its accumulations up to the year 1810, and also two *per cent. per annum* for his life, within 1810 and 1820; but this benefit does not accrue to members entering at the close of the year 1809. Whether this plan will be continued after the year 1820, time will show. The number of the members in this society made it necessary to change some of their regulations respecting votes; and it was wisely resolved, that persons becoming members, after the 19th December 1809, should not have a vote at the general meetings, unless they had been assured for five years, for the whole continuance of life, in the sum of L. 2000; and to be a director, the qualification is an assurance of L. 5000 for the same time, and must have held it for five years.

The history of this society is very important in the subject of assurance for lives; it has been well treated by Dr Price, in his *Observations on reversionary payments*, and by Mr Morgan in his addresses to the society. In consequence of the connection of Dr Price with this institution, he drew up his remarks on the various societies which soon after sprung up, and whose names, but for his notice of them, would now be forgotten. They were formed chiefly about the years 1770 and 1771, offering very fallacious terms to the public, by which the aged were benefited at the expence of their juniors; and the evil is not yet cured; for, notwithstanding the experience of the past, similar societies are formed, but chiefly on the plan of granting annuities at the distance of ten or twelve years from a certain age, by which those at and near this age are promised such advan-

tages, as cannot be produced but by the loss of the younger part of the society.

For some time no other important society arose; but, from the year 1792, in which the *Westminster Life Assurance* was formed, several considerable companies derive their origin. The *Pelican* in 1797; the *Globe* in 1799; the *Albion* in 1805; the *Rock* and the *Provident* in 1806; the *Eagle*, *Hope*, *London Life Association*, and *Atlas*, in 1807.

The *Rock* was founded on the plan of the *Equitable;* the material distinction between them being, that the concerns of the company are vested in a body of proprietors, who are assurers of each other, and also of those who are not proprietors. Both parties, as to the additions made to the policies, are in the same situation; but, in the appropriation of the accumulations, one-third of the excess of them, above the claims, is affixed to the capital stock, these lying answerable for any claims; and the interest of it is divided among the proprietors for the risk they take among themselves in making assurances. This society confines itself entirely to assurances and annuities on life.

The *Provident* combines with life, policies on fire; but it assigns also, at certain times, additions to its policies. The *Hope* is also a fire and life office, and both are proprietary companies. The rates in these societies are the same as those in the Equitable and Rock.

The *Albion* and the *Globe* are life and fire assurance companies; their rates are also the same. They pay only the sum assured; but it is stated that "a very liberal commission is allowed to solicitors, and to others who effect life assurances."

The *London Life Association* is confined entirely to life assurances; but it differs from the others in this, that its aim is, that the benefits resulting from its transactions shall be enjoyed by the members during life; in other words, the society assures to a person the sum named in the policy and no more; but at certain times it considers, whether the surplus of the accumulations above the claims is sufficient to admit of a diminution of premium, and one is made accordingly. In this society, all are members and assurers one of the other, and consequently the surviving members at any time are bound to make up the deficiency, if any should arise by this mode of arrangement. This could be done by raising, in the first instance, the premiums that have been lowered; and it is very improbable, that, with good management, any thing farther would be necessary.

In imitation of the London Companies, several have been formed throughout the country; and it may in general be observed of them all, that where they differ from the common table of rates, it has been rather by supposing that a deduction may be made from those rates, and acting according to their discretion in this case, than by assuming a scale of life, and thence forming calculations for the premium on each age. There is some difference also in the manner in which an assurance is effected; some being supposed to be stricter in their examinations than others, and requiring greater formalities; but it must be taken into consideration, that an assurance is a contract between two parties on certain conditions, and on both sides it is desirable, that the greatest care should be taken in the formation of the contract. In fact, circumspection is the great security of both assurers and assured, for without it a society may appear to be very flourishing, when it is in fact hastening to its dissolution.

A cause in which a company out of London was lately engaged, discovered that the company at first diminished the rates, and after a time increased them, in both cases, without any regard to mathematical calculation, or a table of lives. The company refusing to pay a claim, forgot this circumstance, which was detected by the production of the two books of rates, formed at different times; and the objection to pay the claim, on the ground that the premium was not sufficient, was overruled, by comparing it with that required by the table of rates in existence when the policy was effected. Where the premium is less than that generally required, the person desirous of effecting an assurance on his life should be particularly on his guard, lest he may be a considerable sufferer by the apparent cheapness of his contract.

The following is a TABLE of the RATES generally acted upon by the Life Assurance Offices in the Capital. (BB.)

TABLE

## ASSURANCE ON SINGLE LIVES.

*To secure a Sum to the Nominee, or to the lawful Representatives of the Assured.*

| Age. | PREMIUM *per Cent* if assured from Year to Year. | | | PREMIUM *per Cent. per An.* if assured for Seven Years. | | | PREMIUM *per Cent. per An.* if assured for the whole Term of Life. | | |

# ASTRONOMY, PHYSICAL.

Introduction.

The whole science of Astronomy may be reduced to two general problems. The first is to express the position of all the heavenly bodies in terms of the time reckoned from a given instant, either in the past or the future duration of the world. The same may be otherwise stated by saying, that the thing required is, to express the position of any one of the heavenly bodies in a function of the time, the time being considered as the only variable quantity, though combined with other known quantities, which enter into the function as the co-efficients of the different terms. This is the most general view of that which is usually called Descriptive, or sometimes Geometrical Astronomy. The solution of this problem enables us to determine for any time the places of the heavenly bodies, relatively to one another, and relatively to any point on the earth's surface. It contains under it an endless variety of subordinate problems, embracing a long series of successive generalizations, from the first observations, to the determination of the orbits of the heavenly bodies, and the final reduction of all that concerns their motions into the form of astronomical tables. The second problem is, to compare the laws of motion in the heavens, as discovered from the preceding investigations, with the laws of motion as already known on the surface of the earth, in order to find out whether or not they are the same; and, if not, in what their difference consists. The solution of this problem constitutes what is called Physical Astronomy; it is the same with inquiring into the causes of the celestial motions: for by *causes* we mean the general facts concerning the motion of bodies which are observed to take place on the surface of the earth.

Though the first of these two problems goes necessarily before the second, for the solution of which it affords the *data*, yet, after this solution is obtained, it affords great assistance to many of the researches involved in the first, and exemplifies, in a most remarkable manner, the use of theory in the investigation of facts, and the re-action, as it were, of the second problem on the first.

Taking for granted the solution of the first problem, as given under the article ASTRONOMY in the *Encyclopædia*, we are now to consider the second, and to explain the manner in which it has been resolved by Newton and the philosophers who have come after him.

The history of the first of these two problems is long and interesting, beginning from the remotest period to which the records or the traditions of mankind have ventured to ascend, and coming down to the present time; and, in the ages to come, it is never likely to know any limit but the moveable instant which separates the past from the future,—as long, at least, as science and civilization are inhabitants of the earth.

The history of the second comes within small compass; because between the first rude effort, and the last refined investigation, there is hardly any intermediate step but one.

Introduction.

The concentric orbs of the ancient philosophers were an attempt at an explanation of the Physical causes of the Celestial Motions, or at an assimilation of those motions to such as we are accustomed to see on the surface of the earth. The great phenomenon to be explained was, the diurnal motion of the heavens, by which so many bodies, very distant from one another, all describe circles round the earth, keeping time so precisely with one another, that the revolutions, whether great or small, are accomplished in the same interval. This could not be, unless a connection subsisted between those bodies; and the most simple idea of that connection was, that the bodies were fixed in the surface of a sphere which revolved on an axis, and carried them along with it.

If the whole of Astronomy had been confined to the single fact of the diurnal revolution of the fixed stars, the hypothesis just mentioned would have been quite satisfactory. But as some of the heavenly bodies, such as the sun and planets, did not revolve precisely in the same time with the rest, it was necessary to assign to them particular spheres of their own. Those spheres therefore must be transparent; light must find an easy passage through them, and hence they must be crystalline. By degrees, as more accurate knowledge was obtained of the motion of the planets, it was found necessary so to increase the number of the spheres, that the complication of the structure was burdensome to the imagination; the hypothesis did not answer the very first object of a theory, that of connecting the facts together; and it was so unlike any process of nature with which we are acquainted, that it was highly improbable. The hypothesis of the homocentric orbs therefore fell into discredit; and, after the discovery of the earth's motion, was entirely abandoned.

The next attempt to explain the whole system of the celestial motions was that of Descartes, by means of vortices of subtle matter, and the pressure which, by the centrifugal force of those vortices, was produced on the grosser bodies of the stars. But, as a taste for accurate knowledge increased, and as men reflected more on the true objects of philosophic theory, the system of vortices appeared more and more defective, and at length ceased to have any followers.

Newton succeeded, who, rejecting all the cumbersome machinery, both solid and fluid, of his predecessors, adopted a plan far more philosophical in the design, and far more difficult in the execution, than any thing yet known in the physical or mathematical sciences. Assuming as true the three general facts concerning the planetary system known by the name of the laws of Kepler, he proceeded to inquire by what sort of action on one another the planets could be made to describe orbits having the properties indicated by these three general facts. The general facts to which we now refer, are,

I. *That every planet moves so that the line drawn from it to the sun describes about the sun areas proportional to the time.*

II. *That the planets describe ellipses, each of which has one of its foci in the same point, viz. the centre of the sun.*

III. *That the squares of the times of the revolutions of the planets are as the cubes of their mean distances from the sun.*

### Section I.

### *Of the Forces which retain the Planets in their Orbits.*

1. *If a body gravitating to a fixed centre, have a motion communicated to it in a direction not passing through that centre, it will move in a curve, and the straight line drawn from the body to the centre will describe areas proportional to the times.*

Let S (fig. 1.) be the centre to which the body A gravitates, at the same time that a motion is communicated to it in the direction AB. And first, let the gravitating or centripetal force be supposed to act not continually but at intervals, producing instantaneously, at the beginning of each interval, the same velocity that it would have produced by acting continually during the whole of that time: let AC be the space which the body would describe by the action of this force alone; also let AB be the space which it would describe in the same time by the projectile force acting on it alone. It will therefore describe the line AD, the diagonal of the parallelogram contained by AB and AC, and at the end of the first interval will be in D. If, then, no new impulse of gravity were to act on it, it would in the second interval of time go on in the direction AD, and describe DF equal to AD. But, if, at the beginning of the second interval, an impulse of the centripetal force be instantaneously impressed, sufficient to carry the body in that time from D to E, in the line DS, it will describe the line DG, the diagonal of the parallelogram contained by DE and DF. The same is true of the third interval, in which the body will go from G to L, and of every subsequent interval. Join SB, SF, SK, &c. The areas of the triangles ABS, ADS are equal, the triangles being on the same base AS, and between the same parallels AS and BD. For the same reason, the triangles DGS, DFS are equal, and DFS is equal to ADS, because they have equal bases and the same altitude. For the same reason, the triangle SGL is equal to SDG, or to ADS; and the same is true of all the other triangles that are described in the equal intervals of time by the line drawn from the body to the centre S. This holds, however short the intervals may be, and however great their number; and therefore, it is true, when the intervals are infinitely small, and their number infinitely great, that is, when the action of the centripetal force is continual.

But when the intervals of time become infinitely small, the rectilineal figure ADGL passes into a curve. For when these intervals diminish, the lines AB, DF, &c. the lengths of the parallelograms, diminish in the same proportion, but the lines AC, DE, &c. the breadths, diminish in a greater proportion, viz. in that of the squares of these intervals. Hence, the angles which AD, DG, GL, the diagonals, make with the sides AB, DF, GK, continually diminish; and therefore, the angles ADG, DGL, or the angle which each diagonal makes with that which is contiguous, increases without limit, so that, as the diagonals diminish in length, the angles they make with one another become greater than any finite rectilineal angles, and therefore the figure becomes a curve line.

That the lines AC, &c. or the supposed effect of the centrifugal force diminish as the squares of the times, is evident from the laws of the descent of heavy bodies, as explained under the head of Dynamics.

2. Hence, conversely, if a body move in a curve, so that the line drawn from it to a fixed point, describe areas proportional to the times, the body gravitates to that point, or tends continually to descend to it.

For, since it does not move in a straight line, it must be continually acted on by a deflecting force; and the direction of the deflecting force must always pass through the same point, otherwise the areas described about that point would not be proportional to the time.

3. Corollary. The velocities of a body in different points of the curve, which it describes about a centre of force, are inversely as the perpendiculars drawn from the centre to the tangents of the curve at these points. Let ACA′, fig. 2., be the curve which a body describes about the centre S. Let A$a$ and A′$a'$ be two arches of the curve, described in the same indefinitely small portion of time. Join S$a$, S$a'$, then the areas of the triangles AS$a$, A′S$a'$ are equal by this proposition. At A and A′, draw the tangents AB′ A′B′, and from S let fall on them the perpendiculars SB and SB′. Because the areas of the triangles AS$a$, A′S$a'$, are equal, $Aa \times SB = A'a' \times SB'$, or $Aa : A'a' :: SB' : SB$; but A$a$ is to A′$a'$ as the velocity of the body describing the curve at A to its velocity at A′; therefore, these velocities are inversely as the perpendiculars SB, SB′.

The straight line AB, (fig. 1.), according to which the projectile motion was impressed on the body, is a tangent to the curve at the point A.

4. On comparing the first and second of these propositions, with the first of Kepler's laws, as just enumerated, it is evident that the primary planets all gravitate to the sun, and that the secondary planets gravitate every one to its primary. The next thing, therefore, is to discover the law observed by this force, or the function of the distance to which it is proportional; and also, whether, in that function, other variable quantities are not involved beside the distance. The general fact that the orbits, or curves described by the planets round the sun are ellipses, may assist in this investigation, and in expressing the velocity of a planet, in terms of the radius vector, or its distance from the sun.

5. Let ADBE (fig. 3.) be the orbit of a planet, S the focus in which the sun is placed, AB the transverse, and DE the conjugate axis, C the centre, and F the superior focus. Let the planet be anywhere at P; draw a tangent to the orbit in P, on which from the foci let fall the perpendiculars SG, FH. Draw also DK touching the orbit in D, and let SK be perpendicular to it. Let the velocity of the planet, when at the mean distance, or at D, be $= c$, and when at

$P = v$. Join SP, FP. Then, by the corollary to the last proposition, the velocity at D is to the velocity at P as SG to SK, that is, $c : v :: SG : DC$, or $v = c . \frac{DC}{SG}$.

But because the triangles SGP, FHP, are equiangular, having right angles at G and H, and also the angles SPG, FPH equal, from the nature of the ellipse, $SP : PF :: SG : FH$, and, therefore, also $SP : PF : SG^2 : SG \times GH$. But $SG \times FH = CD^2$, therefore $SP : PF :: SG^2 : CD^2$, and $\frac{CD^2}{SG^2} = \frac{PF}{SP}$.

Now $v = c . \frac{CD}{SG}$, or $v^2 = c^2 . \frac{CD^2}{SG^2}$, and therefore $v^2 = c^2 . \frac{PF}{SP}$.

*Hence, as the distance of a planet from the sun, at any point in its orbit to its distance from the superior focus, so the square of its velocity at its mean distance from the sun to the square of its velocity at the point just mentioned.*

6. If SL be taken in the greater axis equal to SP, and $FN = PF$, so that $SN =$ the tranverse axis AB, $v^2 = c^2 . \frac{NL}{LS}$. Then as SN is a given line, $v$ is expressed in terms where SP, the distance from the sun, is the only variable quantity.

If, from the velocity of the revolving body thus expressed, in terms of the distance, a transition can be made to that of a body descending in a straight line, the law of the centripetal force will be easily investigated. This will be facilitated by the following proposition:

*An equal approach to the centre of force, produces an equal increase of the square of the velocity, whether the body revolve in a curve about the centre, or descend to it in a straight line. In like manner, equal recesses from the centre of force, produce equal diminutions of the square of the velocities, in whatever lines the bodies move.*

Let ABC (fig. 4.) be a curve which a body describes about a centre, S, to which it gravitates, while another body descends in a straight line AS, to that centre. Let BC be any arch of the curve ABC, and let BD, CH, be arches of circles described from the centre S, intersecting the line AS in D and H; the square of the velocity of the body, which describes the arch BC, will be as much increased as the square of the velocity of that which falls through DH.

From the centre S, describe the arch $bd$, indefinitely near to BD, and draw E$f$ perpendicular to the arch B$b$. Also let the centripetal force at B or D, be called G. Now, the part of this force which is in the direction B$b$, and which is employed in accelerating the body moving in that line, is $G \times \frac{Bf}{BE}$ and the increment of the space being B$b$, therefore, $2G \times \frac{Bf \times Bb}{BE}$ is the momentary increment of the square of the velocity of the body at B. But $Bf \times Bb = BE^2$, because BE$b$ is a right-angled triangle, and E$f$ the perpendicular on the hypothenuse. Therefore $2\,G \times \frac{Bf \times Bb}{BE} = 2\,G \times \frac{BE^2}{BE} = 2G \times BE = 2G \times Dd$. But $2G \times Dd$ is the momentary increment of the square of the velocity of the body at D, or the increment of that square, while the body falls from D to $d$. These momentary increments therefore are equal; and as the same may be shown for the next and every subsequent instant, the whole increase of the square of the velocities of the bodies in moving over BO and DH are equal.

If the bodies moved in the opposite directions, the one from C to B, and the other from H to O, it would be proved, in the same manner, that the squares of their velocities would be equally diminished.

7. Hence it is evident, that, if the velocities of the revolving and of the falling body, are equal in any one instance when they are equally distant from the centre, their velocities will always be equal when they are equally distant from that point. For equal quantities receiving equal increments continue equal.

8. Suppose now, that a planet revolves in the elliptical orbit APB (fig. 3.), it will have at A, the higher apsis, a velocity $= c \times \sqrt{\frac{AF}{AS}}$, or (if AN in the axis produced, be taken equal to AF) $= c \times \sqrt{\frac{AN}{AS}}$.

Let a body at A begin to descend towards S with the same velocity, then if $SL = SP$, the velocity of the planet at P, will be the same with that of the falling body at L. But the velocity of the planet at P is $c \times \sqrt{\frac{PF}{PS}} = c \times \sqrt{\frac{NL}{SL}}$, therefore, a body descending from A, and falling directly to the sun, under the action of the same centripetal force which urges the planet, would at any point L in its fall have its velocity $= c \times \sqrt{\frac{LN}{LS}}$. Hence at the point N, its velocity would be equal to 0, or the body must begin to fall from N, in order that its velocity may be everywhere equal to that which the planet has in its orbit, when at the same distance from the sun.

The law, therefore, according to which the planets gravitate is such, *that any body under the influence of the same force, and falling direct to the sun, will have its velocity at any point equal to a certain velocity, multiplied into the square-root of the distance it has fallen through, divided by the square-root of the distance between it and the sun's centre.*

This is a fact with respect to the law of gravity in the solar system, of which, though there be no direct example, yet is it no less certain than the ellipticity of the planetary orbits, of which it is a necessary consequence.

From the law thus found to regulate the velocity of bodies falling in straight lines to the sun, the law of the force by which that velocity is produced, may be derived by help of reasoning which is quite elementary.

Let C (fig. 5.) be the centre to which the falling body gravitates, A the point from which it begins to fall,

Physical Astronomy.

and let its velocity at any point B, be to its velocity in the point G, which bisects AC as $\sqrt{\frac{AB}{BC}}$ to 1; it is required to find the law of the force with which the body gravitates to C.

Let DEF be a curve, such, that if AD be an ordinate or a perpendicular to AC, meeting the curve in D, and BE any other ordinate, AD is to BE, as the force at A to the force at B, then will twice the area ABED be equal to the square of the velocity which the body has acquired in B. If, therefore, the velocity at B be $v$, that at the middle point $b$ being $c$, $v = c\sqrt{\frac{AC}{BC}}$, by hypothesis, and, therefore, $2ABED = c^2 . \frac{AB}{BC}$, and since $AB = AC - BC$, $2ABED = c^2 . \frac{AC - BC}{BC} = c^2\left(\frac{AC}{BC} - 1\right)$. For the same reason $2AbED = c^2\left(\frac{AC}{bc} - 1\right)$ and, therefore, the difference of these areas, or $2BbeE$, that is, $2EB \times Bb = c^2\left(\frac{AC}{bc} - \frac{AC}{BC}\right) = c^2 . \frac{AC . Bb.}{BC^2}$ Wherefore, dividing by $Bb$, $2 EB = c^2 . \frac{AC}{BC^2}$, or $EB = c^2 . \frac{AG}{BC}$; now $c^2$ and AG are given, therefore, EB is inversely as $BC^2$, that is, the centripetal force at B is inversely as the square of BC, the distance from the centre of force. *In the planetary system, therefore, the force with which any planet gravitates to the sun, varies in the inverse ratio of the square of the distance of the planet from the sun's centre.*

10. The line CG is the same with the mean distance of the planet, in an orbit of which AC is the length of the transverse axis, and if the gravitation at that distance $= F$, and the mean distance itself $= a$, $F = c^2 . \frac{a}{a^2} = \frac{c^2}{a}$, or $aF = c^2$.

Let it next be required, the elliptic orbit of a planet being given, to find the time in which the planet will revolve round the sun.

If $a$ be the mean distance, or the semitransverse axis, $b$ the semiconjugate, then $\pi ab =$ the area of the orbit. But as $c$ is the velocity at the mean distance, or the elliptic arch which the planet moves over in a second when it is at D, the vertex of the conjugate axis, therefore $\frac{1}{2} bc$ is the area described in that second by the radius vector; and since this area is the same for every second of the planet's revolution, therefore the area of the orbit divided by $\frac{1}{2} bc$ will give the number of seconds in which the revolution is completed, which is therefore $= \frac{\pi ab}{\frac{1}{2} bc} = \frac{2\pi a}{c}$, or since $c^2 = a F$, the time of a revolution $= \frac{2\pi a}{\sqrt{aF}} = 2\pi\sqrt{\frac{a}{F}}$.

11. Hence it is easy to compare the times of the revolutions of any two planets of which the mean distances are known. Let $t$ and $t'$ be the times of revolution for two different planets, of which the mean distances are $a$ and $a'$, and the gravitation at those distances F and F′, and, by what has just been $F : F' :: a'^2 : a^2$, by what is already shown, therefore shown $t : t' :: \frac{a^{\frac{1}{2}}}{F^{\frac{1}{2}}} : \frac{a'^{\frac{1}{2}}}{F'^{\frac{1}{2}}}$, or $t^2 : t'^2 :: \frac{a}{F} : \frac{a'}{F'}$. But $t^2 : t'^2 :: \frac{a}{a'^2} : \frac{a'}{a^2}$, or $\tau^2 : \tau'^2 :: a^3 : a'^3$, *that is, the squares of the times of revolution of any two planets, are as the cubes of their mean distances from the sun.* Thus the third law of Kepler is explained by the conclusions deduced from the other two.

Physical Astronomy.

12. The share which this third law has in establishing the principle of universal gravitation, does not seem to have been always clearly apprehended. From the elliptical orbit of a planet, it is fairly inferred that, over all the circumference of that orbit, gravitation is inversely as the square of the distance from the centre of the sun. That force is shown to be $\frac{c^2 a}{x^2}$, and the same is true of every individual planet; but whether $c^2 a$ was a constant quantity, or one which retained the same value through the whole planetary system, could not be known without comparing the periods of different planets, with their distances from the sun. It was indeed highly probable, that $c^2 a$ was a given quantity, or the same for every part of our system; but it could not be considered as a thing demonstrated till the evidence of the third law was introduced.

13. These laws hold of the secondary planets relatively to their primary, just as with the primary planets relatively to the sun. Each system of secondary planets, however, has a different numerator to the fraction which expresses gravity; that is, the quantity $c^2 a$ is the same for all the satellites of Jupiter, but it is a different quantity from that which belongs to the satellites of Saturn, and different from that which belongs to the primary planets. The quantity $c^2 a$ seems therefore to depend on the central body of each system of planets, and the precise nature of this connection requires to be farther examined into.

14. Let the centripetal force tending to a given centre $s$ be inversely as the squares of the distances, and let the intensity of that force at any given distance from the centre be also given; then, if a body be projected from a given point, with a given velocity, and in a given direction, it is required to determine the conic section which it will describe.

Let the semitransverse, or the mean distance to be found $= a$, the semiconjugate $= b$, the velocity at the distance $a = c$, and at the given distance $d$ let the centripetal force $= f$, and first let the direction of the initial motion be at right angles to the radius vector, so that the point of projection is either the higher or the lower apsis. Let the velocity of the projection $= v$, and the radius vector at the point of projection $= r$.

Because the areas described in equal times are

equal, $bc = rv$; and if F denote the centripetal force at the distance $a$, $c^2 = a\text{F}$, and $\text{F} = \frac{c^2}{a}$. But $\text{F} = \frac{d^2f}{a^2}$, therefore $\frac{c^2}{a} = \frac{d^2f}{a^2}$, and $c = d\sqrt{\frac{f}{a}}$. Hence, by substituting for $c$, $bd\sqrt{\frac{f}{a}} = rv$, and $b^2d^2f = ar^2v^2$. But $b^2 = \text{AS} \times \text{SB} = r\ (2\,a - r)$, wherefore $r\ (2\,a - r)\ d^2f = ar^2v^2$, and $a = \frac{rd^2f}{2d^2f - rv^2}$. Thus $a$, the semitransverse axis, and therefore the transverse axis itself is found, and thence with the focus S and the apsis A, the conic section may be described.

15. The cônic section will be a circle, when $a = r$, that is, when $2\,d^2f - v^2r = d^2f$, or when $d^2f = v^2r$, and $v^2 = \frac{d^2f}{r}$.

16. But if $2d^2f = rv^2$, or $v^2 = \frac{d^2f}{r}$, the denominator vanishes, and $r$ becomes infinite, so that the trajectory is a parabola, of which the focus is S, the vertex A, and the parameter $4r$. *The square of the velocity which determines the trajectory to be a parabola, is, therefore, double of the square of the velocity which determines it to be a circle.*

17. When $2d^2f > v^2r$, the value of $a$ is affirmative, and the conic section is an ellipsis, and this ellipsis has its higher apsis at A, if $v^2 < \frac{d^2f}{r}$, but when $v^2 > \frac{d^2f}{r}$, and less than $\frac{2d^2f}{r}$, A *is the lower apsis.*

18. When $v^2$ goes beyond this last limit, or when $v^2 > 2\,d^2f$, the value of $a$ is negative, and the trajectory become a hyperbola.

19. Next, let the body be projected from B (fig. 6.) with the velocity $v$, in the direction BD, oblique to BS. Find the distance from which a body must fall to acquire at B the velocity $v$, and let OB taken in SB produced, be equal to this distance; then is SO equal to the transverse axis. Let BE be drawn, making with BD the same angle that SB makes with BG, and let BE = BO, then is E the higher focus. Produce SE to N, so that SN = SO, and bisect EN in A, then is A the higher apsis, and if SP be made equal to EA, P is the lower apsis, and AP the transverse axis, and therefore the foci and the transverse axis being given, the elliptic orbit may be described.

20. From what has been shown at Art 9. it is evident, that the primary planets gravitate to the sun with forces that are inversely as the squares of the distances, and that the secondary gravitate toward the primary, according to the same law. This inference, however, does not apply exactly to the moon, which, being a single satellite, does not by comparison with any other, afford a proof that, in bodies revolving round the earth, the squares of the periodic times are as the cubes of the distances. The centripetal force at the moon, however, from our knowledge of her periodic time, may be compared with the force of gravity at the earth's surface, and will determine whether that force decrease as we recede from the earth in the inverse ratio of the squares of the distances.

Let $a$ be the distance of the moon from the centre of the earth, $r$ the radius of the earth, $g$ the velocity acquired by a heavy body at the earth's surface, by falling during one second; let $t$ be the period of the moon's revolution in seconds, and $c$ the velocity of her motion. Then by sect. 14. $ac^2 = r^2g$, and, therefore, $c = r\sqrt{\frac{g}{a}}$.

Now, the circumference of the circle described by the moon is $2\pi a$, and this, divided by $c$, gives the periodic time of the moon in seconds, or $\frac{2\pi a}{r} \times \sqrt{\frac{a}{g}} = t$, so that $t^2 = \frac{4\pi^2a^3}{r^2g}$, and $a^3 = \frac{r^2gt^3}{4\pi^2}$. Hence $\frac{a^3}{r^3} = \frac{gt^2}{4\pi^2r}$, and $\frac{a}{r} = \left(\frac{gt^2}{4\pi^2r}\right)^{\frac{1}{3}}$. Hence as $g$, $r$, and $t$, are known, we may find $\frac{a}{r}$ or the ratio of the moon's distance to the radius of the earth, which, if it come out the same that it is known to be, from observations of the moon's parallax, will prove, that the force which retains the moon in her orbit, is the same that causes bodies to fall at the surface of the earth, but diminished in the same ratio that the square of the moon's distance is greater than the square of the radius of the earth.

Now $g = 32.166$ feet, $r = 3481279.4$ fathoms, or $20887676.4$ feet, and $t = 2360591.5$ seconds. Hence $\frac{a}{r} = 60.218$.

Now the mean equatorial parallax of the moon is found by observation, $= 57'11''.4$ from which the mean distance in semidiameters of the equator is found $= 60.121$.

But it is in mean semidiameters of the earth, that the moon's distance is given in the former computation; therefore, to reduce the last measure to the same scale, it must be increased by a 600th part, as the mean radius of the globe is about that much less than the radius of the equator; the distance 60.121, then becomes 60.221, which agrees with the former number to the small fraction .003 of the earth's radius.

Thus, from the theory of gravity, combined with the time of the moon's sidereal revolution, her distance from the earth is found to be less than a twenty-thousandth part of the whole.

21. *It is, therefore, a general proposition, derived from the most rigorous induction, that the primary planets gravitate to the sun, and the secondary planets to the primary, with forces which are inversely as the squares of the distances.* But since, in all communication of motion, the reaction is equal to the action, when a planet gravitates to the sun, analogy forces us to conclude, that the sun gravitates to the planet, in such

a manner, that, if the momentary approach of the planet to the sun, and of the sun to the planet, were respectively multiplied by the quantity of matter in those bodies, the products, or the *quantities of motion*, would be equal. Such a mutual tendency, therefore, of the great bodies of our system to the sun, and of the sun to them, doubtless takes place; but whether this be in consequence of an attractive force residing in their centres, as the magnetic force does in certain parts of the loadstone; or if it arise from the mutual attraction of all the particles of the one for all the particles of the other, does not appear from the phenomena hitherto examined. We may, however, observe that the bodies between which this attraction in the inverse ratio of the squares of the distances takes place, are all of a round form, and are either accurately spherical, or nearly approaching to that shape. It will therefore be of use for resolving this question, to inquire whether, if the particles of matter did attract one another with forces inversely as the squares of their distances, the spherical bodies, compounded of such particles, would attract one another according to the same law. If this is found to be the case, it will be reasonable to conclude, that the gravitation of large bodies to one another arises from the mutual attraction of their particles to one another.

22. In order to determine the relation between the attraction of a sphere and that of the particles of which it consists, we may consider the sphere as made up of plates or *laminæ* infinitely great in number, and infinitely small in thickness. The attraction of each of these is to be estimated, and from thence the attraction of the whole may be computed. Let AFBG (fig. 7.) therefore, be a circular plate, of which the centre is C, CE a straight line passing through C, and perpendicular to the plane AFBG; E any particle in that line attracted by each particle of the circular plate, as D, with a force inversely as the square of DE, the distance between the particles; it is required to find the whole force with which E is attracted in the direction EC.

If DC be drawn, the force with which D attracts E in the direction ED is inversely as $DE^2$ or as $\frac{1}{DE^2}$, and that same force, reduced to the direction EC, is as $\frac{1}{DE^2} \times \frac{EC}{DE} = \frac{EC}{DE^3}$. From the centre C, with the radius DC, let a circle DKH be described, and indefinitely near it the circle $d\,k\,h$, then, since every particle in the *ring* of matter contained between these circles has its attraction proportional to $\frac{EC}{ED^3}$, the attraction of the whole ring will be as $\frac{EC}{ED^3}$ multiplied into the number of particles, or into the solidity of the ring. But if $EC = a$, $ED = x$, and $AC = r$, $CD^2 = x^2 - a^2$, and the surface of the ring $= 2\pi x\dot{x}$. If then the thickness of the plate $AFBG = m$, the solidity of the ring $= 2\pi m x\dot{x}$, and its attraction in the direction EC is $= \frac{2\pi m x\dot{x} \times a}{x^3} = \frac{2\pi a m\dot{x}}{x^2}$, the fluent of which taken so as to vanish when $DC = 0$, or when $x = a$, is $2\pi m - \frac{2\pi m a}{x} = 2\pi m\left(1 - \frac{a}{x}\right) =$ the attraction of the circle DKH. Therefore, when $x = AE$, the whole attraction of the plate, or the whole force which it exerts on the particle E, is $2\pi m\left(1 - \frac{EC}{ED}\right)$.

23. Next, let ADB (fig. 8.) be a circle of which the centre is C, and E a particle of matter any where in the diameter AB produced. Draw ED to any any point D in the circumference; draw also DC, and let DF be at right angles to AB. Then, when the whole figure revolves about EB, the semicircle ADB will generate a sphere, and DF a circle perpendicular to the plane ABD, and having its centre in F. If all the particles of the sphere attract the particle E with forces inversely as the squares of their distances from it, then, by the last proposition, the attraction of the circular plate, of which the centre is F, will be $2\pi m\left(1 - \frac{EF}{ED}\right)$.

Let $CE = a$, $AC = r$, $ED = x$, $EF = y$, and the attraction above will be $2\pi m\left(1 - \frac{y}{x}\right)$; and if $x$ and $y$ be variable, the quantity $m$ in this formula, or the thickness of the circular plate will be $= \dot{y}$, and therefore the attraction of the plate $= 2\pi\dot{y}\left(1 - \frac{y}{x}\right)$. In order to integrate this quantity, $y$ must be expressed in terms of $x$, or $x$ in terms of $y$.

Now, because $AE = a - r$, and $AF = y - a + r$, $FB = 2r - y + a - r = a + r - y$, and $AF \times FB = (y - a + r)(a + r - y) = r^2 - a^2 + 2ay - y^2 = DF^2 = x^2 - y^2$. Hence $r^2 - a^2 + 2ay = x^2$, or $y = \frac{a^2 - r^2 + x^2}{2a}$, and therefore $\dot{y} = \frac{x\dot{x}}{a}$. By substituting these values of $y$ and $\dot{y}$ in the expression for the attraction of the circular plate, that attraction

$$= \frac{2\pi x\dot{x}}{a}\left(1 - \frac{a^2 - r^2 + x}{2ax}\right)$$

$$= \pi\left(\frac{2ax\dot{x} - a^2\dot{x} + r^2\dot{x} - x^2\dot{x}}{a^2}\right).$$

But the attraction of this circular plate may be considered as the fluxion of the attraction of the spherical segment, generated by the revolution of the arch AD, and therefore the fluent of the above fluxionary quantity will give the attraction of that segment. Now, this fluent $= \pi\left(\frac{ax^2 - a^2x + r^2x - \frac{1}{3}x^3}{a^2}\right) + C.$

Here C must be so determined, that the fluent may be equal to 0, when the arch AD = 0, or when $x = y = a - r$. Therefore $C = \frac{\frac{1}{3}a^3 - ar^2 + \frac{2}{3}r^3}{a^2}$; and the attraction $= \frac{\pi}{a^2}(ax^2 - a^2x + r^2x - \frac{1}{3}x^3 + \frac{1}{3}a^3 - ar^2 + \frac{2}{3}r^3)$. This is the attraction of the spherical segment, generated by the arch AD, and will become equal to that of the whole sphere when AD = the semicircle ADB, or when $x = a + r$. This substitution being made, and the terms reduced, the attraction is found $= \frac{4\pi r^3}{3a^2}$. But $\frac{4\pi r^3}{3}$ is the solid content of the sphere; *therefore the attraction of the sphere, on any particle* E, *is as the quantity of matter in the sphere, divided by the square of the distance of its centre from* E. *Hence also the sphere attracts any particle without it, as if all its matter were united in its centre.* The sphere, it is also obvious, would attract another sphere, just in the ratio of its quantity of matter, divided by the distance of the centres of the spheres.

24. Thus, supposing that the particles of matter attract one another, with forces which are inversely as the squares of the distances, it is certain that the spherical bodies composed of these particles would do so likewise, or would attract one another with forces directly as their quantities of matter, and inversely as the squares of the distances of their centres. Since, therefore, it has been found that round or spherical bodies, such as the sun and the planets, do attract other bodies with forces that are inversely as the squares of the distances, it is reasonable to suppose, that these bodies are composed of particles gravitating towards one another, or attracting one another with forces inversely as the squares of the distances. *Gravitation, therefore, is not to be considered as a force residing in the centres of the planets, but as a force belonging to all the particles of matter, and as universally diffused throughout the universe.*

And, as it has been shown, that, between spherical bodies constituted of such particles, the force of attraction is as the quantity of matter in the attracting body, divided by the square of the distance between its centre and that of the attracted body; if $m$ be the mass or quantity of matter in the former body, and $x$ the distance of the centres, $\frac{m}{x^2}$ is the value of $f$, the accelerating force with which it attracts the other body.

25. Hence the masses of any two planets which have bodies revolving round them, may be compared with one another. Let $a$ and $a'$ be the mean distances at which satellites revolve about any two planets, $m$ and $m'$ the quantities of matter in those planets, $t$ and $t'$ their periods of revolution; it has been shown that $t = \frac{2\pi a^{\frac{3}{2}}}{f^{\frac{1}{2}}} = \frac{2\pi a^{\frac{3}{2}}}{m^{\frac{1}{2}}}$, and consequently $t : t' :: \frac{a^{\frac{3}{2}}}{m^{\frac{1}{2}}} : \frac{a'^{\frac{3}{2}}}{m'^{\frac{1}{2}}}$, and $m : m' :: \frac{a^3}{t^2} : \frac{a'^3}{t'^2}$

*The masses, therefore, of any two planets are as the cubes of the mean distances at which their satellites revolve, divided by the squares of the periodic times of those satellites.*

26. In this way, the masses of the four planets which have satellites may be compared with one another, and with the mass of the sun.

When this calculation is undertaken with the most correct data, it is found that the mass of the sun being - - - 1,

| | | |
|---|---|---|
| That of the Earth | - = | $\frac{1}{329630}$ |
| Of Jupiter | - | $\frac{1}{1067.1}$ |
| Saturn | - | $\frac{1}{3359.4}$ |
| Uranus | - | $\frac{1}{19504}$ |

Or if we make the mass of the Earth 1, that of the Sun = 329630; of Jupiter, 308.9; of Saturn, 98.122; and of Uranus, 16.94. From this also may be derived the densities of the sun, and of the four planets just mentioned. Seen from a distance equal to the mean radius of the earth's orbit, the diameter of the sun subtends an angle of 1914″; that of the earth would subtend 17″.4; of Jupiter, 186″.8; of Saturn, 177″.7; and of Uranus, 74″. The real diameters, therefore, are in the proportion of these numbers, and the bulk in the proportion of their cubes. By dividing the quantities of matter by the bulks, we have the densities; and if that of the earth be 4.713, which is its mean density, that of water being = 1.

| | | |
|---|---|---|
| The Sun | - | 1.1775 |
| The Earth | - | 4.713 |
| Jupiter | - | 1.1678 |
| Saturn | - | 0.4055 |
| Uranus | - | 1.0348 |

The mean density of the earth, in respect of water, is here taken from the experiments made at Schehallien. *Phil. Trans.* 1811, p. 376.

27. It has been already observed, that, because action is always accompanied by an equal reaction, when the sun attracts a planet, the planet also attracts the sun, and that the velocities impressed on the bodies by their mutual attraction are in the inverse ratio of their masses.

In consequence of this mutual action, the sun and the planet must both move, and must describe orbits about their common centre of gravity, the only point which the mutual action of those bodies has no tendency to put in motion.

In the solar system, therefore, the centre of gravity of the whole is the focus about which all the orbits are described. Thus if C be that centre (fig. 9.), S the sun, and P a planet, while P describes the elliptic arch PP′ about C, S describes the arch SS′ similar to PP′, and having to it the ratio that SC has to CP, or the ratio which the mass of the planet has to the mass of the sun.

The true orbits, therefore, are all described about the same immoveable point; but the orbit of any of the planets may be referred to the sun as a centre,

by supposing a body placed in that centre equal to the sum of the masses of the sun and of the planet. This is true, because the bodies appear to approach one another, or to recede from one another, with a force that is equal to the sum of the forces with which they tend towards their centre of gravity. Thus if S denote the mass of the sun, and E that of the earth, the distances from the centre being CP and CS, the orbit which each of the two bodies will appear to describe round the other, is that which would be described about an immoveable centre C, with a centripetal force $= \frac{S+P}{SP^2}$.

Thus we have arrived at the knowledge of the principle of UNIVERSAL GRAVITATION, a power which pervades all nature, extending to an unlimited distance, and determining the condition of every body in the universe, at any instant from its state in the former instant, and from the relations in which it stands to all other bodies. Whether this force can be explained upon any principle more general than itself, is yet undecided, though, from the bad success which has hitherto attended all attempts towards that object, it seems probable that such explanation is not within the reach of the human understanding. This much, however, we know with certainty, that the law of Gravity, as just announced, may be considered as a very accurate expression of all the phenomena of the planetary motions.

## SECTION II.

### *Of the Forces which disturb the Elliptic Motion of the Planets.*

1. *Of the force by which the Sun disturbs the motion of the Moon round the Earth.*

28. The motion of the moon in an elliptic orbit round the earth is disturbed by the action of the sun; the gravity of the moon to the earth is increased at the quadratures, and diminished at the syzygies, and the areas described by the radius vector, except near these four points, are never exactly proportional to the times.

Let ADBC (fig. 10.) be the orbit, nearly circular, in which the moon M revolves, in the direction CADB round the earth E. Let S be the sun, and let SE, the radius of the earth's orbit, be taken to represent the force with which the earth gravitates to the sun. Then $\frac{1}{SE^2} : \frac{1}{SM^2} :: SE : \frac{SE^3}{SM^2} =$ the force by which the sun draws the moon in the direction MS. Take $MG = \frac{SE^3}{SM^2}$, and let the parallelogram KF be described, having MG for its diagonal, and having its sides parallel to EM and ES. The force MG may be resolved into the two MF, and MK, of which MF, directed towards E, the centre of the earth, increases the gravity of the moon to the earth, and does not hinder the areas described by the radius vector from being proportional to the times.

The other force MK draws the moon in the direction of the line joining the centres of the sun and earth. It is, however, only the excess of this force above the force represented by SE, or that which draws the earth to the sun, which disturbs the relative position of the moon and earth. This is evident; for if KM were just equal to ES, no disturbance of the moon relatively to the sun could arise from it. If, then, ES be taken from MK, the difference HK is the whole force in the direction parallel to SE, by which the sun disturbs the relative position of the moon and earth. Now, if in MK, MN be taken equal to HK, and if NO be drawn perpendicular to the radius vector EM produced, the force MN may be resolved into two, MO and ON; the first, lessening the gravity of the moon to the earth, and the second, being parallel to the tangent of the moon's orbit in M, accelerates the moon's motion from C to A, retards it from A to D, and so alternately in the other two quadrants.

Thus the whole solar force directed to the centre of the earth is composed of the two parts MF and MO, which are sometimes opposed to one another, but which never affect the uniform description of the areas about E. Near the quadratures, the force MN vanishes, and the force MF, which increases the gravity of the moon to the earth, coincides with CE or DE. As the moon approaches the conjunction at A, the force MO prevails over MF, and lessens the gravity of the moon to the sun. In the opposite point of the orbit, when the moon is in opposition at B, the force with which the sun draws the moon is less than that with which the sun draws the earth, so that the effect of the solar force is to separate the moon and earth, or to increase their distance; that is, it is the same as if, conceiving the earth not to be acted on, the sun's force drew the moon in the direction from E to B. This force is negative, therefore, in respect of the force at A, and the effect in both cases is to draw the moon from the sun, in a direction perpendicular to the line of the quadratures.

29. The analytical values of these forces must be found, if a more exact estimate is to be made of their effects. Let SE, considered as constant, $= a$, EM, the radius vector of the moon's orbit, $= r$, the angle CEM $= \varphi$; the mass of the sun $= m$. The force SE then, which retains the earth in its orbit, is $\frac{m}{a^2}$, and the sun's force in the direction SM, if ML be drawn perpendicular to ES, is $\frac{m}{SM^2} = \frac{m}{SL^2 + LM^2}$ $= \frac{m}{(a - r\sin\varphi)^2 + r^2\cos^2\varphi} = \frac{m}{a^2 - 2ar\sin\varphi + r^2}$. The part of this force, which is in the direction ES or MK, is therefore $\frac{ma}{(a^2 - 2ar\sin\varphi + r^2)^{\frac{3}{2}}}$. By raising the denominator to the power $-\frac{3}{2}$, rejecting the terms which involve the higher powers of $r$, and multiplying $ma$ by those that are left, the force MK comes out $= \frac{m}{a^2}\left(1 + \frac{3r}{a}\sin\varphi\right)$ nearly. Taking away from this ES or MH $= \frac{m}{a^2}$, there remains the force $MN = \frac{m}{a^3} \times 3r\sin\varphi$.

Hence the force MO $= \frac{m}{a^3} \cdot 3r \sin \overline{\varphi^2}$; and the force NO at right angles to the radius vector $= \frac{m}{a^3} \cdot 3 \sin \varphi \times \cos \varphi = \frac{m}{a^3} \cdot \frac{3r}{2} \sin 2\varphi$. Also the force MF $= \frac{mr}{a^3}$, rejecting such terms as involve the square and higher powers of $r$. Therefore MF — MO, or the whole solar force increasing or diminishing at any point, the moon's tendency to the earth is $\frac{mr}{a^3}(1 - 3\,\overline{\sin \varphi^2})$.

30. At the quadratures where $\varphi$ vanishes, this force is $\frac{mr}{a^3}$, and is affirmative, increasing the moon's gravity to the earth. At a certain point, between the quadratures and the syzygies, when $3\,\overline{\sin \varphi^2} = 1$, or $\sin \varphi = \frac{1}{\sqrt{3}}$, that is, when $\varphi = 35^\circ.\ 15'.\ 5''$, the same force becomes equal to 0, and at this point in each quadrant, the moon's gravity to the earth is neither increased nor diminished. From these points to the conjunction and opposition, as $\sin \varphi$ increases, the quantity $1 - 3\,\overline{\sin \varphi^2}$ is negative, and the moon's gravity to the earth suffers a diminution. At the opposition and conjunction $\sin \varphi = 1$, and therefore the disturbing force is $-\frac{2mr}{a^3}$, and by this quantity the moon's gravitation is diminished.

The mean quantity of the force which is thus continually directed to, or from the centre of the earth, may also be easily computed. Since for any point in the moon's orbit, where the radius vector makes the angle $\varphi$ with the line of the quadratures, this force $= \frac{mr}{a^3}(1 - 3 \sin^2 \varphi)$; multiplying by $\dot{\varphi}$, we have $\frac{mr}{a^3}(\dot{\varphi} - 3\dot{\varphi} \sin^2 \varphi)$, the fluent of which $= \frac{mr}{a^3}(-\frac{1}{2}\varphi + \frac{3}{2} \sin \varphi \cos \varphi)$, and this, when $\varphi$ is an entire circumference or four right angles, is $\frac{mr}{a^3} \times -\frac{\pi}{2}$. This is the sum of the forces for an entire revolution, and when divided by $\pi$, gives the mean force $-\frac{mr}{2a^3}$, which being negative, shows that the solar force, on the whole, diminishes the gravitation of the moon to the earth.

*Thus it appears, that at the quadratures the gravity of the moon to the earth is increased by a quantity equal to the mass of the sun, multiplied into the radius of the moon's orbit, and divided by the cube of the sun's distance from the earth: at the syzygies it is diminished by twice this quantity; and the effect on the whole is a diminution by one half of the same quantity.*

If $\frac{mr}{a^3}$ be reduced to its numerical value, supposing the moon's gravitation to the earth to be 1, it is found $= \frac{1}{174}$ nearly. Hence the mean disturbing force of the sun is nearly $= \frac{1}{583}$ of the moon's gravity to the earth.

31. From the disturbing force of the sun arise two kinds of inequalities which affect the lunar motions. The one kind affects the form and position of the orbit of that planet, the other immediately affects the motion of the planet in the orbit. When any of these inequalities is expressed numerically, the measure it so obtained is, in the language of astronomy, called *an Equation*.

32. The line in which the plane of the moon's orbit cuts the ecliptic is called the line of the nodes, and this line is subject to change its position continually, in such a manner as to go back annually $19^\circ\ 18'\ 11''$. The way in which this effect is produced may be thus conceived. That part of the solar force which is parallel to the line joining the centres of the sun and earth, is not in the plane of the moon's orbit except when the sun itself is in that plane, or when the line of the nodes, being produced, passes through the sun. In all other cases, it is oblique to the plane of the orbit, and may be resolved into two forces, one of which is at right angles to that plane, and is directed towards the ecliptic. This force of course draws the moon continually towards the ecliptic, or produces a continual deflection of the moon from the plane of her own orbit towards that of the earth. Hence the moon meets the plane of the ecliptic sooner than it would have done if that force had not acted. At every half revolution, therefore, the point in which the earth meets the ecliptic advances in a direction contrary to that of the moon's motion, or contrary to the order of the signs. This retrograde motion is such that, in its mean quantity, it amounts to $19^\circ\ 18'\ 11''$ in a year. The manner of deducing it from the theory of gravity is explained by Newton, *Princip.* Lib. iii. Prop. 31. This motion is subject to many inequalities, depending on the changes in the quantity and direction of the solar force.

If the earth and the sun were at rest, the effect of the deflecting force just described would be to produce a retrograde motion of the line of the nodes till that line was brought to pass through the sun, and of consequence the plane of the moon's orbit to do the same, after which they would both remain in their position, there being no longer any force tending to produce a change in either. The motion of the earth carries the line of the nodes out of this position, and produces, by that means, its continual retrogradation.

33. The same force produces a small variation in

the inclination of the moon's orbit, giving it an alternate increase and decrease within very narrow limits.

34. The line of the moon's apsides, that is, the longer axis of her orbit, has also a slow angular motion round the centre of the earth, which is progressive, or in the same direction with the motions of the moon itself. To conceive the cause of this phenomenon, we may begin with supposing the moon at the lower apsis, or perigee; and, it is plain, if that planet were urged by no other force than its gravitation to the earth, that after the *radius vector* had moved over 180°, the moon would be at the higher apsis, where its motion would be at right angles to the said radius. But as the mean disturbing force in the direction of the radius vector, tends, on the whole, to diminish the gravitation of the moon to the earth, the portion of her path, described in any instant, will be less bent or deflected from the tangent, than if this disturbing force did not exist. The actual path of the moon, therefore, will be less incurvated than the elliptic orbit, that would be described under the influence of gravity alone, and will not be brought to intersect the radius vector at right angles, till this last have moved over an arch of more than 180°.

Hence, the solar force, by lessening the moon's gravity to the earth, produces a progressive motion in the apsides of the lunar orbit. If the disturbing force had increased the moon's gravity to the earth, the motion of the apsides would have been *in antecedentia*.

The precise quantity of the motion of the apsides is not however easily determined. Newton left this part of the lunar theory almost untouched, and the only investigation he has entered into having any reference to it, assigned a measure only the half of that which is known from observation to belong to it. Several years afterwards, when Clairaut attempted a more accurate investigation of the lunar inequalities than was to be obtained by the method which Newton had followed, he at first encountered the same difficulty, and found that his calculus gave the motion of the apogee only half of the real quantity. He began, therefore, to suspect that gravity does not follow so simple a law as the inverse of the squares of the distances; but one which is more complex, and such as cannot be expressed but by a formula of two terms. The second of these terms he supposed to be inversely as the fourth power of the distance, and proceeded to inquire what must be the co-efficient of that term, in order to make this new supposition represent the true motion of the apsides. In order to this, he found it necessary to carry his approximation farther than he had yet done, and to include terms which he had before neglected. When these terms were included, he found, that the co-efficient he was seeking for came out equal to 0; the necessary inference from which was, that there was no such term; and that the Newtonian law of gravity, when the approximation was carried far enough, was quite sufficient to explain the motion of the apsides. This doubt concerning the law of gravity terminated, therefore, in the confirmation of it.

35. When the doubts excited by Clairaut's first attempt were made known, and before his final solution of the difficulty was fully understood, there were several mathematicians who, still following the method of Newton, endeavoured to deduce the true motion of the moon's apsides from the theory of gravity. Among those who were most successful in this attempt, were Dom. Walmesley, and afterward Dr Matthew Stewart, Professor of Mathematics in the University of Edinburgh. In his *Mathematical and Physical Tracts*, he has demonstrated this remarkable theorem.

Let $r$ be the radius of the moon's orbit, supposing it to be a circle, and the moon to be acted on only by F, her gravity to the earth. If the mean disturbing force by which the sun diminishes the moon's gravity be $f$; then will the greatest distance to which the moon will recede from the earth be $r \times \frac{F-3f}{F-5f}$; and the cube of this distance will be to the cube of $r$, in the duplicate ratio of the angle described by the moon, from one apsis to the same apsis again, to four right angles.

Hence the angle described by the radius vector from one apsis to the same apsis, is $360° \times \left(\frac{F-3f}{F-5f}\right)^{\frac{3}{2}}$.

This proposition, which is demonstrated by Dr Stewart in the 4th of his Tracts, in a manner somewhat prolix, on account of his rigorous adherence to the manner of the ancient geometry, but in a way perfectly clear and elementary, is employed by him to deduce the mean disturbing force, from the motion of the apsides as ascertained by observation. But when the mean disturbing force is known from other phenomena, the same proposition may be employed to deduce the motion of the apsides from that force. Accordingly, if the disturbing force be taken $= \frac{1}{357.7}$, the motion of the apsides will come out $= 3° \; 1' \; 20''$ for a sideral revolution of the moon, very near the quantity actually observed.

36. Having determined the sun's mean disturbing force from the motion of the apsides, Dr Stewart proceeded to determine, from the former of these, the sun's distance from the earth. The result of a very nice investigation gave the sun's parallax $6''.9$, a quantity that is no doubt too small, and makes, of course, the sun's distance too great. It is indeed but an inconsiderable part of the sun's disturbing force into which the parallax enters as an element, and therefore any deduction founded on it must be liable to this inaccuracy, that a small error in the data will produce a great one in the result.

37. After the inequalities which are conceived as belonging to the moon's orbit, come those which directly affect the place of the moon in that orbit. The most considerable of these, after what is called the equation of the centre, arising from the elliptic figure of the lunar orbit, and independent of all disturbance, is the equation or inequality called the evection, which was discovered by the Greek astronomers. This depends on the position of the transverse axis of the moon's orbit in respect of the line of the syzygies. When that axis is in the line just mention-

ed, because the quantity by which the solar force diminishes the gravitation of the moon in the syzygies is *cæteris paribus* proportional to her distance from the earth, it is greatest when the moon is in the apogee, and least when in the perigee. In this situation of the orbit, therefore, the greatest diminution is made from the quantity of the moon's gravitation, which is already the least, and the least from that which is already the greatest, the gravitation at the perigee, and therefore the difference, is augmented, and the orbit appears to have its eccentricity increased. When the line of the apsides is in the quadratures, the contrary happens; the gravitation at the apogee is most augmented, and at the perigee least; the difference is therefore diminished, and the eccentricity of the lunar orbit seems also to be diminished. This is conformable to observation; and when the evection is accurately deduced from the theory of gravitation, it appears $= (1^{0}\ 25'\ 5''\tfrac{1}{2})\,sin\left(2(☾ - ⊙) - a\right)$ where ☾ is the mean longitude of the moon, ⊙ that of the sun, and $a$ the mean anomaly of the moon counted from the perigee.

38. The moon's variation is an inequality which was discovered by Tycho, and found to depend on the angular distance of that planet from the sun. It is derived from that part of the sun's disturbing force which is at right angles to the radius vector, and which accelerates the motion of the moon from the quadratures to the syzygies, and retarding it from the syzygies to the quadratures. The effect of this force is found, from the theory of gravity, to be represented by three terms, which, if $\triangle$ be the angular distance of the moon from the sun, are,

$$+ (35'\ 47'')\ sin\ 2\ \triangle$$
$$+ (\ 0'\ 2'')\ sin\ 3\ \triangle$$
$$+ (\ 0'\ 14'')\ sin\ 4\ \triangle.$$

39. The lunar inequality, called the annual equation, arises from the variation of the sun's disturbing force according to the place which the earth occupies in its orbit. It is shown above that the sun's disturbing force is *cæteris paribus* as the cube of his distance from the earth, so that, when the earth is in its perihelion, this force is the greatest, and at the aphelion the least, its effect varying at the same rate with the equation of the sun's centre, or having everywhere the same ratio to that equation. Hence this equation is nearly $(11'\ 12'') \times sin$ sun's mean anomaly, with a contrary sign to the equation of the sun's centre.

40. These inequalities are all phenomena which were observed before the explanation of them was known. To them may be added a fourth inequality, known by the name of the moon's acceleration. It appeared to Astronomers as a continual increase in the velocity of the moon, or in the rate of her mean motion, amounting to about 10″ in a century; and its effect, like that of all other constant accelerations, accumulating as the squares of the times. It did not seem to be periodical, like the other lunar inequalities, but to be a constant increase of the velocity, and a corresponding diminution of the periodical time of the moon, which must in the end change entirely the relation of that body to the earth.

It is but within these few years that La Place discovered it to be a periodic inequality, though requiring, in order to accomplish the series of its changes, a length of time which science has not yet ventured to calculate. For many centuries to come it may be expressed by this formula, taking $n$ to denote the number of centuries reckoned from the year 1700, viz.

$$10''.1816127 \times n^2 + 0.018538441 \times n^3.$$

The first term includes all that was known from observation previously to the discovery of *La Place*. This, however, must be considered not as the true form of the equation, which must include the sines or cosines of certain angles, but merely a provisional formula, to serve till the true one can be rigorously assigned.

This inequality has, in its cause, a great affinity to the annual equation.

Whatever changes the form of the earth's orbit has an effect on the disturbing force of that body on the moon, which is in the inverse ratio of the cube of the distance between the sun and earth. But it is found that though the mean distance remains invariable, the eccentricity of the earth's orbit changes, on account of the action of the other planets, and in fact has been diminishing, from a more remote antiquity than that to which the history of astronomy extends. From this cause La Place has deduced the supposed acceleration of the moon's mean motion.

41. All these inequalities have been pointed out by observations, and have been explained in the most satisfactory manner by the principle of universal gravitation. But when all these were reduced into equations and arranged in tables, yet the places of the moon calculated from them were never quite exact; and there seemed a cause of error or a mass of small inequalities unknown in their magnitude and form, to which this inaccuracy was to be ascribed, and which operated, as it may be said, like a mist which concealed the true place of the moon from the calculator, and prevented his results from agreeing completely with those of the observer. The most likely way to discover these inequalities, if they arose from gravity, was to push the approximation to the moon's place still farther, and to try if the terms hitherto neglected in the approximation would not, when taken into account, afford a complete analysis of the circle of confusion, which might be said to surround the moon on all occasions.

The problem on which mathematicians now entered, and which Clairaut, already mentioned, Euler, and D'Alembert, all three resolved nearly about the same time, has been called the *Problem of Three Bodies*. The thing proposed is, Three bodies which attract one another with forces directly as their quantities of matter, and inversely as the squares of their distances, being given, and any motions whatever being impressed on them, to find the orbits which they will describe round their common centre of gravity. It is, however, only in certain cases, that this general problem admits of solution, and one of these is, when one of the bodies is at a vast distance from the other two. This is exactly the case with the moon and earth in respect of the sun, the orbit of the earth being nearly the same

as if there only existed the sun and earth; and the orbit of the moon relatively to the earth being nearly the same as if there were only the moon and earth. This solution of the problem, however, in this direct way, leads to far more exact conclusions than can be obtained from the more simple but more indirect method which Newton followed. The general view which leads to the most exact estimate of the merit of the two solutions, is, that the motions of the moon, when analytically and fully expressed, necessarily form a number of different series, each of which converges with more or less rapidity. The prosecution of the direct method, allows the terms of these series to be computed to an indefinite extent, or till the quantities omitted are too small to affect observation. The method of Newton can go no farther than to compute the first, or at most a few of the leading terms of each of the series. Its accuracy is therefore limited; that of the other knows no limits. Though this be a true estimate of the value of the methods, yet that of the original inventor possesses infinite merit, as having first led the way to this arduous investigation, and as still serving to carry the imagination better along with it than the other, and to keep the mechanical principles more directly in view.

The complete solution of the problem of the *three bodies*, has accordingly discovered a great number of new equations, each individually small, which would sometimes nearly destroy one another, and, at other times, having many of them the same sign, would accumulate to a considerable amount. This was the triumph of the theory, and the strongest evidence of its truth. The effect of these irregularities varied so much, and depended on so many elements, that it may be doubted whether the most accurate and most constant observation would ever have enabled astronomers to discover their precise quantities, and to separate them from one another.

The tables of the moon in the state to which they are now (1816) brought, contain twenty-eight equations for the longitude, twelve for the latitude, and thirteen for the horizontal parallax of the moon. Of the first of these, twenty-three have been deduced from theory alone; of the second nine, and of the third eleven. This applies to the tables of De Bürgh; those since published by Burckhardt contain more equations, and are still more accurate.

### 2. *Of the Disturbance in the Motion of the Primary Planets, produced by their action on one another.*

42. It is evidently necessary, in this inquiry, to know the quantities of matter in the different planets, or which comes to the same, the intensity of the attraction of each at a given distance from its centre. With respect to those planets which have satellites, the Earth, Jupiter, Saturn, and Uranus, their masses or quantities of matter have been already determined. The masses of Venus and Mars have been estimated by M. La Place, from the effects which they appear to produce on the earth's motion. The mass of Mercury has been estimated on the supposition that the densities of that planet and of the earth are inversely as their mean distances from the sun. This law holds with respect to the Earth, Jupiter, and Saturn, and analogy renders it probable that the same law includes the other planets. Thus, the mass of the Sun being 1, that of Mercury is $\frac{1}{2025810}$, of Venus $\frac{1}{383137}$, and of Mars $\frac{1}{1846082}$, the masses of the other planets being as already stated.

43. The effects of the action of the planets on one another is more difficult to be investigated than the effects of the sun's action on the moon, because the disturbing forces are not only more numerous, but because the distance of the disturbing from the disturbed body, is not so great that the quantities divided by higher powers of that distance, can be so safely rejected. The general principle, however, according to which the solar action on the moon was resolved into forces either in the direction of the radius vector, or at right angles to it, is applicable to both questions.

Thus supposing P and P′ (fig. 11.) to be two planets revolving in orbits, nearly circular, about the sun at S, in order to find how the motion of P′ is affected by the action of P, let PP′, PS, and P′S be drawn, and let the line A denote the force with which P attracts a particle of matter at the distance PS, then the force with which it attracts a particle at the distance PP′, will be $A \times \frac{PS^2}{P'P^2}$. Let P′R= $A \times \frac{PS^2}{P'P^2}$, and if P′R be resolved into two forces, P′M and P′N, the one in the direction of the radius vector P′S, and the other parallel to PS; take NO= A, then the remaining forces OP′ and P′M are those which disturb the motion of P′, as was proved in the case of the moon. The former of these, OP′, may be resolved into OQ and P′Q, of which P′Q diminishes the gravity of the planet to the sun, and OQ accelerates its motion in a direction perpendicular to the *radius vector*. Therefore, as the force P′M always increases the planet's gravity to the sun, P′M—P′Q is the whole force increasing or diminishing the gravity of P′ to S; and the force directly employed in increasing or diminishing the angular motion of P about S, is OQ or P′T. The analytical values of these quantities may be found, as in the theory of the moon, though not with equal simplicity, because SP cannot always be supposed great in respect of SP′.

44. In consequence of these actions, the orbit of every planet may be considered as an ellipsis, which is undergoing slowly certain changes in its form, magnitude, and position, or in what are called its elements. By the elements of the orbit of any heavenly body, are meant the quantities that determine the position and magnitude of that orbit, viz. the position of the line of the nodes, the inclination of the plane of the orbit to the plane of the ecliptic, the position of the line of the apsides, the eccentricity, and the mean distance. These are all quantities independent of one another, and from them may be deduced all other circumstances with respect to the elliptic orbit. Of these five elements, which would be invariable, if the planet only gravitated to the sun, all, except the mean distance, are subject to slow, but perpetual changes.

45. The line of the nodes in every one of the planets, has a retrograde angular motion, which goes on continually, and of which the amount, when calculated as due to each planet, agrees very well with observation. The plane of the orbit also varies its inclination by certain small periodical changes which alternately increase and diminish it, as in the case of the moon. The line of the apsides, from the same cause as in the planet just mentioned, has a continued motion forward, or according to the order of the signs. Thus, in Mercury, the node goes back about 9″ annually. The aphelion goes forward about 6″ 2‴, and the inclination of the orbit in the course of a century, increases about 2″ 1‴, which, in the course of succeeding ages, will be compensated, by an equal diminution, so as to preserve it always nearly of the same quantity. In the same planet the equation of the centre, which depends on the eccentricity, increases about 20″ 1½ in a century, indicating a small increase of eccentricity. These variations in the orbit of Mercury, arise from the action of Venus, the Earth, Mars, Jupiter, and Saturn; the effects of the first of these planets, on account of its vicinity, being by much the most considerable. The mean distance, however, of Mercury from the Sun, does not, any more than that of the other planets, undergo any change whatever.

46. Similar conclusions apply also to the orbit of Venus. The orbit of the earth also is subject to similar changes, the line of the apsides moving forward annually at the rate of 11″ 8‴, in respect to the fixed stars. The earth's eccentricity is also diminishing, and the secular variation of the greatest equation of the centre is — 17″.66.

The motion of the earth is subject to another inequality on account of the action of the moon; for, to speak strictly, it is not the centre of the earth, but the centre of gravity of the moon and earth, which describes equal areas in equal times about the centre of the sun. It is evident, that, on this account, the earth will be sometimes advanced before, and sometimes will fall behind, the point which describes the circumference of the ellipsis, in conformity with the general law of the planetary motions. From the same cause also, as the moon does not move in the plane of the ecliptic, the earth will be forced out of that plane, in order to preserve a position diametrically opposite to the moon. These irregularities, however, are inconsiderable. By observers on the earth's surface, they are transferred to the sun, but in an opposite direction. The sun, therefore, has a motion in longitude, by which he alternately advances before the point which describes the elliptic orbit in the heavens, and falls behind it, and also a motion in latitude, by which he alternately ascends above, and descends below the plane of the ecliptic. As the mass of the moon, however, is not more than $\frac{1}{68.5}$ part of that of the earth, the distance of the centre of gravity of the moon and earth, from the centre of the latter, must be less than a semidiameter, and therefore the inequality thus produced in the sun's longitude, must be less than his horizontal parallax. The alteration in latitude can hardly amount to a second. This inequality in the sun's motion is called the menstrual parallax, and was first mentioned by Smeaton, *Phil. Trans.* 1768.

47. In the orbit of Mars, the node moves backward 23″ 1 annually, and the line of the apsides moves forward 16″ 3, both in respect of the fixed stars. The eccentricity of the orbit is diminishing, and the secular variation of the greatest equation of the centre is — 37″.

In the case of this planet, however, the elliptic orbit is not only changed by these quantities, but the place of the planet in that orbit is sensibly affected by the action of Venus, Jupiter, and the Earth. The effect of the action of Venus is expressed by this formula 5″.7 sin. (long. ♀ — 3 long ♂); of the earth, 7″.2 sin. (long. ⊙ — long. ♀). Several inequalities are produced by Jupiter.

48. The inequalities of the small planets *Vesta*, *Juno*, *Ceres*, and *Pallas*, have not yet been computed; the disturbances which they must suffer from Mars and Jupiter, are no doubt considerable, and, on account of their vicinity, though their masses are small, they may somewhat disturb the motions of one another. Their action on the other bodies in the system is probably insensible.

As two of these planets have nearly the same periodic time, they must preserve nearly the same distance, and the same aspect with regard to one another. This offers a new case in the computation of disturbing forces, and may produce equations of longer periods than are yet known in our system.

The motion of the apsides and the change of eccentricity in the orbits of Jupiter and Saturn are chiefly produced by their action on one another, but a part also depends on the action of the other planets. The node of Jupiter moves backward annually 19½″, and his aphelion forward 6″.58. The secular change in the inclination of the orbit is 27″, and in the first and last of these inequalities the action of Venus has the principal share. The equation of the centre increases 56¼″ in a century, of which nearly the whole arises from the action of Saturn. In Saturn again the node goes back at the rate of 21″ annually, and the aphelion forward at the rate of 16″, the secular change of the inclination is — 23″, and the secular diminution of the equation of the centre 1′ 50″.

There is, beside these variations in the orbits, an inequality in the motion of each of these planets, which it has been found very difficult to explain, and has only lately been fully accounted for, according to the theory of gravity, by the profound investigations of La Place. These inequalities are both of a long period, viz. 918.76 years, which is the time that they take to run through all their changes. If $n$ express a number of years reckoned from the beginning of 1750, S the mean longitude of Saturn, and I that of Jupiter, reckoned from the same time, then the equation which must be applied to the mean longitude of Jupiter, or the amount of this inequality, is

$$+(20' \, 49''.5 - n \times 0''.042733) \times \sin(5\,S - 2\,I + 5^0 \, 34' \, 8'' - n \times 58''.88)$$

and that which must be applied to S, is

$$-(48' \, 44'' - n \times 0''.1) \times \sin(5\,S - 2\,I + 5^0 \, 34'.8'' - n \times 58''.88).$$

These two equations are to one another nearly in the ratio of 3 to 7. The reason of the long period above mentioned is, that the argument $5S - 2I - n \times 58''.88$, requires all that time to increase from 0 to 360°.

Uranus, on account of his great distance, suffers hardly any disturbance in his motion, but from Saturn and Jupiter. The node moves backward at the rate of $34''\frac{1}{4}$ annually, and the aphelion forward at that of $2''.55$. The eccentricity is increasing, and the secular variation of the greatest equation of the centre is $11''.03$.

There is also an inequality in the longitude of this planet depending on the action of Saturn. If S be the longitude of this last planet, U the longitude of Uranus, and A the longitude of the aphelion of Saturn, the inequality in question amounts to $2'.30'' \times \sin (S - 2U + A)$.

49. *Of all these inequalities, and of many other smaller ones which theory has discovered, it must be observed that they are periodical, each returning after a certain time to run through the same series of changes which it had formerly exhibited.*

*Another general remark is, that one element in every planetary orbit, viz. the mean distance, is exempted from all change; and since on the mean distance depends the time of revolution, that time remains also unchanged. From the invariability of the mean distance, and the periodical revolution of all the inequalities, it follows that the actual condition of the planetary system can never deviate far from the mean, about which, we may, therefore, conceive it to be continually making small oscillations, which, in the course of ages, compensate one another; and, therefore, produce nothing like disorder or permanent change. It is in this manner that the stability of the planetary system is provided for by the wisdom of its Author.*

50. *Comets*, in describing their elliptic orbits round the sun, have been found to be disturbed by the action of the larger planets, Jupiter and Saturn; but the great eccentricity of their orbits makes it impossible, in the present state of mathematical science, to assign the quantity of that disturbance for an indefinite number of revolutions, though it may be done for a limited portion of time, by considering the orbit as an ellipsis, the elements of which are continually changing. This is the method of La Grange, and is followed in the *Mecanique Celeste*, Part II. chap. 9. Dr Halley, when he predicted the return of the comet of 1682, took into consideration the action of Jupiter, and concluded that it would increase the periodic time of the comet a little more than a year; he therefore fixed the time of the re-appearance to the end of the year 1758, or the beginning of 1759. He professed, however, to have made this calculation hastily, or, as he expresses it, *levi calamo*. (*Synopsis of the Astronomy of Comets.*)

The effects both of Jupiter and Saturn on the return of the same comet were afterwards calculated more accurately by Clairaut, who found that it would be retarded 511 days by the action of the former planet, and 100 by the action of the latter; in consequence of which, the return of the comet to its perihelion would be on the 15th of April 1759. He admitted, at the same time, that he might be out a month in his calculation. The comet actually reached its perihelion on the 13th of March, just 33 days earlier than was predicted; affording, in this way, a very striking verification of the theory of gravity, and the calculation of disturbing forces. The same comet may be expected again about the year 1835.

In some instances, the effect which the planets produce on the motion of comets are far more considerable than in this example. A comet which was observed in 1770 had a motion which could not be reconciled to a parabolic orbit, but which could be represented by an elliptic orbit of no great eccentricity, in which it revolved in the space of five years and eight months. This comet, however, which had never been seen in any former revolution, has never been seen in any subsequent one. On tracing the path of this comet, Mr Burckhardt found that, between the year 1767 and 1770 it had come very near to Jupiter, and had done so again in 1779. He therefore conjectured, that the action of Jupiter may have so altered the original orbit as to render the comet for a time visible from the earth; and that the same cause may have so changed it, after one revolution, as to restore the comet to the same region in which it had formerly moved. This is the greatest instance of disturbance which has yet been discovered among the bodies of our system, and furnishes a very happy, as well as an unexpected, confirmation of the theory of gravity.

Though the comets are so much disturbed by the action of the planets, yet it does not appear that their re-action produces any sensible effect. The comet of 1770 came so near to the earth as to have its periodic time increased by two days .246 according to *La Place's* computation, and if it had been equal in mass to the earth it would have augmented the length of the year by not less than two hours and forty-eight minutes. It is certain that no such augmentation took place, and therefore that the disturbing force by which the comet diminished the gravity of the earth is insensible, and the mass of the comet, therefore, less than $\frac{1}{500}$th of the mass of the earth. The same comet also passed through the middle of the satellites of Jupiter. Hence it is reasonable to conclude, that no material or even sensible alteration has ever been produced in our system by the action of a comet.

### 3. *Of the disturbances which the satellites of Jupiter suffer from their action on one another.*

51. The same resolution of the forces by which one satellite acts upon another, into two, one directed to the centre of the primary, and the other at right angles to it, serves to explain the irregularities which had been observed in their motions, and to reduce under known laws, several other inequalities, of which the existence only is indicated by observation.

An instance of this we have in the very remarkable relation which takes place between the mean motions of the first three satellites; the mean motion of the first satellite, together with twice the mean motion of the third, being equal to three times the

mean motion of the second. La Place has shown that, if the primitive mean motions of these satellites were nearly in this proportion, the mutual action of these bodies on one another must, in time, have brought about an accurate conformity to it.

The first satellite moves nearly in the plane of Jupiter's equator, and has no eccentricity, except what is communicated from the third and fourth, the irregularities of one of these small planets producing similar irregularities in those that are contiguous to it. The first satellite has beside an inequality, chiefly produced by the action of the second, and circumscribed by a period of 437.659 days.

52. The orbit of the second satellite moves on a fixed plane, to which it is inclined at an angle of 27′ 13″, and on which its nodes have a retrograde motion, so that they complete a revolution in 29.914 years. The motion of the nodes of this satellite, is one of the principal data used for determining the masses of the satellites themselves, which are so necessary to be known for computing their disturbances. This satellite has no eccentricity but that which it derives from the action of the third and fourth. The third satellite moves on a fixed plane, to which it is inclined at an angle of 12′ 20″, and its nodes make a tropical revolution backwards in 141.739 years. The equator of Jupiter is inclined to the plane of his orbit at an angle of 3° 5′ 27″. The fixed planes on which the planes of the orbits move are determined by theory, and could not have been discovered by observation alone.

The orbit of the third satellite is eccentric, but appears to have two distinct equations of the centre; one which really arises from its own eccentricity, and another which theory shows to be an *emanation*, from the equation of the centre of the fourth satellite. The first equation is referable to an apsis, which has an annual motion of 2° 36′ 39″ forward in respect of the fixed stars; the second equation is referable to the apsides of the fourth satellite.

These two equations may be considered as forming one equation of the centre, referable to an apsis that has an irregular motion. The two equations coincided in 1682, and the sum of their *maxima* was 13′ 16″. In 1777, the equations were opposed, and their difference was 5′ 6″.

The two last inequalities were perceived by Mr Wargentin by observation alone, but their exact amount, and the law which they observe in their changes, he could not discover. The orbit of the fourth satellite moves on a fixed plane, to which it is inclined at an angle of 14′ 58″, and its nodes complete a sideral revolution backward in 531 years. The fixed plane on which the orbit moves is inclined at an angle of 24′ 33″ to the equator of Jupiter; the orbit is sensibly elliptical, and its greater axis has an annual motion of 43′ 35″. The motion of this axis is one of the principal data from which the quantities of matter of the different satellites have been determined.

If the mass of Jupiter be supposed unity, the mass of the 1st Satellite = .0000173281.
Of the 2d = .0000232355.
Of the 3d = .0000884972.
Of the 4th = .0000426591.

If the mass of the earth be supposed unity, that of the third satellite will be found = .027337; and, as the mass of the moon is $\frac{1}{68.5}$, = .014599, the quantity of matter in the third satellite is about twice as great as that in the moon. The fourth satellite is therefore nearly equal to the moon; the second about one half, and the first somewhat more than one third.

53. The general result of this investigation concerning the inequalities in the motion of the planets, both primary and secondary, is, that in every one of these orbits, two things remain secure against all disturbance, the mean distance and the mean motion; or, which is the same, the transverse axis of the orbit, and the time of the planet's revolution. Another result is, that all the inequalities in the planetary motions are periodical, and observe such laws, that each of them, after a certain time, runs through the same series of changes. This last conclusion follows from the fact, that every inequality is expressed by terms of the form $A \sin nt$ or $A \cos nt$, where $A$ is a constant co-efficient, and $n$ a certain multiplier of $t$ the time, so that $nt$ is an arch of a circle, which increases proportionally to the time. Now, in this expression, though $nt$ is capable of indefinite increase, yet, since $nt$ never can exceed the radius or 1, the maximum of the inequality is A. Accordingly, the value of the term $A \sin nt$ first increases from 0 to A, and then decreases from A to 0; after which it becomes negative, extends to — A, and passes from thence to 0 again. If, when the inequality was affirmative, it was an addition to the mean motion, when negative, it will become a diminution of it; and the sum of all these increments and decrements, after $nt$ has passed over an entire circumference or 360°, is equal to 0; so that, at the end of that period, the planet is in the same position as if it had moved on regularly all the while, at the rate of the mean motion. As this happens to every one of the inequalities, the deviation of the system from its mean state can never go beyond certain limits, each inequality in a certain course of time destroying its own effect.

It would be far otherwise, if into the value of any inequalities, a term entered of the form $A \times nt$, $A \tan nt$, $\frac{A}{\sin nt}$. The inequalities so expressed would continually increase with the time, so as to go beyond any assignable limit, and of consequence to destroy entirely the order of any system to which they belonged.

La Grange and La Place, who discovered and demonstrated, that no such terms as these last can enter into the expression of the disturbances which the planets produce by their action on one another, made known one of the most important truths in physical science. They proved that the planetary system is stable, that it does not involve any principle of destruction in itself, but is calculated to endure for ever, or till the action of an external power shall put a period to its existence. After the knowledge of the principle of gravitation, this may be fairly considered as the greatest discovery to which men have been led by the study of the heavens.

The accurate compensation, just remarked, depends on three conditions, belonging to the primitive or original constitution of our system, but not necessarily determined, inasmuch as we know, by any physical principle. The first of these conditions is, that the eccentricities of the orbits are all inconsiderable, or contained within very narrow limits, not exceeding in any instance $\frac{1}{10}$ or $\frac{1}{8}$ part of the mean distance. The second condition is, that the planets all move in the same direction, or from west to east. This is true both of the primary and secondary planets, with the exception only of the satellites of Uranus, which may be accounted retrograde, but their planes being nearly at right angles to the orbit of their primary, the direction of their motion, whether retrograde or otherwise, can have little effect. Lastly, the planes of the orbits of the planets are not much inclined to one another. This is true of all the larger planets, though it does not hold of some of the new and smaller ones; of which, however, the action on the whole system must be wholly insensible.

Unless these three conditions were united in the constitution of the solar system, terms of the kind just mentioned, admitting of indefinite increase, might enter into the expression of the inequalities, which would indicate a gradual and unlimited departure from the original order and constitution of the universe. Now, the three conditions just enumerated, do not necessarily arise out of the nature of motion, or of gravitation, or from the action of any physical cause with which we are acquainted. Neither can they be considered as arising from chance, for the probability is almost infinite to one, that, without a cause particularly directed to that object, such a conformity could not have arisen in the motions of thirty-one different bodies, scattered over the whole extent of the solar system. *The only explanation, therefore, that remains is, that all this is the work of intelligence and design, directing the original constitution of our system, and impressing such motions on the parts as were calculated to give stability to the whole.*

For some farther particulars, connected with *Physical Astronomy*, see EARTH, FIGURE OF, in this Supplement. (L.)

---

ASTRONOMY, PRACTICAL. See the article OBSERVATORY, in this Supplement.

ATMOMETER (from *ατμος, vapour*, and *μετρον, a measure*), an instrument lately contrived by Professor Leslie, for measuring the quantity of moisture exhaled from any humid surface in a given time. It consists of a very thin ball of porous earthen-ware, from one to three inches in diameter, having a small neck firmly cemented to a long and rather wide tube of glass, to which is adapted a brass cap, with a narrow collar of leather to fit close. Being filled with distilled or pure water, the waste and descent of this column serves to indicate the quantity of evaporation from the external surface of the ball. The tube is marked downwards through its whole length by the point of a diamond, with divisions across it, amounting from 200 to 500, each of which corresponds to a ring of fluid, that, spread over the whole exhaling surface, would form a film only one thousand part of an inch in thickness. This graduation is performed by previously sealing one of the ends of the tube with wax, and introducing successive portions of quicksilver, to mark every 20, 50, or 100 of those divisions; being calculated of equal bulk to discs of water, that have the surface of the ball (exclusive of the neck) for their base, and so many thousand parts of an inch for their altitude.

The instrument, being thus constructed, has its cavity filled with pure water, and its cap screwed tight, and is then suspended freely out of doors, sheltered indeed from rain, but exposed to the action of the wind. The water transudes through the porous substance of the ball, just as fast as it evaporates from the external surface; and this waste is measured by the corresponding descent of the liquid in the stem. At the same time, the column is suspended in consequence of the tightness of the cap, and prevented from oozing so freely as to drop from the ball. As the process of evaporation goes on, minute globules of air, separated by the removal of atmospheric pressure from the body of the water, or partly introduced by external absorption, continue to rise in fine streamlets to the top, where they partially occupy the space left by the subsidence of the fluid column. We need scarcely observe, that, after the water has sunk to the bottom of the stem, it will be requisite again to fill the cavity.

It is a fact of main importance for the accuracy of the Atmometer, that the rate of evaporation is nowise affected by the quality of the porous ball, and continues precisely the same, whether the exhaling surface appears almost dry or glistens with excess of moisture. This rate must evidently depend on the effect of the dryness of the air combined with its quickness of circulation. In a close room, the instrument might therefore serve the purpose of an hygrometer; and, placed out of doors, first screened, perhaps, for an hour, and then exposed during an equal space of time, it would furnish data for calculating the velocity of the wind.

This elegant instrument is of extensive application, and great practical utility. To ascertain readily and accurately the rate of evaporation from any surface, is an important acquisition, not only in Meteorology, but in Agriculture, and in the various mechanical arts. The quantity of exhalation from the surface of the ground is not of less consequence than the measure of the fall of rain, and a knowledge of it might often direct the farmer advantageously in his operations. On the rapid dispersion of moisture, depends the efficacy of drying-houses, which are generally constructed on most erroneous principles.

We shall select a few observations made with the Atmometer, from a register kept last season at Abbotshall, near Kirkcaldy in Fifeshire, by the very intelligent gardener of Robert Ferguson, Esq. of Raith. During the months of July, August, September, October, and November, the mean quantity of evaporation, in twenty-four hours, was respectively .111,—.090, .060,—.045, and—.022; and distinguishing the whole interval into equal spaces of twelve hours, from six o'clock in the morning to six

Atmometer. o'clock in the evening, for the measure of the day and of the night; the corresponding results are .092, .029, —.078, .012,—.050, .010,—.032, .013, .020. On the 21st of July 1815, the quantity of evaporation, during twenty-four hours, was 208; and, on the 27th of the same month, it was 200, the thermometer having sunk as low during the night as 46° and 49° of Fahrenheit's scale.—If we reckon the mean daily evaporation through the year at .040, this would give $14\frac{6}{10}$ inches, for the whole amount, or about half the annual quantity of rain that falls in this climate.

The atmometer, in its most compendious form, is admirably fitted for delicate experiments on the evaporation which takes place in close vessels, when absorbent substances are introduced. Let the ball of the instrument, for example, be immersed in air variously rarefied or condensed, under a receiver covering a surface of sulphuric acid, which has different degrees of strength; and, things being thus disposed, on extracting the common air, and introducing hydrogen gas, the rate of evaporation will then be nearly tripled. But we purpose to take some future opportunity of stating the results of such curious and interesting researches.

We shall close this short notice, with mentioning a striking fact, which shows the necessity of extreme caution in all physical inquiries. Let the ball of an atmometer be cemented to a narrow glass tube of three or four feet in length, and the whole capacity filled with fresh distilled water. Now invert the instrument upright in a basin of quicksilver, and secure it in that situation; the quicksilver, following the column of water, will rise at first quickly, and then by degrees more slowly till it reaches, perhaps, an elevation of 28 inches, where it will remain stationary and afterwards sink down, when the evaporation is nearly spent. Ice-water is raised in this way about 26 inches only, and common water scarcely 24 inches; the air separated from such liquids forming near the top of the ball, a thin medium, which, by its elasticity, counteracts in part the pressure of the external atmosphere supporting the mercurial column. But a similar experiment, where the shoot of a vine was cemented to a tube holding quicksilver, has been thought, by Dr Hales and M. Du Hamel, quite conclusive, in proving the *power* of the living principle of vegetation. It is obvious, that the force of evaporation alone was sufficient to explain the facts advanced by those ingenious philosophers. See Leslie's *Short Account of Experiments and Instruments depending on the Relations of Air to Heat and Moisture*. (D.)

ATMOSPHERE. We have to regret, that the experiments to which we alluded, in referring from AIR to this article, are not yet completed; and must again postpone the consideration of the various points connected with this subject, till other opportunities shall occur, particularly under the articles CLIMATE and METEOROLOGY. There are already articles of some extent, both on AIR and ATMOSPHERE, in the *Encyclopædia*, to which we beg, in the meantime, to refer our readers.

# ATOMIC THEORY.

ATOMIC THEORY, a species of philosophy lately introduced into *Chemistry*, which deserves to be fully explained in this place.

History. It is well known to have been the doctrine of some of the most eminent of the Greek philosophers, that the ultimate elements of matter consisted of *atoms* or particles incapable of farther division or diminution. This doctrine was adopted by Sir Isaac Newton, and, indeed, has been almost universally embraced by modern philosophers. But it was in *chemistry* alone that it could be applied with any advantage. The object of chemists was to determine the component parts of bodies, and to ascertain the different elements out of which all substances are compounded. Considerable progress was gradually made in this difficult investigation. Thus it was soon ascertained that the *salts*, which constitute a very numerous class of bodies, contain always at least two constituents, namely, an *acid* and a *base*. Thus, saltpetre is a compound of the acid called *nitric acid*, and the base called *potash*. Now, how small a portion soever of saltpetre you examine, whether a grain or the millionth part of a grain, you will always find it to contain both the ingredients of which saltpetre is composed. The same thing holds with respect to all the other salts, and, indeed, with respect to all compound bodies whatever. Now, this could not be the case, unless these compounds were formed by the union of the minutest possible particles of the constituents with each other; that is to say, unless it were the ultimate atoms of the elements which united together and constituted the compound. Accordingly, it has been admitted as an axiom in chemistry, that *chemical union consists in the combination of the atoms of bodies with each other*.

Chemistry originated from the absurd pursuits of the alchymists; and many years elapsed before it was able to shake off its connection with the chimerical notions respecting the *philosopher's stone* and the *universal medicine*. Dr Cullen was perhaps the first man that viewed the science as constituting a great and important branch of natural philosophy. His views were followed out by Black, Cavendish, Priestley, and a cloud of other eminent men, who have added so much lustre to the scientific pre-eminence of Great Britain. Margraaf, Bergman, and Scheele, were the first scientific chemists who appeared on the Continent. Bergman, in particular, was of the most essential service to the science. Educated in those branches of mechanical philosophy which had already made such progress, and accustomed to the rigid accuracy of mathematical reasoning, he introduced the same correct views, the same precise reasoning, the same generalization to which he had been already

Atomic Theory.

habituated. Lavoisier, who had the advantage of a similar education, adopted a similar conduct. His industry was indefatigable, and he contributed much more than any other person to introduce that precision in experimenting, and that accuracy of reasoning, which characterize the chemists f the present day.

The exertions of these eminent men led to the discovery of the art of analysis, such, though in a rude state, as it is practised at present. Bergman, Kirwan, and Wenzel, particularly distinguished themselves by the analysis of the salts. Of these three, Wenzel is by far the most accurate. The result of their experiments was, the demonstration that salts, and, indeed, all compound bodies, are universally composed of the same constituents united in the same proportions. Thus, water is always a compound of 1 part by weight of hydrogen, and $7\frac{1}{2}$ parts of oxygen; sulphate of copper always contains equal weights of sulphuric acid and black oxide of copper; and sulphate of barytes is always a compound of 100 parts by weight of sulphuric acid, and 194 of barytes.

Discovery of Richter.

J. B. Richter, who was for sometime Mining Secretary at Breslau, and afterwards *Arcanist* in the Porcelain manufactory at Berlin, where he died on the 4th of April 1807, employed himself, during the whole of his life, in endeavouring to introduce the use of mathematics into chemistry. His inaugural dissertation, printed in 1789, was entitled *De usu mamathescos in chymia*. In the year 1792, he published the first part of a work entitled *Anfangsgründe der Stochiometrie, oder Messkunst chymischer Elemente; Foundation of Stochiometry, or geometry of the chemical elements*. This work he continued to publish in successive parts, in 1793, 1794, 1795, 1802. Richter observed, that when two neutral salts, which mutually decompose each other, are mixed together, the two new salts which are formed still retain the same neutral state as the two original ones from which they were formed. Thus, *sulphate of potash*, and *nitrate of barytes*, are two neutral salts, which decompose each other when mutually mixed; *sulphate of barytes*, and *nitrate of potash*, being formed both in a neutral state. This circumstance enabled him to examine the accuracy of the results obtained by preceding experimenters, and he showed that the numbers assigned both by Bergman, Kirwan, and Wenzel, for the constituents of the salts, were inaccurate, as they were unable to stand the test of this double decomposition. He was induced, in consequence, to make a new set of experiments, in order to determine the constituents of the salts with more precision, and these experiments occupied him about ten years. He first analyzed the alkaline and earthy muriates and sulphates, then the nitrates, then the fluates, then the carbonates, oxalates, succinates, tartrates, citrates, acetates, and some others; and lastly the phosphates. He placed in a table the quantity of each of the bases required to saturate 100 parts of muriatic acid, beginning with that base of which the smallest quantity was necessary for the purpose, and terminating with the base of which the greatest quantity was requisite. Similar tables were drawn up, representing the weight of the different bases requisite to saturate 100 parts of sulphuric acid, nitric acid, carbonic acid, and all the other acids contained in the different genera of salts which he had subjected to analysis. A comparison of these tables with each other enabled him to draw the two following remarkable consequences: *First*, The different bases follow exactly the same order in all the tables, and that order is as follows:

Alumina.
Magnesia.
Ammonia.
Lime.
Soda.
Strontian.
Potash
Barytes.

*Second*, The numbers in each table constitute a series, which have the same ratio to each other in all the tables. Suppose, for example, that in the table representing the muriates, the quantity of potash requisite to saturate 100 parts of muriatic acid were three times as great as the quantity of alumina requisite to produce the same effect, the same thing would hold in the sulphates, nitrates, and all the other genera of salts. Three times as much potash would be requisite to saturate 100 sulphuric, nitric, or any other acid, as would be required of alumina. In the same way, if three times as much barytes be requisite to saturate a given weight of one acid as is required of lime, the same proportion will hold when we saturate any other acid; with these earths we must always employ three times as much barytes as of lime. When the quantity of each of the acids requisite to saturate a given weight of each successive base, was placed in tables in a similar way, it was found, as might have been anticipated, that the acids followed precisely the same law.

These facts explain why, when two neutral salts decompose each other, the new formed salts are also neutral, and why there is never any excess of acid or base upon the one side or the other. The same proportions of bases that saturate a given weight of one acid, saturate all the other acids, and the same proportion of acids that saturate one base, saturate all the other bases. Hence numbers may be attached to each acid and base, indicating the weight of it which will saturate the weights attached to all the other bases or acids. This accordingly was done by Fischer from Richter's experiments and tables. We shall here insert his numbers, not because they are accurate, which is very far from being the case, but because they constitute the first specimen of the kind ever offered to the chemical world. (Berthollet's *Essai de Statique Chimique*, I. 136.)

| | | | |
|---|---|---|---|
| Alumina, | 525 | Fluoric acid, | 427 |
| Magnesia, | 615 | Carbonic acid, | 577 |
| Ammonia, | 672 | Sebacic acid, | 706 |
| Lime, | 793 | Muriatic acid, | 712 |
| Soda, | 859 | Oxalic acid, | 755 |
| Strontian, | 1329 | Phosphoric acid, | 979 |
| Potash, | 1605 | Formic acid, | 988 |

Atomic Theory.

| | | | |
|---|---|---|---|
| Barytes, | 2222 | Sulphuric acid, | 1000 |
| | | Succinic acid, | 1209 |
| | | Nitric acid, | 1405 |
| | | Acetic acid, | 1480 |
| | | Citric acid, | 1583 |
| | | Tartaric acid, | 1694 |

According to this table, 525 of alumina is saturated by 427 of fluoric acid, 577 of carbonic acid, 755 of oxalic acid, 1000 sulphuric acid, &c.; and 427 of fluoric acid, is saturated by 525 of alumina, 615 of magnesia, 672 of ammonia, &c. It is obvious, therefore, that this table, supposing it accurate, would give us the composition of all the salts into which the bases and acids contained in it enter.

Discovery of Proust.

M. Proust, a French chemist of great sagacity, who was settled as Professor of Chemistry at Madrid, was the first person who attempted an accurate examination of metallic oxides. He studied the oxides of iron, zinc, arsenic, antimony, &c. The result of his examination was, that every metal is capable of forming a certain determinate number of oxides and no more. Zinc forms only one oxide; iron, arsenic, and antimony, form two each; tin forms three, &c. Each of these oxides he found composed of a determinate proportion of metal, and oxygen, which remained always the same in all cases. Thus, the oxide of zinc, according to him, is always a compound of 100 parts zinc, and 25 oxygen. The two oxides of iron are the *black* and the *red*. If iron be combined with oxygen at all, it is either connected with the quantity of oxygen which constitutes the black oxide, or with the quantity which constitutes the red oxide, but it is incapable of uniting with any other proportion of oxygen. Wherever iron, already in the state of black oxide, combines with more oxygen, it becomes red oxide, being incapable of existing in any intermediate state between the black and the red oxide. The same law holds with respect to tin, antimony, arsenic, and all the metals; thus, M. Proust proved that metals unite only with determinate proportions of oxygen, which may be assigned in numbers. He showed that the same law held with respect to the combinations of the metals with sulphur. When Berthollet published his *Chemical Statics*, one of his objects was to show that there are two proportions of oxygen which unite with metals, a minimum and a maximum, and that between these two extremes, usually placed at a considerable interval from each other, there are an infinity of proportions of oxygen capable of uniting with every metal. Hence he inferred that there is no such thing as permanent definite metallic oxides; but an infinite number of shades of oxydizement graduating into each other, and each capable of uniting with acids, and thus of forming an infinite variety of salts, differing from each other by minute shades of character. This extraordinary opinion, which, if correct, would have put an effectual period to all chemical investigation, as it would have been useless and absurd to attempt to examine compounds, which had no permanence and no analogy to each other, occasioned a discussion between Proust and Berthollet. Proust showed, by decisive experiments, that the indefinite numbers of metallic oxide, supposed by Berthollet, does not exist, and that metals are only capable of combining with 1, 2, or 3 dozes of oxygen; that there is no indefinite number of oxides between the black and the red oxides of iron; but that the instant that iron combined with more oxygen than existed in the black oxide, it is converted into the red oxide.

Discovery of Dalton.

Such was the state of the subject when Mr Dalton turned his attention to the combination of bodies with each other about the year 1804. At that period, it was known that hydrogen combines only in one proportion with oxygen; that carbon, sulphur, and phosphorus, unite each in two proportions; that carbon unites in two proportions with hydrogen, sulphur in two proportions with the same substance, and phosphorus in one proportion; that azote unites in one proportion with hydrogen, and in four proportions with oxygen. It was known, too, that several of the metals combine with only one dose of oxygen, while some unite with two doses, and others with three. It had been ascertained, that, in certain cases, when metals combine with two doses of oxygen, the second dose is exactly double the first dose, while in other cases it is to the first dose as 3 to 2. Thus, in platinum, the second oxide contains just double the quantity of oxygen that the first oxide contains, while in iron, the quantity of oxygen in the red oxide, is, to the quantity in the black oxide, as 3 to 2. None of the combinations of oxygen or hydrogen, with the simple combustibles, had been accurately analyzed; though approximations to a correct analysis of most of them existed, and what was chiefly wanting, was a criterion for distinguishing the comparative merits of the different analysis of these bodies which had been presented to the chemical world.

Mr Dalton was struck with the small number of compounds which the elementary bodies are capable of forming with each other, and with the very simple relations which existed between the numbers that denote the weight of the different constituents in these compounds; and he set himself down to endeavour to account for these circumstances not hitherto inquired into.* Water, he found, was always a compound of 1 part by weight of hydrogen, and 8 parts by weight of oxygen.

| | | | | |
|---|---|---|---|---|
| Carbonic oxide is composed of | 750 | carbon | + | 1000 oxy. |
| Carbonic acid | 750 | | + | 2000 |
| Sulphurous acid | 2 | sulph. | + | 2 oxy. |
| Sulphuric acid | 2 | | + | 3 |
| Nitrous oxide | 175 | azote | + | 100 oxy. |
| Nitrous gas | 175 | | + | 200 |
| Nitrous acid | 175 | | + | 300 |
| Nitric acid | 175 | | + | 500 |

* In the following examples, instead of using the imperfect analysis with which Mr Dalton was obliged to be satisfied, and which misled him in some cases, we have thought it better to employ the most precise experiments hitherto made.

Atomic Theory.

Now, in all these compounds, it will be perceived, that the numbers denoting the oxygen, united to a given weight of the same base, bear a very simple and obvious ratio to each other. The oxygen in carbonic acid is twice as great as in carbonic oxide; the oxygen in sulphuric acid is to that in sulphurous as the numbers 3 to 2; while the oxygen, in the respective compounds of azote and oxygen, bears the ratio of the numbers 1, 2, 3, 5.

These and many other similar examples which Mr Dalton registered and examined, but which it is unnecessary to state here, led him to the lucky idea that the atoms of bodies unite together; that the atom of each body has a determinate weight, and that this weight regulates the proportion in which bodies combine with each other. Let us suppose, for example, that water is formed by the union of one atom of oxygen, with one atom of hydrogen, it follows, as the oxygen in water is 8 times that of the hydrogen, that the weight of an atom of oxygen is to that of an atom of hydrogen as 8 to 1. So that, if we represent the weight of an atom of hydrogen by 1, that of an atom of oxygen will be 8; or if, as is more convenient in practice, we pitch upon 1 for the weight of an atom of oxygen, an atom of hydrogen will weigh 0.125. As carbon unites with two proportions of oxygen, we may suppose that an atom of carbon unites with 1 atom, and with 2 atoms of oxygen. Hence, the reason why the quantity of oxygen in carbonic acid is twice as great as in carbonic oxide. If an atom of oxygen weigh 1, it is obvious that an atom of carbon will weigh 0.751, supposing the numbers which we have given in the preceding table to be accurate. It is equally obvious, that sulphurous acid must contain 2 atoms of oxygen, and sulphuric acid 3 atoms; and that an atom of sulphur will weigh 2, on the supposition that an atom of oxygen weighs 1. Finally, nitrous oxide is a compound of 1 atom azote, and 1 atom oxygen; nitrous gas of 1 atom azote, and 2 atoms oxygen; nitrous acid of 1 atom azote, and 3 atoms oxygen; and nitric acid of 1 atom azote, and 5 atoms oxygen. And, supposing the numbers in our table correct, if an atom of oxygen weigh 1, an atom of azote will weigh 1.75.

Mr Dalton did not rest satisfied with this simple and luminous explanation, which threw a new and strong light around chemical combinations,—which afforded the means of correcting and checking chemical experiments, hitherto conducted without any guide, and promised, in time, to introduce mathematical precision, and mathematical reasoning, into a science which hitherto has been able only to boast of analogical and probable conclusions. He contrived a set of symbols to represent the different elements, and make the nature of the combinations which they form obvious to the eye of the most careless reader. A few examples will be sufficient to make the nature and use of these symbols perfectly well understood.

Let ○ be an atom of oxygen
⊙ - - - - hydrogen
⦶ - - - - azote
◍ - - - carbon

Let ⊕ be an atom of sulphur
☮ - - - - phosphorus,

Then ⊙○ represents an integrant particle of water

| | |
|---|---|
| ◍○ - - - - | of carbonic oxide |
| ○◍○ - - - - - | of carbonic acid |
| ○⊕○ - - - - - | of sulphurous acid |
| ○<br>○⊕○ - - - - - | of sulphuric acid |
| ⦶○ - - - - - | of nitrous oxide |
| ○⦶○ - - - - - | of nitrous gas |
| ○<br>○⦶○ - - - - | of nitrous acid |
| ○○<br>○⦶○<br>○ - - - - | of nitric acid |
| ⊙◍⊙ - - - - - | of carbureted hydrogen |
| ◍⊙ - - - - - | of olefiant gas. |

It would be easy to multiply these symbols much farther; but the preceding specimen is sufficient, we conceive, to make the use of them understood, and even to make Mr Dalton's doctrine more simple to those who are still strangers to it. Mr Dalton has already published two volumes of what he entitles a *New System of Chemical Philosophy*, in order to explain and show the accuracy and importance of this doctrine. Our object, in the present article, will be to lay the whole of it in its present state before our readers. But we must, in the first place, trace the history of the improvements which it has received to its termination.

Improvements of Gay-Lussac and others.

In the year 1809, M. Gay-Lussac, who had already distinguished himself by many important chemical discoveries, and who was well acquainted with Mr Dalton's theory, published a curious paper on the combinations of gaseous substances with each other. (*Memoires d'Arcueil*, II. 205.) He showed that they follow a very simple law in their combinations; that one volume of one gas always combines either with one volume of another gas, or with two volumes, or with three volumes. Thus,

1 volume ammonia saturates 1 vol. of muriatic acid
1 vol. of carbonic acid
1 vol. of fluoboric acid.

The resulting compounds are neutral muriate, carbonate, and fluoborate of ammonia.

Nitrous gas is composed of one volume of azote, and one volume of oxygen.

Subcarbonate of ammonia is composed of one volume carbonic acid, and two volumes ammoniacal gas.

Subfluoborate of ammonia of one volume fluoboric acid, and two volumes ammoniacal gas.

Water of one volume of oxygen, and two volumes of hydrogen gas. Nitrous oxide of one volume oxygen, and two volumes azote. Nitric acid of one volume oxygen, and two volumes nitrous gas. Sulphuric acid of one volume oxygen, and two volumes sulphurous acid. Carbonic acid gas of one volume oxygen, and two volumes carbonic oxide.

Finally, ammonia is composed of one volume azote, and three volumes hydrogen; and nitrous acid gas of one volume oxygen, and three volumes of nitrous gas.

Gay-Lussac showed likewise, that the diminution of volume which takes place on the combination of these gases, follows as simple a law as the volumes in which they combine. In nitrous gas, the oxygen and azote undergo no condensation. Accordingly, the specific gravity of nitrous gas is the mean between that of oxygen and azote. Frequently one of the two gases retains its bulk unaltered, while the other totally disappears. Thus, when 100 measures of carbonic oxide, and 50 measures of oxygen gas, are united together by combination, the resulting compound constitutes 100 measures of carbonic acid. Sometimes the bulk is reduced to one half. Thus, when 100 measures of azote, and 300 measures of hydrogen, are united, they form 200 measures of ammoniacal gas.

This curious law, discovered by Gay-Lussac, when coupled with the doctrine of Mr Dalton, shows us, that there exists a very simple relation between the weight of the atoms and the bulk of the gaseous bodies. Accordingly, the weight of the atoms of these bodies may be deduced, with sufficient accuracy, from their specific gravity. This method was employed both by Sir Humphry Davy and Dr Wollaston.

Professor Berzelius of Stockholm, one of the most accurate and indefatigable chemists of the present time, was led, some years ago, to study the composition of the salts, in consequence of the perusal of Richter's *Stochiometry*. He soon satisfied himself that neither the analyses of Richter, nor of preceding chemists, could be depended on for accuracy. He resolved, therefore, to institute a new analysis of a considerable number of saline bodies, and to be at particular pains to ensure the greatest possible precision which the present state of the science enabled him to attain. The result of this laborious undertaking has been published in the *Annales de Chimie*, the *Annalen der Physik*, *Nicholson's Journal*, and the *Annals of Philosophy*. It constitutes by far the most complete and valuable set of chemical analyses of which the science is possessed. Berzelius not only satisfied himself of the accuracy of Richter's law, but was so fortunate as to discover another of a very unexpected nature, and of the greatest importance in chemical analysis, because it enables us to subject the results of all our analyses to calculation, and thus to determine with certainty how far their accuracy may be depended on. All the acids, with a very few exceptions, contain oxygen. This is the case likewise with all the salifiable bases, so that the salts may be considered as combinations of two sets of oxides with each other. Now, Berzelius compared the oxygen in the base of a salt with the oxygen in its acid, and he found that they always bore a very simple relation to each other. They were either equal, or the oxygen in the acid was twice as much as that in the base, or thrice as much, or four times as much, &c. If the acid contained twice as much oxygen as the base, this was a proof that the acid contained two atoms of oxygen; if it contained thrice as much, it contained three atoms of oxygen, and so on. Thus, in the sulphates, the sulphuric acid contains three times as much oxygen as the quantity of base which it saturates. Hence we infer, that sulphuric acid is a compound of 1 atom sulphur, and 3 atoms oxygen. In the sulphites, the acid contains twice as much oxygen as the base which it saturates. Hence, we infer that sulphurous acid is composed of 1 atom sulphur, and 2 atoms oxygen. In the carbonates, the oxygen in the acid is twice as much as in the base which it saturates. Hence we infer that carbonic acid is composed of 1 atom of carbon, and 2 atoms of oxygen.

Berzelius, during his experimental investigation of the atomic theory, met with some objections which he was not able immediately to surmount. In consequence of these difficulties, he substituted for the atomic theory what he calls the *theory of volumes*, derived from Gay-Lussac's discovery respecting the proportions in point of volume in which gaseous substances combine. This is merely substituting another name for the atomic theory. For it is easy to show, that the theory of volumes, as Berzelius considers it, is precisely the same thing as Dalton's atomic theory. The difficulties of Berzelius will come under our consideration hereafter.

After the preceding historical sketch, which we thought necessary in order to do justice to all parties concerned in this important branch of chemistry, we shall proceed to lay the atomic theory, with the proofs in support of it, before our readers.

### I. Outline of the Atomic Theory.

With respect to the nature of the ultimate elements of bodies, we have no direct means of obtaining accurate information. But it is the general opinion, that they consist of *atoms* or minute particles, incapable of farther division. It is impossible to demonstrate the truth of this opinion; but, for our part, we can conceive no other. It has been almost universally admitted, by mechanical philosophers, since the time of Newton. We shall, therefore, adopt it here as the foundation of our reasoning.

When two bodies unite chemically, so as to form a third body, the two substances combined are dispersed everywhere through the new compound. Water, for example, is composed of oxygen and hydrogen. Now, how minute a portion soever of water we examine, we shall find it to contain both oxygen and hydrogen. Saltpetre is a compound of nitric acid and potash. If we examine the salt, whether we take an ounce or the hundredth part of a grain, we shall always find it to be a compound of nitric acid and potash. If any portion of it were to want one of these constituents, it would no longer be saltpetre; it would be potash, or nitric acid, according to the constituent which is not present. Limestone is a compound of carbonic acid and lime. Now, we

may reduce it to an impalpable powder; but if we take one of the grains of this powder, however small, and throw it into nitric acid, we shall perceive an effervescence, indicating the presence of carbonic acid, and it will dissolve, indicating that lime was also one of its constituents. Mechanical trituration, however carefully made, is quite incapable of separating from each other substances which are chemically combined. Now, this distribution of the constituents could never be so complete through every part of the compound, unless it were the atoms of the combined bodies that united with each other. This, accordingly, is the opinion respecting chemical combinations, which appears always to have been entertained by chemical philosophers. Nor do we believe that any person will be disposed to call its truth in question.

All chemical compounds contain the same constant proportion of constituents with the most rigid accuracy, no variation whatever ever taking place. Water is universally a compound of 1 part by weight of hydrogen, and 8 of oxygen; sulphuric acid, of 1 part sulphur, and $1\frac{1}{2}$ oxygen; carbonic acid, of 1 part carbon, and 2.666 of oxygen. This permanency in the constituents of chemical compounds, indeed, is generally admitted. It constitutes, in fact, the basis of the whole science. For, if the proportions of the constituents of bodies were variable, chemical analysis would be nugatory, and the whole science of little importance. Even Berthollet, who contends for indefinite proportions in the abstract, admits the incontrovertible fact that the proportions of chemical combinations in general are permanent.

Since, then, bodies unite chemically atom to atom; and since they always unite in the same proportions, without the smallest deviation, this regularity can be ascribed to nothing else than the constant union of one atom of one body with one atom of another; or of a determinate number of atoms of one body with a determinate number of atoms of another. At first sight, it may appear impossible to determine how many atoms of each constituent combine with an indefinite number of atoms of the other. But there are some circumstances which afford us considerable assistance in this apparently intricate investigation.

Thus, oxygen has the property of uniting in different proportions with the same base; sometimes in two, sometimes in three, sometimes in four, &c. proportions. Thus, with carbon it unites in two proportions, with mercury in two, with copper in two. With tin it unites in three proportions, while with manganese it unites in four proportions. Now, if we represent the weight of base with which the oxygen unites by $a$, and suppose all the different proportions of oxygen to unite with this proportion of base; and if we denote the first portion of oxygen by $b$, then, in general, the constituents of the different compounds formed by the union of the different doses of oxygen with the base will be as follows:

1st compound $a + b$.
2d compound $a + 2b$.
2d compound $a + 3b$.
4th compound $a + 4b$.

Suppose 10 parts of oxygen enter into the first compound, then 20 parts enter into the second, 30 parts into the third, and 40 parts into the fourth compound. Hence, whatever number of atoms enter into the first compound, twice that number enters into the second compound, thrice the number into the third compound, and four times the number into the fourth compound. Hence it is clear, that there is a determinate number of atoms of oxygen, which always enter into these combinations. If we represent this number by $x$, then $a + x$ is the first compound, $a + 2x$ the second, $a + 3x$ the third, and $a + 4x$ the fourth. Now, it would be singular, if 2, 3, 4, &c. atoms of oxygen, were to be always inseparably linked together, so as never to be able to enter into combinations separate. It is much more simple to conceive, that $x$ represents only 1 atom. Indeed, there can be little doubt that this is actually the case. For oxygen gas, being a permanently elastic fluid, must consist of atoms that repel each other. Hence a compound atom of oxygen, or a number of atoms united together, seems to be impossible. But even though the opinion that $x$ represents one atom should not be mathematically true, still it would be proper to adopt it. For, as far as our calculations are concerned, a number of atoms of oxygen, constantly and invariably united together, would constitute a compound atom, about which we may reason as accurately and justly as we could do about the simple atoms themselves. But if $x$ in these combinations be considered as representing an atom of oxygen, there can be no doubt that $a$ represents an atom of the body, which unites with oxygen. So that, by knowing the proportions in which they unite, we have the relative weight of an atom of oxygen, and of the body with which it unites.

This reasoning may be applied to hydrogen as well as oxygen. Hydrogen has the property of uniting in different proportions with various bodies, as with carbon, phosphorus, sulphur, &c. In these different proportions, we find the hydrogen always denoted by $y$, $2y$, &c. just as is the case with oxygen. Hence we have the same reason for concluding that $y$, which represents the minimum of hydrogen which unites with the other constituent, is an atom.

The numbers $x$ and $y$ are easily discovered by making an accurate analysis of the different compounds into which various proportions of oxygen and hydrogen enter; and, when reduced to their lowest terms, they are very nearly $x = 8$, and $y = 1$. Hence these numbers represent the ratios of the weight of an atom of oxygen and an atom of hydrogen to each other. Now, it deserves attention, that these numbers represent the composition of water. For it has been ascertained, by very careful experiments, that water is composed of 100 measures of oxygen gas, and 200 measures of hydrogen gas. Now, the specific gravity of these gases is as follows:

| | |
|---|---|
| Oxygen, - - - | 1.111. |
| Hydrogen, - - - | 0.069. |

Hence water is composed by weight of

| | |
|---|---|
| Oxygen, - - - | 8.00. |
| Hydrogen, - - - | 1.00. |

From this coincidence we are entitled to conclude, that water is formed by the union of an atom of oxygen with an atom of hydrogen. And consequently, that an atom of hydrogen is to an atom of oxygen in weight, as 1 to 8. This very important conclusion is supported by other considerations. Oxygen and hydrogen have never been made to combine in any other proportion than that in which they exist in water. Hence this proportion must be that which unites most readily and with the greatest force. Now, as the atoms of hydrogen repel each other, as is the case also with the atoms of oxygen, it is obvious, that when they are mixed equably, as is the case when 200 measures of hydrogen gas, and 100 measures of oxygen gas, are put into a tube and fired by electricity, they will most readily unite atom to atom. This, though not in itself decisive, is a corroborating circumstance. It follows from it, that a given bulk of hydrogen gas contains only one half the number of atoms which exist in the same bulk of oxygen gas.

But we must not conceal that there is another view of this subject, which has been taken by Davy and Berzelius, and certainly possesses much plausibility. It is founded on this curious fact, first noticed, we believe, by Dr Wollaston, and confirmed by the theory of Gay-Lussac, detailed in the historical introduction to this article, that if we determine the weight of an atom of the gaseous bodies from their specific gravity (or at least a multiple of it), the numbers obtained will correspond with the atomic theory, as well as the numbers found by the method above described, which is the method of Dalton. In fact, they will always be the same numbers, or their halves or their doubles. This shows us, that a very simple relation exists between the bulk of a gas and the number of atoms which it contains. If the weight of an atom of a gas were always the same as its specific gravity, it would follow, that the same bulk of every gas contains always the same number of atoms. But cases occur in which this simple rule does not answer. Thus, it is admitted even by Davy and Berzelius, that the weight of an atom of azote is twice that of its specific gravity. So that, in a given measure of azotic gas, there is only one half of the number of atoms that exist in an equal measure of oxygen gas.

Those who found their weights of the atoms of bodies on the specific gravity of the gases, consider water as composed of 2 atoms of hydrogen, and 1 atom of oxygen. If this notion be correct, the weight of an atom of hydrogen, is to that of an atom of oxygen, as 1 to 16. This is nearly the proportion given by Davy and Berzelius. Davy, who rejects decimals, makes an atom of hydrogen weigh 1, and an atom of oxygen 15. Berzelius makes an atom of oxygen weigh 15.069, supposing that of hydrogen to weigh 1. As oxygen and hydrogen cannot be united in any other than 1 proportion, we have no means of putting it to the test of experiment. But the example of azote (admitted at least by Davy, though Berzelius, by his hypothesis, that azote is a compound of *nitricum* and oxygen, gets over the difficulty) is sufficient to show us that it is not necessary that the weights of the atoms of gases should be directly as the specific gravity of these bodies. On this account, the reasons before urged in favour of the opinion, that water is a compound of 1 atom of oxygen, and 1 atom of hydrogen, seems to us sufficient to give a preponderancy to this opinion, and to induce us to embrace it.

Knowing the weight of an atom of oxygen, and an atom of hydrogen, we have it in our power to determine the weight of an atom of the other substances, which unite with oxygen or with hydrogen, or with both. For example, 100 parts of sulphur unite with two proportions of oxygen, namely, with 100 parts constituting sulphurous acid, and with 150 parts constituting sulphuric acid, both by weight. Here, the proportions of oxygen being to each other as the numbers $1:1\frac{1}{2}$ or $2:3$; it is reasonable to suppose, that the first proportion represents 2 atoms of oxygen, and the second 3 atoms. There may, perhaps, exist another compound, consisting of 1 atom sulphur, and 1 atom oxygen, or by weight of 100 sulphur and 50 oxygen. But such a compound is at present unknown. It is evident, if sulphurous acid be composed of 1 atom sulphur, and 2 atoms oxygen, that an atom of sulphur is twice as heavy as an atom of oxygen. So that if we were to represent the weight of an atom of oxygen by 8, that of an atom of sulphur would be 16. Davy makes an atom of oxygen 15. Accordingly, his atom of sulphur is represented by 30.

We have it in our power to verify this reasoning by means of the combinations which sulphur makes with hydrogen. This verification may be made two ways, and we shall employ both to show how they serve to corroborate one another. 1. It has been ascertained, that 100 measures of hydrogen gas may be united to sulphur, and converted into sulphureted hydrogen gas, without undergoing any change of bulk. Hence, to know with precision the composition of sulphureted hydrogen, we have only to determine with care the specific gravity of hydrogen gas, and sulphureted hydrogen gas. Now,

100 cubic inches of hydrogen gas weigh 2.117 grains.
100 cubic inches of sulphur. hyd. gas 35.89.

Hence it follows, that sulphureted hydrogen gas is composed of

| | | |
|---|---|---|
| Hydrogen - - - | 2.117 | or 1.00 |
| Sulphur - - - - | 33.773 | 16.00 |

This shows us, that if sulphureted hydrogen gas is composed of 1 atom sulphur, and 1 atom hydrogen, and if we suppose an atom of hydrogen to weigh 1, an atom of sulphur will weigh 16. The combination of oxygen and sulphur gave us 16. Thus the two processes of reasoning lead to the same conclusion, since the difference really existing is greatly within the limits of the unavoidable errors in such kinds of experiment. 2. Sulphureted hydrogen gas requires for its complete combustion $1\frac{1}{2}$ times its bulk of oxygen gas. The products of the combustions are sulphurous acid and water. The sulphurous acid gas amounts exactly to the bulk of the sulphureted hydrogen gas consumed. Suppose 100 measures of sulphureted hydrogen gas to

be burned. We must employ for the purpose 150 measures of oxygen gas. The gaseous product consists of 100 measures of sulphurous acid gas; 100 measures of the oxygen gas go to the formation of the sulphurous acid gas, and 50 measures go to the formation of water. Now, 100 cubic inches of sulphurous acid gas weigh 66.89 grains, and contain 33.445 grains of sulphur; 50 cubic inches of oxygen combine with 100 cubic inches of hydrogen, or with 2.117 grains. So that, according to this analysis, sulphureted hydrogen is composed of

| | | | |
|---|---|---|---|
| Hydrogen - - | 2.117 | or | 1.000 |
| Sulphur - - - | 33.445 | | 15.8 |

So that, according to this determination, the weight of an atom of sulphur is 15.8. This differs only .2 from the preceding, and is also within the limits of the unavoidable errors of chemical experiment. We may, therefore, consider these two methods of determining the weight of an atom of sulphur as all coinciding, and giving absolutely the same result.

By a similar mode of reasoning, we may determine, with considerable accuracy, the weight of an atom of azote, phosphorus, carbon, the metals, and almost all those bodies which at present are considered as simple. It would be tedious to give any more illustrations here. Enough, we conceive, has been said to explain the nature of the theory, and to render the manner of proceeding in determining the weights of the atoms of bodies intelligible to the reader. In a future part of this article, we shall give a table of the weights of the atoms of bodies, and state, at the same time, the documents on which these weights are founded.

It is hardly necessary to observe, how very powerfully a particular conclusion is confirmed, when we arrive at it by different processes. This advantage we have in full perfection, when we set about determining the weight of the atoms of the simple substances. In most cases, we come to the same conclusions by two, three, or four different methods. These coincidences could not exist, unless the conclusions were well founded.

With respect to the number of atoms capable of uniting together, no general rule can be given. In organic bodies, this number is often very great. Hence, probably, the reason why we cannot succeed in our attempts to form animal and vegetable bodies. In unorganic bodies, the number of atoms united is much smaller. In primary compounds, we do not recollect an example of any substance containing more than 7 atoms. These atoms are always confined to two different kinds of matter, as *hydrogen* and *oxygen*, *carbon* and *oxygen*, *sulphur* and *oxygen*, *carbon* and *hydrogen*, *sulphur* and *phosphorus*, &c. We never find three different kinds of matter united together in any primary compound, provided it does not belong to the vegetable or animal kingdom. For primary compounds of organized matter contain usually three, and sometimes four, or even five or six, different kinds of substances; as *hydrogen*, *carbon*, and *oxygen*; *hydrogen*, *carbon*, *azote*, *oxygen*; *hydrogen*, *carbon*, *azote*, *iron*, *oxygen*; *hydrogen*, *carbon*, *azote*, *phosphorus*, *sulphur*, *oxygen*. According to Berzelius, one of the constituents of unorganized bodies always amounts only to 1 atom. This law certainly holds in the primary compounds. Whether it holds in those compounds called salts, is not so clear. We shall be better able to judge, when we have examined the composition of the salts in a subsequent part of this article.

In organic bodies, on the contrary, none of the constituents exists of necessity to the amount of 1 atom; though this may sometimes happen from accident. Hence the reasons of the very complex nature of organic bodies, and the numerous modifications of most of them that exist.

The *secondary* compounds, or those bodies formed by the union of primary compounds with each other, are of a much more complex nature. They frequently contain three or four different ingredients united together; as, for example, *alum*, *tartar emetic*, *Rochelle salt*. Now, as each of these constituents is composed of several atoms, it is obvious, that the composition of the secondary compounds is much more complicated than that of the primary compounds. It will be convenient, on that account, to consider each separately.

## II. Weight of the Atoms of the Simple Substances.

Before we can draw up a table of the relative weights of the simple substances, we must fix upon some one whose atom shall be represented by unity. Mr Dalton has made choice of hydrogen for this purpose, because it is the lightest of all known bodies. Sir Humphry Davy has followed his example; but he has doubled the weight of an atom of oxygen, and of most other bodies, by the arbitrary supposition, that water is composed of 2 atoms of hydrogen, and 1 atom of oxygen. Dr Wollaston, Professor Berzelius, and Dr Thomson, have adopted oxygen as the most convenient unit: nor can there be any hesitation in embracing their plans. Oxygen is, in fact, the substance by means of which the weights of the atoms of almost all other bodies are determined. It enters into a much greater number of combinations than any other known body. Hence, if we denote the weight of its atom by 1, a considerable convenience will result to the practical chemist. We shall exhibit the weights of the atoms of the simple bodies, under the form of tables, and we shall state at the bottom of each, the documents by means of which these weights were obtained.

### 1. *Simple Supporters.*

| Substances. | Weight of Atom. |
|---|---|
| 1 Oxygen - - | 1.000 |
| 2 Chlorine - - | 4.500 |
| 3 Iodine - - | 15.621 |

Oxygen having been chosen for the unit, we have already stated our reasons for the weight assigned. The weight is arbitrary, and adopted merely for the sake of convenience.

Chlorous oxide (the euchlorine of Davy) is composed of 2 volumes of chlorine gas, and 1 volume of

Atomic Theory.

oxygen gas. The specific gravity of chlorine gas is 2.483; that of oxygen gas 1.104. If we suppose chlorous acid to be composed of 1 atom chlorine, and 1 atom oxygen, a supposition which gives the simplest view of the composition of the chlorides, we have for the weight of an atom of chlorine this proportion, $1.104 : 4.966 :: 1 : 4.498 =$ the weight of an atom of chlorine.

The weight of an atom of iodine is the result of the experiments of Gay-Lussac, and may be considered as nearly correct. But we could not explain, in this place, the manner of conducting the experiments by which it was ascertained, without entering into details respecting the properties of this newly discovered substance that would be quite foreign to the present article.

### 2. *Simple Combustibles.*

| | Substances. | Weight of an Atom. |
|---|---|---|
| 4 | Hydrogen | 0.125 |
| 5 | Boron | 0.733 |
| 6 | Carbon | 0.750 |
| 7 | Phosphorus | 1.625 |
| 8 | Azote | 1.750 |
| 9 | Sulphur | 2.000 |
| 10 | Silicon | 2.000 |

The method of determining the weight of an atom of hydrogen has been explained in a preceding part of this article. It was there shown from the composition of water, that the weight of an atom of hydrogen is to that of an atom of oxygen as 1 to 7.56. Now, $7.56 : 1 :: 1 : 0.132 =$ weight of an atom of hydrogen. We have given 0.125 in the table, as the weight of an atom of hydrogen, because we consider it as established by a paper in the *Annals of Philosophy*, Vol. VI. p. 322, that the specific gravity of oxygen is 16 times that of hydrogen.

The experiments of Davy on the combustion of boron in oxygen gas, and those of Berzelius on the borates (*Annals of Philosophy*, Vol. III. p. 66.), have shown that boracic acid is composed of 100 oxygen + 36.649 boron. The resemblance between boron and carbon is so great, that it is very probable they will be analogous to each other in the proportion of oxygen with which they combine. Now, we shall see afterwards that carbonic acid is a compound of 1 atom carbon, and 2 atoms oxygen. Supposing boracic acid to be a compound of 1 atom boron, and 2 atoms oxygen, to determine the weight of an atom of boron, we have this proportion $\frac{100}{2} : 36.649 :: 1 : 0.733 =$ weight of an atom of boron.

When charcoal is burnt in oxygen gas, the bulk of the gas is not altered; it is merely converted into carbonic acid gas. Therefore, if we subtract the specific gravity of oxygen gas from that of carbonic acid gas, the remainder denotes the quantity of carbon in carbonic united with the weight of oxygen indicated by the specific gravity. Now,

| | Grains. |
|---|---|
| 100 cubic inches of carbonic acid weigh | 46.313 |
| 100 oxygen gas - | 33.672 |
| Remainder, - | 12.641 |

Therefore carbonic acid is composed of

| | | |
|---|---|---|
| Carbon - | 12.641 or | 27.29 |
| Oxygen - | 33.672 | 72.71 |
| | | 100. |

We shall see afterwards that carbonic acid is composed of 1 atom carbon + 2 atoms oxygen. Therefore, to find the weight of an atom of carbon, we have this proportion, $\frac{72.71}{2} : 27.29 :: 1 : 0.751 =$ weight of an atom of carbon.

The writer of this article has ascertained, by experiments which it would be too tedious to adduce here, that phosphoric acid is composed of 100 phosphorus + 123 oxygen, and that it consists of 1 atom phosphorus + 2 atoms oxygen. Hence the weight of an atom of phosphorus is 1.625.

The determination of the weight of an atom of azote is attended with considerable difficulty. We have no doubt, that it is in reality a compound. But whether it consists of hydrogen united to oxygen, as is the opinion of Mr Miers, or of nitricum and oxygen, as Berzelius believes, has not yet been decided by satisfactory experiments. We must, therefore, in the present state of our knowledge, allow it a place among the undecomposed bodies. It scarcely belongs to the combustibles, as it does not in any case exhibit the phenomena of combustions. But we give it a place among them for want of any better situation under which it could be arranged. Azote combines with four proportions of oxygen, and constitutes four compounds, all of which have been analyzed with care. If we denominate the quantity of oxygen that unites with 100 parts of azote by $x$, the following table will exhibit the constituents of these compounds.

| | |
|---|---|
| Nitrous oxide . | 100 azote + 1 $x$ |
| Nitrous gas . . | 100 azote + 2 $x$ |
| Nitrous acid . . | 100 azote + 3 $x$ |
| Nitric acid . . | 100 azote + 5 $x$ |

From this table there can be no doubt, that $x$ represents an atom of oxygen. Hence we have only to ascertain the value of $x$, to be able to determine the weight of an atom of azote. Now nitrous oxide, nitrous gas, and nitric acid, have been analyzed with care, and the number in the table is the mean resulting from these analyses.

It has been ascertained by many and careful experiments, that sulphurous and sulphuric acids are composed as follows:

Sulphur.

| | | |
|---|---|---|
| Sulphurous acid . | 100 + | 100 oxygen. |
| Sulphuric acid . . | 100 | 150 |

Hence we see, that the first contains two atoms of oxygen, and the second three atoms of oxygen, combined each with one atom of sulphur. Therefore for the weight of an atom of sulphur, we have this proportion $\frac{100}{2}:100::1:2=$ weight of an atom of sulphur.

The atom of silicon, which is a combustible substance analogous to charcoal, the base of the earth called silica, is derived from the experiments of Berzelius, for which we refer to his *mineralogical essay*, lately translated into English, as it would not be possible to make these experiments intelligible here, without entering into details, quite inconsistent with the nature of this article. These details will probably find a place under the article CHEMISTRY, to which therefore we refer the reader.

3. *Metals.*

| | | Weight of an Atom. |
|---|---|---|
| 11 | Aluminum | 1.125 |
| 12 | Ammonium | 1.125 |
| 13 | Magnesium | 1.500 |
| 14 | Calcium | 2.625 |
| 15 | Tellurium | 4.027 |
| 16 | Zinc | 4.095 |
| 17 | Zirconium | 4.625 |
| 18 | Chromium | 4.750 |
| 19 | Potassium | 5.000 |
| 20 | Arsenic | 6.000 |
| 21 | Sodium | 5.875 |
| 22 | Strontium | 5.500 |
| 23 | Molybdenum | 6.013 |
| 24 | Glucinum | 6.833 |
| 25 | Manganese | 7.125 |
| 26 | Iron | 7.143 |
| 27 | Nickel | 7.305 |
| 28 | Cobalt | 7.326 |
| 29 | Yttrium | 7.375 |
| 30 | Copper | 8.000 |
| 31 | Barytium | 8.750 |
| 32 | Bismuth | 9.000 |
| 33 | Antimony | 11.250 |
| 34 | Cerium | 11.500 |
| 35 | Uranium | 12.000 |
| 36 | Tungsten | 12.125 |
| 37 | Platinum | 12.125 |
| 38 | Silver | 13.750 |
| 39 | Palladium | 14.075 |
| 40 | Tin | 14.750 |
| 41 | Rhodium | 15.000 |
| 42 | Titanium | 18.000 |
| 43 | Gold | 24.875 |
| 44 | Mercury | 25.000 |
| 45 | Lead | 26.000 |

In the preceding table we have been obliged to omit the weight of an atom of three metals, namely, osmium, iridium, and columbium, because we are at present unacquainted with the analyses of their oxides, and of all the compounds which they form. The weights of the atoms of the metals inserted, have been taken from the best documents at present in possession of chemists. But we are far from supposing that they are all correct. Some have little better than analogical reasoning in their favour, while the weight of others is founded upon a law discovered by Berzelius relative to the salts; namely, that the oxygen in the acid of a neutral salt, is always a multiple of the oxygen in the base, by 2, 3, 4, 5, &c. and this number is always constant for every particular acid.

The weight of an atom of aluminum is calculated from the composition of alum. This salt is a combination of sulphate of potash and sulphate of alumina. Sulphuric acid is saturated by a quantity of base containing one third of the oxygen in the acid. Knowing the analysis of the salt, we obtain from this law the quantity of oxygen in a given weight of alumina. If we suppose alumina a compound of 1 atom aluminum, and 1 atom oxygen, the weight of an atom of aluminum will be as in the table. This hypothesis, however, is quite arbitrary. But it seems better to be satisfied with it at present, because we are not in possession of any data to enable us to reason on the subject. The weight of the atoms of the bases of the alkaline earths, and earths proper, were ascertained by a similar process of reasoning. They are smaller than the weights of those atoms assigned by Berzelius, because he conceives them to be united with more than one atom of oxygen. We have given, however, in the table, the weight of an atom of glucinum, as determined by Berzelius in a set of new experiments, which he has published as an appendix to his treatise on mineralogy, above referred to. The weights of the atom of potassium and sodium, are obtained from the experiments of Davy, and Gay-Lussac, and Thenard. It appears that potash is a compound of 100 potassium, and 20 oxygen, and peroxide of potassium of 100 potassium, and 60 oxygen. Hence the weight of an atom of potassium is obvious. Soda is composed of 100 sodium and 34.1 oxygen; peroxide of sodium of 100 sodium, and 51.1. Now 34.1 is to 51.1 as 2:3. Hence soda must contain 2 atoms of oxygen. For its weight therefore we have this proportion $\frac{34.1}{2}:100::1:5.882=$ weight of an atom of sodium.

Ammonium is a problematic substance which never yet has been obtained in a separate state. But when a globule of mercury is moistened with ammonia, and acted on by a galvanic battery, the mercury is converted into an amalgam of the consistence of butter, and not the fourth part of its original specific gravity. This fact cannot be explained any other way than by supposing ammonia to be a compound of oxygen, and an unknown metallic base which amalgamates with the mercury in the galvanic experiment. Analogy comes strongly in favour of this opinion. We are acquainted with nearly fifty bases which have the property of neutralizing acids, of which ammonia is one. Now it is known, that all the rest contain oxygen as a constituent. Hence, it would be singular if ammonia alone, of all

the bases, should constitute an exception to a general rule. There seems to be little doubt, that sal-ammoniac is a compound of chlorine and ammonium. This salt is formed by the union of equal volumes of muriatic acid gas, and ammoniacal gas. Hence, it consists of

| | |
|---|---|
| Muriatic acid - - | 100 |
| Ammonia - - - | 46.178 |
| By weight - - | 146.178 |

Now, muriatic acid is a compound of 75.731 chlorine, and 2.23 hydrogen. Therefore, 100 muriatic acid contain 2.86 hydrogen. We must suppose this hydrogen to find in the ammonia a quantity of oxygen capable of converting it into water. Now, 2.86 hydrogen require $21\frac{2}{3}$ oxygen to convert them into water. Therefore ammonia must be a compound of

| | | |
|---|---|---|
| Ammonium | 24.511 | or 100. |
| Oxygen . . | 21.666 | 88.39. |

Now, if ammonia be composed of 1 atom oxygen, and 1 atom ammonium, we have, for finding the weight of an atom of ammonium, this proportion :— $21.666 : 24.511 :: 1 : 1.149 =$ weight of an atom of ammonium.

The weight of an atom of zinc is founded on Dr Thomson's analysis of Blende (*Annals of Philosophy*, IV. 89). It agrees almost exactly with the analysis of oxide of zinc by Berzelius. But Berzelius doubles the weight of an atom of zinc, by supposing the existence of another oxide, containing less oxygen than the white oxide. But as this oxide has never been obtained nor examined by any one, we have no right to suppose its existence. The weight of an atom of tellurium is derived from the experiments of Berzelius. Its oxide, according to him, is composed of 100 tellurium + 24.83 oxygen.

Berzelius (*Annals of Philosophy*, III. 101.) has shown that there are three oxides of chromium, the green, the brown, and chromic acid. The first contains 100 metal + 42.37 oxygen, while the acid is composed of 100 metal + 84.74 oxygen. These numbers are to each other as 1 to 2. As the brown oxide is intermediate, we must suppose the green oxide a compound of 1 atom metal + 2 atoms oxygen ; the brown of 1 atom metal + 3 oxygen ; and the acid of 1 atom metal + 4 atoms oxygen. This gives us the weight of an atom of chromium, stated in the table. But it would not be surprising if the brown oxide were merely a mixture or combination of the green oxide and chronic acid. On that supposition the weight of an atom of chromium would be only 2.375.

Berzelius has published an elaborate set of experiments on arsenic (*Annals of Philosophy*, III. 93.), in which he endeavours to prove that there are four oxides of arsenic, namely, 1. The black oxide, composed of 1 atom metal + 1 atom oxygen. 2. Salipable oxide of arsenic, composed of 1 atom metal + 3 atoms oxygen. 3. Arsenious acid, composed of 1 atom metal + 4 atoms oxygen ; and, 4. Arsenic acid, composed of 1 atom metal + 6 atoms oxygen. But his experiments are too complicated, and his reasoning too hypothetical, to produce conviction ; especially as they appear inconsistent with the much simpler experiments of Proust, Thenard, Rose, Bucholz, and Thomson, from which it appears that 100 arsenic, when converted into arsenic acid, becomes 152.4. It was from this experiment of Dr Thomson that the weight of an atom of arsenic in the table was derived.

The weight of an atom of molybdenum is deduced from the experiments of Bucholz. He found two oxides of molybdenum, the blue and the white, composed of 100 metal united with 34 and 50 oxygen. Now 34 is to 50 as 2 to 3. Hence the first is a deutoxide, and we have for the weight of molybdenum this proportion $\frac{34}{2} : 100 :: 1 : 6.013 =$ weight of an atom of molybdenum.

There are four oxides of manganese, the green, the olive, the brown, and the black. The composition of these oxides is as follows :

| | | |
|---|---|---|
| 1st oxide composed of | 100 metal | + 14.0533 oxygen. |
| 2d oxide | 100 | + 28.107. |
| 3d oxide | 100 | + 42.16. |
| 4th oxide | 100 | + 56.213. |

Now, the quantities of oxygen in these oxides are to each other as the numbers 1, 2, 3, 4. Hence the first is a protoxide ; and for the weight of an atom of manganese we have this proportion $14.0533 : 100 :: 1 : 6.833 =$ weight of an atom of manganese.

Iron forms two oxides, the black and the red. The first of these, according to the experiments of Dr Thomson, is composed of 100 metal + 28 oxygen, the second of 100 metal + 42 oxygen. Now 28 is to 42 as 2 to 3. Hence $\frac{28}{2} : 100 :: 1 : 7.143 =$ weight of an atom of iron.

Nickel and cobalt agree with iron in being magnetic. They agree, likewise, in the number of oxides which they form, and almost in the proportion of oxygen with which they unite. Probably future experiments will show these proportions to be absolutely identical. At present it is believed, that the two oxides of nickel are composed as follows :

| | | |
|---|---|---|
| 1st oxide | 100 nickel | + 27.6 oxygen. |
| 2d oxide | 100 | + 41. |

while those of cobalt consist of

| | | |
|---|---|---|
| 1st oxide | 100 cobalt | + 27.3 oxygen. |
| 2d oxide | 100 | + 40.95. |

These slight differences in the proportion of oxygen occasion the difference between the weights of the atoms of these metals and that of iron.

There are two oxides of copper, the red and the black, composed of

1st oxide 100 metal + 12.5 oxygen.
2d oxide 100 + 25.

Hence 12.5 : 100 :: 1 : 8 = weight of an atom of copper.

Bismuth forms only one oxide. A mean of the experiments of Thomson, Lagerhjelm, and John Davy, gives its composition 100 metal + 11.229. Hence the number in the table.

There is no metal so difficult to experiment on as antimony. Hence, notwithstanding the laborious efforts of many distinguished chemists, considerable uncertainty still exists, both respecting the number and the composition of its various oxides. Proust makes only two oxides of antimony: Thenard makes six, and Berzelius makes four. We think it safer, in the present state of our knowledge, to deduce the weight of an atom of antimony from the sulphuret, which can be analyzed with accuracy, than from the oxides, respecting the constitution of which considerable doubts still remain. From the experiments of Dr Thomson (*Annals of Philosophy*, IV. 99.), it appears that sulphuret of antimony is composed of 100 metal + 35.556 sulphur. Now, supposing it a compound of 1 atom metal + 2 atoms sulphur, an atom of antimony will weigh 11.249.

The weight of an atom of cerium is founded on the experiments of Hisinger, which may be seen in the *Annals of Philosophy*, IV. 355.

Bucholz has shown that there are two oxides of uranium, the black and the yellow; the first composed of 100 metal + 8.333 oxygen, the second of 100 metal + 25 oxygen. These numbers are to each other as 1 to 3. Hence 8.333 : 100 :: 1 : 12 = weight of an atom of uranium.

Berzelius has shown (*Annals of Philosophy*, III. 244), that there are two oxides of tungsten, brown oxide, and tungstic acid. The first is composed of 100 metal + 16.5 oxygen, the second of 100 metal + 24.75 oxygen. Now 16.5 is to 24.75 as 2 to 3. Therefore $\frac{16.5}{2}$ : 100 :: 1 : 12 : 121 = weight of an oxide of tungsten.

Berzelius obtained two oxides of platinum. The first composed of 100 metal + 8.287 oxygen, the second of 100 metal + 16.36. Now 8.287 is to 16.36 as 1 to 2. Therefore 8.287 : 100 :: 1 : 12.161 = weight of an atom of platinum.

Silver forms only one oxide, and it parts with its oxygen so easily, that it is very difficult to determine the proportion of oxygen with which it unites. The number in the table is derived from horn-silver, which is known to be a compound of 100 chlorine and 304.89 silver. This gives us the weight of an atom of silver 13.714, and the oxide of silver, a compound of 100 silver + 7.291 oxygen.

Berzelius could form only one oxide of palladium. It was brown, and composed of 100 metal + 14.209 oxygen. If we suppose this a deutoxide, which is probable, then we have $\frac{14.209}{2}$ : 100 :: 1 : 14.075 = weight of an atom of palladium.

Proust first proved that tin forms three oxides. According to Berzelius, the first oxide is composed of 100 metal + 13.6 oxygen, and the peroxide of 100 metal + 27.2. As there is an intermediate oxide, we cannot avoid concluding that the first oxide is a compound of 1 atom metal + 2 atoms oxygen. For the oxygen in the peroxide is just double that in the first oxide. Therefore for an atom of tin we have this proportion, $\frac{13.6}{2}$ : 100 :: 1 : 14.705 = weight of an atom of tin.

Berzelius has shown that there are three oxides of rhodium. The first, constituting the base of the muriate, is composed of 100 metal + 6.71 oxygen. The second of a flea brown colour, obtained by heat, is composed of 100 metal + 13.42 oxygen. The third is red, and is obtained by precipitation from the soda-muriate. It contains more oxygen than either of the other two (*Annals of Philosophy*, III. 252.). We have therefore 6.71 : 100 :: 1 : 14.903 = weight of an atom of rhodium.

The weight of an atom of titanium, given in the table, is not much to be depended on. It is the number given by Berzelius from an experiment of Richter (*Annals of Philosophy*, III. 251.), and is merely inserted for want of better data.

To the indefatigable industry and address of Berzelius, we are indebted for our knowledge of the composition of the oxides of gold. His mode of proceeding was not quite beyond the reach of objection, though perhaps, upon the whole, the best that he could have had recourse to, with the prospect of an answer to the problem which he was investigating. A determinate quantity of gold was dissolved in nitromuriatic acid, and thus converted into yellow oxide or peroxide of gold. He ascertained how much mercury was necessary to precipitate this gold in the metallic state. This portion of mercury united with all the oxygen of the gold. Now, as the composition of oxide of mercury is known, it was easy to determine how much oxygen had been united with the gold. By exposing the muriate of gold to heat, its nature was altered, and another oxide of gold formed, containing less oxygen. When water is poured upon this substance, two-thirds of the gold are reduced, and the other third converted into yellow oxide. Hence this new oxide contained only the third part of the oxygen in the yellow oxide. The yellow oxide was composed of 100 gold + 12.077 oxygen. Hence, the protoxide consisted of 100 gold + 4.026 oxygen. Now 4.026 : 100 :: 1 : 24.838 = weight of an atom of gold.

The weight of an atom of mercury, is taken from the experiments of Thenard, and Fourcroy, and Sefstrom. The mean of these give us black oxide of mercury, composed of 100 mercury + 4 oxygen, and red oxide of 100 mercury + 8 oxygen.

There are three oxides of lead, the yellow, the red, and the brown; the first composed of 100 metal + 7.7 oxygen, the second of 100 metal + 11.55 oxygen, and the third of 100 metal + 15.4 oxygen. Now 7.7, 11.55, and 15.4, are to each other as the numbers 2, 3, 4. Therefore, the yellow oxide con-

tains two atoms of oxygen, and we have $\frac{7.7}{2}$ : 100 : : 1 : 25.974 = weight of an atom of lead.

Such are the weights of the atoms of the simple substances, and such the documents upon which these weights are founded. The importance of these weights will best appear by giving a view of the compounds which these bodies form with each other.

### III. Weight of the Integrant Particles of Primary Compounds.

The primary compounds being very numerous, we shall, for the sake of distinctness, subdivide them under different heads.

1. *Compounds of the Simple Combustibles with Oxygen.*

| Substances. | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|
| 46 Water | 1*h* + 1*o* | 1·125 |
| 47 Boracic acid | 1*b* + 2*o* | 2·733 |
| 48 Carbonic oxide | 1*c* + 1*o* | 1·750 |
| 49 Carbonic acid | 1*c* + 2*o* | 2·750 |
| 50 Phosphorous acid | 1*p* + 1*o* | 2·625 |
| 51 Phosphoric acid | 1*p* + 2*o* | 3·625 |
| 52 Nitrous oxide | 1*a* + 1*o* | 2·750 |
| 53 Nitrous gas | 1*a* + 2*o* | 3·750 |
| 54 Nitrous acid | 1*a* + 3*o* | 4·750 |
| 55 Nitric acid | 1*a* + 5*o* | 6·750 |
| 56 Sulphurous acid | 1*s* + 2*o* | 4·000 |
| 57 Sulphuric acid | 1*s* + 3*o* | 5·000 |
| 58 Silica | 1*s* + 2*o* | 6·000 |

Water is composed of two measures of hydrogen gas, united to one measure of oxygen. The reasons for considering it as a compound of 1 atom hydrogen, and 1 atom oxygen, have been already stated.

Boracic acid is conceived to contain two atoms of oxygen, because this is the case with carbonic acid, and the analogy between carbon and boron is very striking.

If 100 measures of carbonic oxide be mixed with 50 measures of oxygen gas, and the mixture be fired by electricity, the result will be 100 measures of carbonic acid. If charcoal be burnt on 100 measures of oxygen gas, the bulk is not altered, but the oxygen is changed into carbonic acid. From these facts, it is obvious that the oxygen in carbonic oxide, combined with a given quantity of carbon, is just half of that in carbonic acid combined with the same quantity of carbon. Hence the first must be a compound of 1 atom carbon + 1 atom oxygen; the second of 1 atom carbon + 2 atoms oxygen. The weights in the table correspond exactly with the analysis of these two substances.

Several of the compounds of azote and oxygen have been analyzed with great care; namely, nitrous oxide, nitrous gas, and nitric acid; and the results coincide with the numbers given in the table. Nitrous acid is merely given from theory. It has not hitherto been possible to analyze it.

Sulphurous acid was first analyzed by Dr Thomson, who showed that it contained two-thirds of the oxygen in sulphuric acid. It seems demonstrated by the experiments of Klaproth, Berzelius, &c. that sulphuric acid is a compound of 100 sulphur + 150 oxygen. Therefore sulphurous acid must be composed of 100 sulphur + 100 oxygen, and the composition of both must be as in the table.

The composition of silica is taken from the experiments and calculations of Berzelius, and depends chiefly upon analogical reasoning.

2. *Compounds of the Simple Combustibles with each other.*

| | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|
| 59 Olefiant gas | 1*c* + 1*h* | 0.875 |
| 60 Carbureted hydrogen | 1*c* + 2*h* | 1.000 |
| 61 Hydrophosphoric gas | 1*p* + 2*h* | 1.875 |
| 62 Phosphureted hydrogen | 1*p* + 4*h* | 2.125 |
| 63 Ammonia | 1*a* + 3*h* | 2.125 |
| 64 Sulphureted hydrogen | 1*s* + 1*h* | 2.125 |
| 65 Sulphuret of carbon | 1*c* + 2*s* | 4.750 |

Olefiant gas requires for complete combustion three times its bulk of oxygen gas, and forms twice its bulk of carbonic oxide; carbureted hydrogen requires twice its bulk of oxygen, and forms its own bulk of carbonic acid. Hence, it is obvious, that supposing the quantity of hydrogen the same in both, the carbon in olefiant gas, is just double that in carbureted hydrogen. We might have conceived carbureted hydrogen to be a compound of 1 atom hydrogen, and 1 atom carbon, and olefiant gas of 1 atom hydrogen, and 2 atoms carbon. But the reasons assigned by Mr Dalton, have induced us to adopt the composition in the table, which comes in fact to the very same thing.

The two gases which are composed of phosphorus and hydrogen, have not been hitherto analyzed. But it appears from Davy that the specific gravity of the first is double that of the second. Davy states his hydrophosphoric gas to be composed of 100 hydrogen by weight, and 489.56 phosphorus. The numbers in the table are founded on these data; though they do not quite correspond.

Ammonia, by electricity, may be resolved into 3 measures of hydrogen, and 1 measure of azote. 300 cubic inches of hydrogen gas weigh 6.69 grains, and 100 cubic inches of azotic gas weigh 29.56 grains. Now 6.69 : 29.56 : : 0.132 × 3 : 1.704 = weight of an atom of azote very nearly.

We have given the data upon which the composition of sulphureted hydrogen is founded in a preceding part of this article. It is therefore unnecessary to repeat them here.

Sulphuret of carbon was analyzed by Berzelius and Marcet, who found it a compound of 84.83 sulphur. and 15.17 carbon. The composition of this substance, as given in the table, supposes it a compound of 84.2 sulphur + 15.8 carbon; numbers which may be considered as identical with the preceding, since the difference is within the limits of the unavoidable errors of experiment.

*3. Metallic Oxides.*

| | Oxides. | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 66 | Alumina - | 1 *a* + 1 *o* | 2.125 |
| 67 | Ammonia - - | 1 *a* + 1 *o* | 2.125 |
| 68 | Magnesia - - | 1 *m* + 1 *o* | 2.500 |
| 69 | Lime - - - | 1 *c* + 1 *o* | 3.625 |
| 70 | Oxide of tellurium - | 1 *t* + 1 *o* | 5.027 |
| 71 | Oxide of zinc - | 1 *z* + 1 *o* | 5.095 |
| 72 | Zirconia - - | 1 *zir* + 1 *o* | 5.625 |
| 73 | Green oxide of chromium | 1 *ch* + 2 *o* | 6.750 |
| 74 | Brown oxide of chromium | 1 *ch* + 3 *o* | 7.750 |
| 75 | Chromic acid - | 1 *ch* + 4 *o* | 8.750 |
| 76 | Potash - - | 1 *p* + 1 *o* | 6.000 |
| 77 | Peroxide of potassium | 1 *p* + 2 *o* | 7.000 |
| 78 | Arsenious acid - | 1 *ars* + 2 *o* | 8.000 |
| 79 | Arsenic acid - | 1 *ars* + 3 *o* | 9.000 |
| 80 | Soda - - - | 1 *sod* + 2 *o* | 7.875 |
| 81 | Peroxide of sodium | 1 *sod* + 3 *o* | 8.875 |
| 82 | Strontian - | 1 *str* + 1 *o* | 6.500 |
| 83 | Deutoxide of molybdenum | 1 *m* + 2 *o* | 8.013 |
| 84 | Peroxide of molybdenum | 1 *m* + 3 *o* | 9.013 |
| 85 | Glucina - - | 1 *gl* + 3 *o* | 9.833 |
| 86 | Protoxide of manganese | 1 *m* + 1 *o* | 7.125 |
| 87 | Deutoxide of manganese | 1 *m* + 2 *o* | 8.125 |
| 88 | Tritoxide of manganese | 1 *m* + 3 *o* | 9.125 |
| 89 | Peroxide of manganese | 1 *m* + 4 *o* | 10.125 |
| 90 | Deutoxide of iron - | 1 *i* + 2 *o* | 9.143 |
| 91 | Peroxide of iron - | 1 *i* + 3 *o* | 10.143 |
| 92 | Deutoxide of nickel | 1 *n* + 2 *o* | 9.305 |
| 93 | Peroxide of nickel | 1 *n* + 3 *o* | 10.305 |
| 94 | Deutoxide of cobalt | 1 *c* + 2 *o* | 9.326 |
| 95 | Peroxide of cobalt | 1 *c* + 3 *o* | 10.326 |
| 96 | Yttria - - | 1 *y* + 1 *o* | 8.375 |
| 97 | Protoxide of copper | 1 *c* + 1 *o* | 9.000 |
| 98 | Peroxide of copper | 1 *c* + 2 *o* | 10.000 |
| 99 | Barytes - - | 1 *b* + 1 *o* | 9.750 |
| 100 | Oxide of bismuth - | 1 *b* + 1 *o* | 10.000 |
| 101 | Deutoxide of antimony | 1 *a* + 2 *o* | 13.250 |
| 102 | Tritoxide of antimony | 1 *a* + 3 *o* | 14.250 |
| 103 | Peroxide of antimony | 1 *a* + 4 *o* | 15.250 |
| 104 | Deutoxide of cerium | 1 *c* + 2 *o* | 13.500 |
| 105 | Peroxide of cerium | 1 *c* + 3 *o* | 14.500 |
| 106 | Protoxide of uranium | 1 *u* + 1 *o* | 13.000 |
| 107 | Peroxide of uranium | 1 *u* + 3 *o* | 15.000 |
| 108 | Deutoxide of tungsten | 1 *t* + 2 *o* | 14.125 |
| 109 | Peroxide of tungsten | 1 *t* + 3 *o* | 15.125 |
| 110 | Protoxide of platinum | 1 *p* + 1 *o* | 13.125 |
| 111 | Peroxide of platinum | 1 *p* + 2 *o* | 14.125 |
| 112 | Oxide of silver - | 1 *s* + 1 *o* | 14.750 |
| 113 | Peroxide of palladium | 1 *p* + 2 *o* | 16.075 |
| 114 | Deutoxide of tin - | 1 *t* + 2 *o* | 16.750 |
| 115 | Tritoxide of tin - | 1 *t* + 3 *o* | 17.750 |
| 116 | Peroxide of tin - | 1 *t* + 4 *o* | 18.750 |
| 117 | Protoxide of rhodium | 1 *rh* + 1 *o* | 16.000 |
| 118 | Protoxide of rhodium | 1 *rh* + 2 *o* | 17.000 |
| 119 | Peroxide of rhodium | 1 *rh* + 3 *o* | 18.000 |
| 120 | Protoxide of titanium | 1 *t* + 1 *o* | 19.000 |
| 121 | Peroxide of titanium | 1 *t* + 2 *o* | 20.000 |
| 122 | Protoxide of gold | 1 *g* + 1 *o* | 25.875 |
| 123 | Peroxide of gold - | 1 *g* + 3 *o* | 27.875 |
| 124 | Protoxide of mercury | 1 *m* + 1 *o* | 26.000 |
| 125 | Peroxide of mercury | 1 *m* + 2 *o* | 27.000 |
| 126 | Deutoxide of lead - | 1 *l* + 2 *o* | 28.000 |
| 127 | Tritoxide of lead - | 1 *l* + 3 *o* | 29.000 |
| 128 | Peroxide of lead - | 1 *l* + 4 *o* | 30.000 |

This table contains all the metallic oxides at present known, which are 62 in number. We have omitted a few which Thenard has admitted into his *System of Chemistry*, just published; but which do not seem to be supported by sufficiently strong evidence, to induce us to admit their existence. The same remark applies to some of the oxides of Gay-Lussac and Thenard; and, perhaps, also to some of the oxides of Berzelius. In short, we have admitted no primary compound into our tables, the existence of which is not demonstrated by the clearest evidence. For the loose admission of hypothetical bodies seems to us injurious, rather than beneficial to the progress of the science.

Alumina, Magnesia, Lime, Zirconia, Strontian, Yttria, Barytes, are supposed compounds of 1 atom base, and 1 atom oxygen; because we do not know any other compounds which these bases form with oxygen; and, therefore, have no data to reason on the subject. Their composition has been calculated from the composition of the sulphates of alumina, magnesia, lime, zirconia, strontian, yttria, barytes, the constitution of which will be shown in a subsequent part of this article. The calculation was made, on the supposition, that the quantity of each base which saturates a given weight of sulphuric acid, contains just one-third of the oxygen in the acid: a law which holds, in every case, in which we have it in our power to verify it.

Ammonia, in the present state of the sciences, is an ænigmatical substance. We have given before a view of its composition, on the supposition, that it is a compound of hydrogen and azote. Here, its composition is seen on the supposition that it is a compound of ammonium and oxygen. Both analyses seem demonstrated. The seeming inconsistency will vanish, whenever it can be shown that azote is a compound of hydrogen and oxygen.

Potash, peroxide of potash, soda, peroxide of soda, are given according to the experiments of Davy, and Gay-Lussac, and Thenard. The French chemists admit an oxide of potassium and sodium, containing each less oxygen than exists in potash and soda. But the existence of these supposed oxides is not made out in a satisfactory manner. For any thing that appears to the contrary, their oxides may be mixtures of potash and potassium, soda and sodium.

In stating the weights of the atoms of the metals, we have noticed the most accurate experiments hitherto made, to determine the number and composition of the different metallic oxides; and it does not seem necessary to resume the subject here. If the reader be at the trouble to make the trial, he will find, that the numbers in the table agree very correctly with the best results of the analysis of the metallic oxides hitherto obtained. Hence there can be no doubt, that at least a considerable part of the table is accurate.

### 4. *Combinations of the Metals and Simple Combustibles.*

(1) *Hydrurets.*

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 129 | Arsenical hydrogen gas | 1 *a* + 9 *h* | 7.125 |
| 130 | Tellurated hydrogen gas | unknown | |
| 131 | Potassurated hydrogen gas | unknown | |

From the experiments of Gay-Lussac and Thenard, it appears, that 100 measures of arsenical hydrogen gas, when deprived of its arsenic, by heating tin in it, expand and become 140 measures. Sir Humphry Davy found this gas 8 times heavier than hydrogen. Trommsdorf found it 0.529, that of common air being 1.000, which is only a very little lighter than Davy's statement. These data give us its composition, 9 atoms hydrogen, and 1 atom arsenic. But it is not unlikely, that part of the hydrogen was only mechanically mixed. From the experiments of Ritter, confirmed by Davy, and Gay-Lussac, and Thenard, it appears, that there exists a solid hydruret of arsenic, which may be formed by attaching slips of arsenic to the negative pole of a galvanic battery, dipping the arsenic in water, and completing the circuit. It is a brown flocky substance, which has not been analyzed. It seems to be more fixed in the fire than arsenic itself.

Telluretted hydrogen gas has not yet been analyzed. Its properties are similar to those of sulphurated hydrogen. Hence analogy would lead us to suppose that its composition is similar. In that case, it would be composed of 1 atom tellurium, and 1 atom hydrogen, and the weight of an integrant particle of it would be 4.152.

(2.) *Sulphurets.*

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 132 | Sulphuret of zinc | 1 *z* + 1 *s* | 6.095 |
| 133 | Sulphuret of tellurium | 1 *t* + 2 *s* | 8·027 |
| 134 | Sulphuret of potassium | 1 *p* + 1 *s* | 7.000 |
| 135 | Sulphuret of arsenic | 1 *a* + 2 *s* | 10.000 |
| 136 | Sulphuret of sodium | 1 *sod.* + 2 *s* | 9.875 |
| 137 | Sulphuret of molybdenum | 1 *m* + 2 *s* | 10.013 |
| 138 | Sulphuret of manganese | 1 *m* + 1 *s* | 9.125 |
| 139 | Prosulphuret of iron | 1 *i* + 2 *s* | 11.143 |
| 140 | Persulphuret of iron | 1 *i* + 4 *s* | 15.143 |
| 141 | Sulphuret of nickel | 1 *n* + 2 *s* | 11.305 |
| 142 | Sulphuret of cobalt | 1 *c* + 2 *s* | 11.326 |
| 143 | Sulphuret of copper | 1 *c* + 1 *s* | 10.000 |
| 144 | Sulphuret of bismuth | 1 *b* + 1 *s* | 11.000 |
| 145 | Sulphuret of antimony | 1 *a* + 2 *s* | 15.250 |
| 146 | Sulphuret of platinum | 1 *p* + 2 *s* | 16.125 |
| 147 | Sulphuret of silver | 1 *sil.* + 1 *s* | 15.750 |
| 148 | Sulphuret of palladium | 1 *p* + 1 *s* | 16.075 |
| 149 | Prosulphuret of tin | 1 *t* + 1 *s* | 16.750 |
| 150 | Persulphuret of tin | 1 *t* + 2 *s* | 18.750 |
| 151 | Sulphuret of gold | 1 *g* + 3 *s* | 30.875 |
| 152 | Prosulphuret of mercury | 1 *m* + 1 *s* | 27.000 |
| 153 | Persulphuret of mercury | 1 *m* + 2 *s* | 29.000 |
| 154 | Prosulphuret of lead | 1 *l* + 2 *s* | 30.000 |
| 155 | Persulphuret of lead | 1 *l* + 4 *s* | 34.000 |

According to the experiments of Dr Thomson (*Annals of Philosophy*, IV. 94.), sulphuret of zinc is composed of 100 metal + 48.84 sulphur. Hence the numbers in the table which have been derived from that analysis.

The composition of sulphuret of tellurium is derived from an experiment of Davy. He found, that tellurium united by fusion with nearly its own weight of sulphur. Hence it ought to combine with two atoms. Analogy, however, is against this conclusion. In all other cases, when a metal forms only one oxide, its sulphuret contains only one atom of sulphur. Hence the composition of sulphuret of tellurium, as stated in the table, is very doubtful.

The composition of sulphuret of potassium is derived from the experiments of Davy. Sulphuret of sodium is stated from the following analogy, having never been analyzed. Berzelius has shown, that all the sulphurets, when treated with nitric acid, are converted into neutral sulphates, without any redundancy of acid or base. Therefore, sulphuret of sodium, by this treatment, would be converted into sulphate of soda. But sulphate of soda is composed of 2 integrant particles of sulphuric acid, and 1 integrant particle of soda. Therefore, sulphuret of sodium must be composed of 2 atoms sulphur, and 1 atom sodium.

From the experiments of Laugier it appears, that sulphuret of arsenic is composed of 42 sulphur + 58 arsenic. According to him, it is often mixed with an excess of arsenic, which occasions the apparent variableness in its composition. The experiments of Proust and Thenard do not agree well with those of Laugier. Hence the subject cannot be considered as completely cleared up.

Sulphuret of manganese is derived from an experiment of Vauquelin, who found that 74.8 manganese united with 25.5 of sulphur by heat.

Bucholz found sulphuret of molybdenum composed of 60 molybdenum + 40 sulphur. Hence its constitution as stated in the table.

The two sulphurets of iron were first analyzed by Hatchett, and the table is conformable to the results of that analysis. We consider the late speculations of Stromeyer on magnetic pysites as erroneous.

Nickel and cobalt have so close an analogy to iron in their combinations, that it is reasonable to expect that the sulphurets will also correspond. Hence the reason for considering these sulphurets as compounds of one atom metal and two atoms sulphur. This statement likewise approaches nearest to the results obtained by Proust.

It has been ascertained that 100 copper combine with 25 sulphur. This coincides exactly with the statement in the table.

John Davy has shown that 67.5 bismuth unite with 15.08 sulphur. Lagerhjelm found that 100 bismuth unite with 22.52 sulphur. Both of these statements coincide sufficiently with the table.

From the analysis of sulphuret of antimony by Dr Thomson (*Annals of Philosophy*, IV. 99.), we learn, that it is a compound of 100 metal + 35.556 sulphur. With this analysis the statement in the table exactly coincides.

Atomic Theory.

Berzelius informs us, that 100 platinum combine with 32.8 sulphur. Now 108 : 32.8 : : 12.161 : 3.938 = 2 atoms of sulphur very nearly.

According to Berzelius, 100 sulphur combine with 14.9 sulphur. Now 100 : 14.9 : : 13.714 : 2.0434 = an atom of sulphur very nearly.

Sulphuret of palladium has not been analyzed; but, as palladium forms only one oxide, we may, without much risk of error, consider the sulphuret as a compound of 1 atom metal and 1 atom sulphur.

From the experiments of Dr Davy it appears, that mosaic gold contains just double the quantity of sulphuret in common sulphuret of tin. According to the experiments of the same chemist, protosulphuret of tin is a compound of 55 tin + 15 sulphur. Now 55 : 15 : : 14.705 : 4.015 = 2 atoms of sulphur very nearly.

Oberkampt has shown, that the sulphuret of gold is composed of 100 gold + 24.39 sulphur. Now 100 : 24.39 : : 24.838 : 6.057 = 3 atoms of sulphur very nearly.

According to the experiments of Sefstrom, black sulphuret of mercury is composed of 100 metal + 8.005 sulphur; and red sulphuret of 100 metal + 16.01 sulphur. Now 100 : 8.005 : : 25 : 2.001 and 100 : 16001 : : 25 : 4.002. But 2.001 and 4.002 are obviously equal respectively to 1 atom and 2 atoms of sulphur.

Galena is a compound of 100 lead + 15.42 sulphur. Now 100 : 15.42 : : 25.974 : 4.005 = 2 atoms of sulphur. Sir John Sinclair found a variety of galena in Caithness, which burned with a blue flame when held to a candle. It was analyzed by Dr Thomson, and found to contain double the quantity of sulphur in common galena. Hence it was a compound of 1 atom lead and 4 atoms sulphur. This variety must be scarce, for it has never been noticed by mineralogists.

Such are the sulphurets with the composition of which we are at present acquainted. A good number are of necessity omitted, because they have never been analyzed by chemists. It would be easy to state the composition of most of these from theory. But we do not see any advantage that would result to the science from such theoretical statements, unsupported by experiment.

Neither the *phosphurets* nor *carburets* have been examined with such precision as to enable us to exhibit their composition in a table. It is probable that the phosphurets are analogous to sulphurets. But certainly no such analogy holds with the carburets and *silicarets;* both of which exist, though they have been hitherto too slightly examined to give us any exact notions of their constitution. Carbon seems to combine with a great number of atoms of iron, in cast iron, and with a still greater number in steel.

### 5. *Organic Bodies.*

Hitherto the only correct analysis of organic bodies are those made by Berzelius, and published in the fifth volume of the *Annals of Philosophy.* As these experiments are so recent as not to be generally known, we shall state in the table the results of each analysis, and likewise the number of atoms of which the body is composed.

| | Constituents. | | Atoms. | Weight. |
|---|---|---|---|---|
| 156 Citric acid | oxygen | 55.096 | 2 | = 3.634 |
| | carbon | 41.270 | 2 | |
| | hydrogen | 3.634 | 1 | |
| | | 100.000 | 5 | |
| 157 Tartaric acid | oxygen | 60.213 | 10 | = 16.668 |
| | carbon | 35.980 | 8 | |
| | hydrogen | 3.807 | 5 | |
| | | 100.000 | 23 | |
| 158 Oxalic acid | oxygen | 66.534 | 12 | = 18.140 |
| | carbon | 33.222 | 8 | |
| | hydrogen | 0.244 | 1 | |
| | | 100.000 | 21 | |
| 159 Succinic acid | oxygen | 47.888 | 3 | = 6.268 |
| | carbon | 47.600 | 4 | |
| | hydrogen | 4.512 | 2 | |
| | | 100.000 | 9 | |
| 160 Acetic acid | oxygen | 46.82 | 3 | = 6.400 |
| | carbon | 46.83 | 4 | |
| | hydrogen | 6.35 | 3 | |
| | | 100.00 | 10 | |
| 161 Gallic acid | oxygen | 38.02 | 3 | = 7.517 |
| | carbon | 56.96 | 6 | |
| | hydrogen | 5.02 | 3 | |
| | | 100.00 | 12 | |
| 162 Saclactic acid | oxygen | 61.465 | 8 | = 12.415 |
| | carbon | 33.430 | 6 | |
| | hydrogen | 5.105 | 5 | |
| | | 100.000 | 19 | |
| 163 Benzoic acid | oxygen | 20.43 | 3 | = 14.306 |
| | carbon | 74.41 | 15 | |
| | hydrogen | 5.16 | 6 | |
| | | 100.00 | 24 | |
| 164 Tannin from Nutgalls | oxygen | 44.654 | 4 | = 8.902 |
| | carbon | 51.160 | 6 | |
| | hydrogen | 4.186 | 3 | |
| | | 100.000 | 13 | |
| 165 Common sugar | oxygen | 49.015 | 20 | = 40.796 |
| | carbon | 44.200 | 24 | |
| | hydrogen | 6.785 | 21 | |
| | | 100.000 | 65 | |
| 166 Sugar of milk | oxygen | 53.359 | 8 | = 16.566 |
| | carbon | 39.474 | 10 | |
| | hydrogen | 7.167 | 8 | |
| | | 100.000 | 26 | |
| 167 Gum Arabic | oxygen | 51.306 | 12 | = 23.347 |
| | carbon | 41.906 | 13 | |
| | hydrogen | 6.788 | 12 | |
| | | 100.000 | 37 | |

Atomic Theory.

Atomic Theory.

| | Constituents. | | Atoms. | Weights. |
|---|---|---|---|---|
| 168 Potatoe starch | oxygen | 49.455 | 12 | =24.230 |
| | carbon | 43.481 | 14 | |
| | hydrogen | 7.064 | 13 | |
| | | 100.000 | 39 | |

For the way in which these experiments were made, we refer to the original paper of Berzelius, quoted above. We have no doubt that the results are very near approximations to the truth, though some slight corrections may perhaps be necessary. The great number of atoms that enter into the composition of some of these bodies is very remarkable. We would find it difficult to explain the nature of such combinations, without having recourse to some hypothesis respecting the nature of elasticity. Twelve atoms of oxygen, and 13 of hydrogen, in a compound possessed of so little elasticity as potatoe starch, is very extraordinary. The old opinion of Dr Black and his contemporaries was, that bodies owe their elasticity to a quantity of heat combined with them. Of course, when the heat is separated, the elasticity disappears. Were we to suppose, in conformity with this hypothesis, that the oxygen and hydrogen which exists in organized bodies, are deprived of the heat requisite to give them the elastic form, there would be no difficulty in understanding how so many atoms unite together, and have no tendency to separate, and how the compound is so speedily decomposed by the application of heat, or by combustion.

Thus, we have gone over all the primary compounds which have been subjected to examination by chemists, without finding a single exception to the atomic theory. On the contrary, the great and unexpected elucidation which this theory throws upon the nature of chemical combinations, is highly pleasing. The simplicity of the proportions in which the atoms of unorganic matter unite, is equally delightful and astonishing, and throws a degree of grandeur around the science, hitherto conversant in minute and apparently unconnected combinations, fully equal to what distinguishes the sublimest branch of mechanical philosophy. The operations of nature are everywhere equally grand, and regulated by general principles equally simple and luminous, whether we examine the laws which regulate the motions of the solar system, or the minutest compound to be found in the terrestrial globe. Let us now examine the secondary compounds, that we may be able to judge how far they come under the dominion of the Atomic Theory.

## IV. Composition of Secondary Compounds.

Here, our task is much more difficult, and the field in a great measure unexplored, or only partially so. The secondary compounds are very numerous, amounting to several thousands. Accurate chemical analysis cannot be dated farther back than a few years. A correct knowledge of the whole of these compounds, therefore, is not to be expected. But, from the indefatigable zeal, uncommon accuracy, and gigantic industry of Berzelius, we have it in our power to examine the composition of many genera of salts with considerable precision; supposing always that the laws which he has pointed out respecting the combination of acids and bases be precise. We shall continue the method which we adopted when treating of the primary compounds; namely, exhibit tables of the composition of the different genera of secondary compounds, and then give the documents on which these tables were founded.

### 1. *Hydrates.*

| | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|
| 169 Hydrate of potash | 1 *p* + 1 *w* | 7.125 |
| 170 Hydrate of soda | 1 *s* + 2 *w* | 10.125 |
| 171 Hydrate of lime | 1 *l* + 1 *w* | 4.750 |
| 172 Hydrate of barytes | 1 *b* + 1 *w* | 10.875 |
| 173 Hydrate of strontian | 1 *st* + 1 *w* | 7.725 |
| 174 Hydrate of magnesia | 2 *m* + 1 *w* | 6.125 |
| 175 Hydrate of alumina | 1 *a* + 1 *w* | 3.250 |
| 176 Hydrate of glucina | 1 *g* + 1 *w* | 10.965 |
| 177 Hydrate of yttria | 1 *y* + 3 *w* | 11.750 |
| 178 Hydrate of zirconia | 1 *z* + 1 *w* | 6.750 |
| 179 Hydrate of silica | 1 *si* + 1 *w* | 3.125 |
| 180 Hydro-sulphuric acid, or acid of 1.85 | 1 *s* + 1 *w* | 6.125 |
| 181 2d hydrate of sulphuric acid, or acid of 1.780 | 1 *s* + 2 *w* | 7.250 |
| 182 3d hydrate of sulphuric acid, or acid of 1.65 | 1 *s* + 3 *w* | 8.375 |
| 183 Hydronitric acid, or acid of 1.62 | 2 *n* + 1 *w* | 14.625 |
| 184 2d hydrate of nitric acid, or acid of 1.54 | 1 *n* + 1 *w* | 7.875 |
| 185 3d hydrate of nitric acid, or acid of 1.42 | 1 *n* + 2 *w* | 9.000 |
| 186 4th hydrate of nitric acid, or acid of 1.350 | 1 *n* + 3 *w* | 10.125 |
| 187 Hydrophosphorous acid | 2 *p* + 1 *w* | 6.375 |
| 188 Hydrate of boracic acid | 1 *b* + 2 *w* | 4.997 |
| 189 Hydrate of peroxide of copper | 1 *c* + 1 *w* | 11.125 |
| 190 Hydrate of black oxide of iron | 1 *i* + 1 *w* | 10.240 |
| 191 Hydrate of red oxide of iron | 1 *i* + 1 *w* | 11.240 |
| 192 Hydrate of deutoxide of tin | 1 *t* + 1 *w* | 17.875 |
| 193 Hydrate of peroxide of tin | 1 *t* + 1 *w* | 19.875 |
| 194 Hydrate of deutoxide of nickel | 1 *n* + 3 *w* | 12.701 |
| 195 Hydrate of deutoxide of cobalt | 1 *c* + 1 *w* | 11.458 |
| 196 Hydrate of protoxide of manganese | 1 *m* + 1 *w* | 9.250 |
| 197 Hydrate of oxide of arsenic | 1 *o* + 1 *w* | 7.125 |
| 198 Hydrate of antimony | 2 *a* + 1 *w* | 31.625 |
| 199 Hydrate of oxalic acid | 1 *o* +12 *w* | 31.724 |
| 200 Hydrate of tartaric acid | 1 *t* + 2 *w* | 18.932 |
| 201 Hydrate of citric acid | 2 *c* + 3 *w* | 10.664 |

By hydrate of potash is understood caustic potash, that has been exposed to a red heat. For it is well known, that the whole water cannot be expelled from potash by heat. The statement in the table supposes this hydrate to be composed of 100 potash + 18.867 water. Now Davy, by heating potash and boracic acid together, actually separated between 17 and 18 water. Berzelius obtained 16 *per cent.*, which is very near the exact quantity. For if our determination be correct, 100 potash ought to contain 15.872 water.

Hydrate of soda has never been analyzed. The number in the table is given from this analogy. Berzelius has shown, that the hydrates of the salifiable bases, are in fact salts, the water acting the part of an acid, and saturating the base. Now, in all the salts of soda hitherto examined, 1 integrant particle of the soda is always combined with 2 integrant particles of acid. We suppose the same thing to hold with water.

Slacked lime, which is the hydrate, according to the experiments of Lavoisier, is composed of 100 lime + 28.7 water; according to Dalton, of 100 lime + 33.333 water. The mean of these two results gives the statement in the table almost precisely.

The experiments of Berthollet and Berzelius prove, that hydrate of barytes is a compound of 100 barytes + 12.121 water. The statement in the table supposes it a compound of 100 barytes + 11.632, which coincides very nearly.

Hydrate of strontian is given merely from analogy. Crystallized strontian is a compound of 1 particle strontian + 13 particles of water.

According to Davy, hydrate of magnesia contains one-fifth of its weight of water. Hence the statement in the table. Probably there may be another hydrate composed of 1 integrant particle magnesia, and 1 integrant particle water, but which cannot be obtained in a separate state.

Wavellite, which is a native hydrate of alumina, is composed of 74 alumina + 26 water. Hence the composition of the hydrate in the table.

Hydrate of glucina has never been analyzed. According to Klaproth, hydrate of yttria is composed of 69 yttria + 31 water. According to Davy, zirconia, when in the state of a hydrate, contains more than one-fifth of its weight of water.

Hydrate of silica has never been analyzed. But silica absorbs about one-fourth of its weight of water.

The hydrate of sulphuric and nitric acids were determined by Mr Dalton. Sulphuric acid of 1.85 is the strongest that can be made. It is composed of 100 real acid + 22.64 water. The second hydrate is composed of 100 acid + 45.28 water. It freezes at the temperature of 42°. It was upon it that Mr Keir made his experiments.

The hydrate of phosphorous acid was determined by Sir Humphry Davy. See his *Elements of Chemical Philosophy*, p. 289.

Davy found hydrate of boracic acid composed of 57 acid + 43 water. Now, this agrees very nearly with the statement in the table.

Hydrate of peroxide of copper is obtained by precipitating the sulphate or nitrate of copper, by means of an alkali. It is a blue powder composed, according to Davy, of 9 peroxide of copper + 1 water. This agrees nearly with the statement in the table.

According to Berzelius, when iron is kept in water, a hydrate is formed, composed of 128 parts of black oxide of iron + 15.866 water. Now, this coincides almost exactly with 1 integrant particle of black oxide, 1 integrant particle of water.

Hydrate of the red oxide of iron is the orange powder obtained from persulphate of iron by an alkali. It has never been analyzed.

The hydrate of deutoxide of tin, is the white powder obtained by precipitating the recent solution of tin in muriatic acid. According to Proust, it is composed of 95 oxide + 5 water. This approaches most nearly to the statement in the table. The other hydrate of tin has never been analyzed.

The hydrate of nickel is a green powder obtained by precipitating sulphate of nickel by an alkali. According to Davy, more than one-fourth of its weight is water. This statement approaches most nearly to the supposition, that it contains 3 particles of water + 1 oxide of nickel.

The hydrates of cobalt, manganese, and arsenic, have never been analyzed. They are stated merely from analogy.

According to Berzelius, the tritoxide of antimony forms a hydrate composed of 95.22 oxide + 4.78 water. This approaches most nearly to the statement in the table; but does not agree with it.

The hydrates of oxalic acid, tartaric acid, and citric acid, were determined by Berzelius. Crystallized oxalic acid is composed of 58 acid + 42 water; crystallized tartaric acid of 88.75 acid, and + 11.25 water; and crystallized citric acid of 100 acid + 20.5 water. These proportions coincide with the statements in the table very nearly.

Thus, it appears that the composition of the hydrates, as far as they have been examined, agree perfectly with the atomic theory. We see, likewise, that the number of particles of water which enter into combination with other bodies is not confined within such narrow limits as most of the other primary compounds are. In many hydrates, only a single particle of water is found; while, in others, no fewer than 12 particles exist.

Let us now proceed to examine the salts, in order to judge how far their composition is regulated by the laws of the atomic theory.

2. *Salts.*

The salts are very numerous, and have been divided into as many genera as there are acids entering into their composition. Some of these genera have been carefully analyzed, while others still remain in a great measure unknown.

GENUS I.—*Sulphates.*

| | | Number of Atoms. | | Weight of an Integrant Particle. |
|---|---|---|---|---|
| 202 | Sulphate of potash | $1s + 1p$ | . | 11.000 |
| 203 | Bisulphate of potash | $2s + 1p$ | . | 16.000 |

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 204 | Sulphate of soda | 2 s + 1 s | 17.875 |
| 205 | Sulphate of ammonia | 1 s + 1 a | 7.125 |
| 206 | Sulphate of magnesia | 1 s + 1 m | 7.500 |
| 207 | Sulphate of lime | 1 s + 1 l | 8.625 |
| 208 | Sulphate of barytes | 1 s + 1 b | 14.750 |
| 209 | Sulphate of strontian | 1 s + 1 str | 11.500 |
| 210 | Sulphate of alumina | 1 s + 1 a | 7.125 |
| 211 | Subsulphate of alumina | 1 s + 2 a | 9.250 |
| 212 | Sulphate of yttria | 1 s + 1 y | 13.400 |
| 213 | Sulphate of glucina | 1 s + 1 g | 14.833 |
| 214 | Sulphate of zirconia | 1 s + 1 z | 10.625 |
| 215 | Alum | 6 s + 1 p + 5 a | 46.625 |
| 216 | Sulphate of potash and ammonia | 2 s + 1 p + 1 a | 18.125 |
| 217 | Sulphate of potash and magnesia | 3 s + 1 p + 2 m | 26.000 |
| 218 | Sulphate of soda and ammonia | 7 s + 1 so + 6 a | 55.625 |
| 219 | Sulphate of soda and magnesia | 4 s + 1 so + 3 m | 35.375 |
| 220 | Sulphate of magnesia and ammonia | 3 s + 2 m + 1 a | 22.125 |
| 221 | Sulphate of copper | 2 s + 1 c | 20.000 |
| 222 | Subsulphate of copper | 1 s + 2 c | 25.000 |
| 223 | Sulphate of iron | 2 s + 1 i | 19.115 |
| 224 | Subsulphate of iron | 2 s + 3 i | 37.345 |
| 225 | Persupersulphate of iron | 3 s + 1 i | 25.115 |
| 226 | Sulphate of lead | 2 s + 1 l | 38.000 |
| 227 | Sulphate of zinc | 1 s + 1 z | 9.095 |
| 228 | Sulphate of mercury | 1 s + 1 m | 31.000 |
| 229 | Persulphate of mercury | 1 s + 1 m | 32.000 |
| 230 | Sulphate of silver | 1 s + 1 si | 19.750 |
| 231 | Sulphate of bismuth | 1 s + 1 b | 15.000 |
| 232 | Sulphate of nickel | 1 s + 1 n | 14.305 |
| 233 | Sulphate of cobalt | 2 s + 1 c | 19.326 |
| 234 | Sulphate of manganese | 2 s + 1 m | 17.833 |
| 235 | Sulphate of uranium | 1 s + 1 u | 20.000 |
| 236 | Persulphate of platinum | 2 s + 1 p | 24.125 |

Dr Thomson found sulphate of potash composed of 42.2 acid + 50.1 potash, which corresponds with the tabular statement almost exactly. Dr Wollaston has shown, that the bisulphate contains just double the acid in the sulphate.

Sulphate of soda, according to Wenzel, is composed of 100 acid + 78.32 base; according to Berzelius, of 100 acid + 79.34. The tabular statement supposes a combination of 100 acid + 78.82 soda. Now, this is the mean of the two experiments.

According to Berzelius, sulphate of ammonia is composed of 100 acid + 42.561 ammonia. Now 100 : 42.561 : : 5 : 2.128 = weight of an integrant particle of ammonia very nearly.

According to Berzelius, sulphate of magnesia is composed of 100 acid + 50.06 magnesia. Now 100 : 50.06 : : 5 : 2.503 = weight of an integrant particle of magnesia very nearly.

Sulphate of lime, according to the analysis of Berzelius, is composed of 100 acid + 72.41 base. Now, 100 : 72.41 : : 5 : 3.620 = weight of an integrant particle of lime almost exactly.

Sulphate of barytes, according to the analysis of Berzelius, is composed of 100 acid + 194 barytes. Now 100 : 104 : : 5 : 9.700 = weight of an atom of barytes very nearly.

The weight of an integrant particle of strontian was deduced from an accurate analysis of carbonate of strontian, which was found to consist of 29.9 carbonic acid + 70.1 strontian.

According to Berzelius's analysis, sulphate of alumina is composed of 100 acid + 42.722 alumina. It was from this analysis, that the weight of an integrant particle of alumina was determined. Of course, the statement in the table must coincide with it entirely.

The sulphates of yttria, glucina, and zirconia, have not hitherto been analyzed. Their composition is stated merely from analogy.

Alum, according to the experiments of Berzelius, is composed of

| | |
|---|---|
| Sulphuric acid | 34.33 |
| Alumina | 10.86 |
| Potash | 9.81 |
| Water | 45.00 |
| | 100.00 |

Now, this will be found to consist of an integrant particle of sulphate of potash, combined with five integrant particles of sulphate of alumina.

Sulphate of potash and ammonia is a compound of 1 integrant particle of sulphate of potash, and 1 integrant particle of sulphate of ammonia. All the other triple salts are formed in the same way, by the combination of 1 integrant particle of 1 salt, with 1 or more integrant particles of another salt. Sulphate of potash and magnesia consists of 1 integrant particle of sulphate of potash, united with 2 integrant particles of sulphate of magnesia; sulphate of soda and ammonia is composed of 1 integrant particle of sulphate of soda, united with 6 integrant particles of sulphate of ammonia; sulphate of soda and magnesia of 1 integrant particle of sulphate of soda, and 3 integrant particles of sulphate of magnesia; and sulphate of magnesia and ammonia of 2 integrant particles of sulphate of magnesia, and 1 integrant particle of sulphate of ammonia.

As an atom of sulphuric acid weighs 5, and an atom of black oxide of copper 10, it is obvious that if sulphate of copper contains 2 particles of acid, and 1 of oxide, the weight of the two constituents must be equal. Now, according to Proust, the salt is composed of 33 acid + 32 base; according to Berzelius of 49.1 acid + 50.9 oxide. The mean of these two experiments gives us the salt composed of 100 acid + 100.317 base, which almost coincides with theory. According to Proust, the subsulphate of copper is composed of 18 acid + 68 oxide. Now 5 : 10 × 2 : : 18 : 72, this does not differ much from the analysis, if we consider the difficulty in getting the salt quite pure, and in a proper state for examination.

Sulphate of iron, according to the analysis of Ber-

zelius, is composed of 100 acid + 88 black oxide of iron. Now $5 \times 2 : 9.115 :: 100 : 91.15$ = very nearly to 88. The composition of subsulphate of iron is founded on the analysis of Berzelius. According to him, it is composed of 100 acid + 266 oxide. Now, these proportions agree only with the supposition of 2 particles of acid, and 3 of oxide. Therefore, if this analysis be correct, the axiom of Berzelius, that in inorganic compounds, one of the constituents enters always in the state of a single atom, does not apply to the salts. Indeed, we shall find other similar cases suggested by Berzelius himself, in which the same thing is to be observed. Nor need we be surprised that combinations of 2 particles with 3 should sometimes occur. It is fortunate for chemists that they occur so rarely, as only to constitute exceptions to a general rule. The subsulphate of iron may be represented in this manner $2\ (sO^3) + 3\ (1O^2)$. The first of the terms represents the sulphuric acid, two particles composed each of 1 atom sulphur, and 3 atoms oxygen. The second term represents the oxide of iron, 3 particles composed each of 1 atom iron, and 2 atoms oxygen. We request the reader's attention to this compound; because it has been brought forward by Berzelius as an objection to the atomic theory. For our parts, we do not perceive any inconsistency whatever between such compounds and the atomic theory; though, no doubt, it is inconsistent with one of the empirical laws which Berzelius wishes to establish. But it is always too soon to lay down general laws, when a subject is under discussion.

According to Berzelius, the persupersulphate of iron is composed of 100 acid + 65.5 peroxide of iron. Now, this analysis agrees very nearly with 3 integrant particles of acid, united to 1 integrant particle of peroxide. The persulphate is probably a compound of 2 particles of acid, and 1 particle of peroxide. Mr Dalton has objected this salt as inconsistent with Berzelius's law, that the oxygen in the acid is always a multiple of the oxygen in the oxide by a whole number. But the law holds, in this case, as it does with all the rest of the sulphates. Its composition is not equally compatible with Gay-Lussac's law, that the quantity of acid in a salt is always proportional to the quantity of oxygen in the base. For the black and red oxides of iron, it would seem, combine with the same weight of acid, though the red contains one-third more oxygen than the black.

Sulphate of lead, according to the analysis of Berzelius, is composed of 100 acid + 280 yellow oxide of lead. Dr Thomson having repeated the experiment, obtained very nearly the same result. The difference amounted only to 1000 part. Now $100 : 280 :: 5 \times 2 : 28$ = an integrant particle of yellow oxide of lead very nearly.

The composition of sulphate of zinc, as given in the table, is founded on the analysis of that salt by Dr Thomson. It appears, from his experiments (*Annals of Philosophy*, II. 411.), that 100 sulphuric acid combine with 102.859 oxide of zinc. Now $100 : 102.859 :: 5 : 5.143$. Now 5.143 is very nearly the weight of a particle of oxide of zinc.

According to Berzelius, sulphate of mercury is composed of 16 acid + 84 oxide. Now $5 : 26 :: 16 : 83.2$, which almost coincides with the analysis. We have no good analysis of *torpeth mineral*, or persulphate of mercury; but it is probable that the two oxides of mercury, like those of iron, combine with the same quantity of sulphuric acid. On that supposition, it will be a compound of

| | |
|---|---|
| Sulphuric acid, - - - | 15.625 |
| Peroxide of mercury, - | 84.375 |
| | 100.000 |

Now, Berzelius gives us 12 acid + 88 oxide, which does not differ very much from our theoretic numbers, if we consider the difficulty of the analysis, and the chance of some of the acid adhering to the oxide.

According to Berzelius, sulphate of silver is composed of 25.78 acid + 74.22 oxide. Now $5 : 14.714 :: 25.78 : 75,865$, which corresponds with the analysis very nearly.

Lagerhjelm found sulphate of bismuth composed of 33.647 acid + 66.653 oxide. Now, this corresponds almost exactly with the statement in the table.

According to Tapputi, sulphate of nickel is composed of 100 acid + 87.266. Now, this does not differ very much from the statement in the table, which supposes the salt composed of 100 acid + 93.05 oxide.

According to the analysis of Rolhoff, sulphate of cobalt is composed of 52.11 acid + 47.89 oxide. If the statement in the table be correct, it will be composed of 51.744 acid + 48.256 oxide. Now, this may be considered as agreeing with the analysis, since the difference is within the limits of the unavoidable errors of experiment.

According to John, sulphate of manganese is composed of 100 acid + 91.326 protoxide. Dr Thomson lately analyzed this salt, and obtained for its constituents 100 acid + 71 protoxide. Now $100 : 71 :: 10 : 7.1$; and 7.1 does not differ much from the weight of a particle of protoxide of manganese. The mean of the two experiments gives 8.113, which comes still nearer the true result.

Sulphate of uranium has hitherto been analyzed by Bucholz only. He makes it a compound of 22.1 acid + 77.9 peroxide. If the statement in the table be correct, as is probable, it ought to be a compound of 25 acid + 75 peroxide.

The persulphate of platinum, according to Berzelius, is composed of 41.223 acid + 58.777 peroxide. Supposing the tabular statement correct, it ought to be a compound of 41.389 acid + 58.611 peroxide. Now, this is identical with the experimental result of Berzelius.

Thus we have gone over the sulphates, the genus of salts, which has been most accurately examined, and have found the whole of them to correspond most accurately with the atomic theory. They all agree with Berzelius's law, that the oxygen in the acid is a multiple by a whole number of the oxygen in the base, except in the instance of subsulphate of iron. But perhaps his law was only meant to ap-

ply to the neutral salts, and not to the subsalts or supersalts. His law, that the oxygen in the acid amounts to three times the oxygen in the base, holds in all the neutral sulphates, except the persulphate of mercury, and sulphate of uranium; and neither of these salts can be considered as analyzed with such accuracy as to lay much stress upon their composition, as stated in the table. Let us now examine the carbonates, which are likewise pretty accurately known.

Genus II.—*Carbonates.*

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 237 | Bicarbonate of potash | 2 *c* + 1 *p* | 11.500 |
| 238 | Carbonate of potash - | 1 *c* + 1 *p* | 8.750 |
| 239 | Supercarbonate of soda | 3 *c* + 1 *s* | 16.125 |
| 240 | Carbonate of soda - | 2 *c* + 1 *s* | 13.375 |
| 241 | Bicarbonate of ammonia | 2 *c* + 1 *a* | 7.625 |
| 242 | Carbonate of ammonia | 1 *c* + 1 *a* | 4.875 |
| 243 | Carbonate of lime - | 1 *c* + 1 *l* | 6.375 |
| 244 | Carbonate of barytes | 1 *c* + 1 *b* | 12.500 |
| 245 | Carbonate of strontian | 1 *c* + 1 *str* | 9.250 |
| 246 | Bicarbonate of magnesia | 2 *c* + 1 *m* | 8.000 |
| 247 | Carbonate of magnesia | 1 *c* + 1 *m* | 5.250 |
| 248 | Carbonate of yttria - | 1 *c* + 1 *y* | 11.151 |
| 249 | Carbonate of zirconia | 1 *c* + 1 *z* | 8.375 |
| 250 | Carbonate of glucina - | 1 *c* + 1 *g* | 12.584 |
| 251 | Carbonate of silver - | 1 *c* + 1 *s* | 17.500 |
| 252 | Percarbonate of mercury | 1 *c* + 2 *m* | 56.750 |
| 253 | Percarbonate of copper | 1 *c* + 1 *cop* | 12.750 |
| 254 | Carbonate of iron - | 2 *c* + 1 *i* | 14.615 |
| 255 | Carbonate of nickel - | 2 *c* + 1 *n* | 14.805 |
| 256 | Carbonate of cobalt - | 2 *c* + 1 *cob* | 14.826 |
| 257 | Carbonate of lead - | 2 *c* + 1 *l* | 33.500 |
| 258 | Carbonate of zinc - | 1 *c* + 1 *z* | 7.845 |
| 259 | Carbonate of manganese | 2 *c* + 1 *m* | 13.335 |
| 260 | Carbonate of cerium - | 2 *c* + 1 *ce* | 19.349 |
| 261 | Percarbonate of cerium | 3 *c* + 1 *ce* | 23.100 |

The bicarbonate of potash is the common crystallized carbonate of the shops. If it be a compound of 2 integrant particles of carbonic acid, and 1 integrant particle of potash, it ought to consist of 47.835 acid + 52.165 base. Now, Berthollet obtained 47.64 acid + 52.36 base, a result which may be considered as quite identical with the theory, the difference being greatly within the limits of error from experiment. Dr Wollaston has shown, that the deliquescent carbonate contains just half the carbonic acid which exists in the bicarbonate.

The supercarbonate of soda is found native in Africa, and may be formed artificially, by passing a current of carbonic acid gas through common carbonate of soda dissolved in water. According to the analysis of Klaproth, it is composed of 39 acid + 38 base. Now, the tabular statement supposes it a compound of 39 acid + 37.247 base. We have different analyses of the carbonate of soda; but they do not agree well with each other. Bergman obtained 16 acid + 20 base; Darcet 16.04 acid + 20.85 base; and Klaproth 16 acid + 22 base. The last is the most correct. According to the tabular statement, which must be correct, the salt ought to be a compound of 16 acid + 22.921 base.

The analysis of the ammoniacal salts is attended with such difficulties, that great exactness can hardly be expected, except in those cases when the acid has a gaseous form. It is then easy to determine the volume of ammoniacal gas capable of saturating a given volume of the acid gas. Carbonic acid being a gas, the composition ammoniacal carbonates may be determined with accuracy. Now, 100 measures of carbonic acid condense and neutralize 100 measures of ammoniacal gas. This will be found, on making the calculation, to be 2 integrant particles of carbonic acid, and 1 integrant particle of ammonia, constituting the first of the ammoniacal salts in the table. Fifty measures of carbonic acid are likewise capable of combining with 100 measures of ammoniacal gas, constituting the second ammoniacal salt in the table. It has not been proved that any other carbonate of ammonia exists.

Supposing carbonate of lime a compound of 1 integrant particle of carbonic acid, and 1 integrant particle of lime, it should be a compound of 43.18 acid + 56.82 lime. Now, Dr Marcet obtained 43.9 acid + 56.1 base; and Dr Thomson, by a careful analysis of very pure calcareous spar, obtained 43.2 acid + 56.8 base. This last result is almost the very same with the theoretical result.

Carbonate of barytes, by the statement in the table, is a compound of 22.04 acid + 77.96 barytes. Now, Kirwan obtained 22 acid + 78 base; and Berzelius 21.6 acid + 78.4 base. Both of these results agree sufficiently with our theoretical result; the first, indeed, coincides with it.

The analyses of carbonate of strontian hitherto made cannot be expected to agree completely with our theoretical statement, because they have been all made upon the native carbonate of that earth, which always contains a certain proportion of carbonate of lime. According to an accurate analysis by the writer of this article, it is composed of 29.9 acid + 70.1 base. Klaproth's analysis gives us 30 acid + 69.5 base. The excess of acid is obviously owing to the presence of carbonate of lime in the native salt.

We have never seen any specimen of carbonate of magnesia composed of 1 integrant particle of acid, and one integrant particle of base, in commerce. But it occurs native in abundance, constituting an ingredient in the magnesian limestone, which is so abundant in the counties of Durham, York, and Derby, and which seems to constitute a peculiar formation. The bicarbonate may be formed by passing a current of carbonic acid through water in which magnesia is suspended. The salt is soluble in water, and crystallizes. It is composed of 69.911 acid + 30.089 base. Kirwan and Fourcroy found 66.6 acid + 33.3 base. Probably their salt was mixed with a little carbonate.

Carbonate of yttria was analyzed by Klaproth; and the tabular statement exactly coincides with

his result. We have no analysis of carbonates of zirconia, and glucina.

Berzelius found carbonate of silver a compound of 15.9 acid + 84.1 base. According to the statement in the table, it ought to be composed of 15.9 acid + 81.407 base, numbers which do not deviate far from those given by Berzelius.

We have no good analysis of the percarbonate of mercury. The statement in the table is given on the authority of Bergman; but is not very likely to be correct.

Percarbonate of copper, according to the analysis of Berzelius, is composed of 19.73 acid + 71.7 peroxide. Dr Thomson analyzed it, with precisely the same result. This analysis coincides exactly with the statement in the table.

Klaproth analyzed the carbonate of iron, and found it a compound of 38.3 acid + 61.6 base. This analysis corresponds sufficiently with the statement in the table.

Nickel and cobalt have so striking an analogy with iron in most particulars, that there is every reason for believing that the salts of the three metals are similarly constituted. Hence, as the carbonate of iron consists of 2 integrant particles of carbonic acid, and 1 integrant particle of black oxide of iron, we have supposed, in the table, that this is the case likewise with the carbonates of nickel and cobalt. The carbonate of nickel has been analyzed by Proust, and his result does not differ much from the tabular statement; but we have no analysis of the carbonate of cobalt.

Berzelius analyzed carbonate of lead, and found it a compound of 16.444 acid + 83.333. The analysis of other chemists corresponds nearly with this result. Now, our statement in the table supposes the salt a compound of 16.446 acid + 83.554 base, which may be considered as absolutely the same with the numbers given by Berzelius.

According to Mr Smithson, the carbonate of zinc is composed of 1 acid + 2 oxide. Now, the statement in the table supposes it a compound of 1 acid + 1.852 base; a coincidence as near as can be expected, when we consider the small quantity of salt upon which Mr Smithson makes his experiments.

If the carbonate of manganese be composed as stated in the table, it will be a compound of 34.16 acid + 50.476 base. John's analysis gives us 34.16 acid + 55.84 base; a result which does not correspond well. Hence there is reason to suspect inaccuracy.

The carbonates of cerium have been analyzed by Hisinger, and the results which he obtained agree tolerably well with the tabular statement.

Thus the carbonates correspond likewise with the Atomic Theory. They all agree with Berzelius's law, that the oxygen in the acid is a multiple by a whole number of the oxygen in the base. Most of them agree with his law, that the oxygen in the acid is double that in the base. But the carbonate of copper constitutes an exception to this rule. Indeed, we must expect to find some exceptions to these laws of Berzelius in almost every genus of salts. But it is surprising in how many unexpected

4

cases they hold. Let us now examine the nitrates.

GENUS III.—*Nitrates.*

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 262 | Nitrate of potash | 1 *n* + 1 *p* | 12.750 |
| 263 | Nitrate of soda | 2 *n* + 1 *s* | 21.375 |
| 264 | Nitrate of ammonia | 1 *n* + 1 *a* | 8.875 |
| 265 | Nitrate of magnesia | 1 *n* + 1 *m* | 9.250 |
| 266 | Nitrate of lime | 1 *n* + 1 *l* | 10.375 |
| 267 | Nitrate of barytes | 1 *n* + 1 *b* | 16.500 |
| 268 | Nitrate of strontian | 1 *n* + 1 *str* | 13.250 |
| 269 | Nitrate of ammonia and magnesia | 4 *n* + 3 *m* + 1 *a* | 36.625 |
| 270 | Nitrate of copper | 2 *n* + 1 *c* | 23.500 |
| 271 | Subnitrate of copper | 1 *n* + 2 *c* | 26.750 |
| 272 | Nitrate of iron | 2 *n* + 1 *i* | 22.625 |
| 273 | Pernitrate of iron | 3 *n* + 1 *i* | 29.375 |
| 274 | Nitrate of zinc | 1 *n* + 1 *z* | 10.840 |
| 275 | Nitrate of lead | 2 *n* + 1 *l* | 41.500 |
| 276 | 1st subnitrate of lead | 1 *n* + 1 *l* | 34.750 |
| 277 | 2d subnitrate of lead | 2 *n* + 3 *l* | 97.500 |
| 278 | 3d subnitrate of lead | 1 *n* + 3 *l* | 90.750 |
| 279 | Nitrate of nickel | 3 *n* + 1 *nick* | 29.555 |
| 280 | Subnitrate of nickel | 1 *n* + 7 *nick* | 71.885 |
| 281 | Nitrate of silver | 1 *n* + 1 *s* | 21.500 |
| 282 | Nitrate of mercury | 1 *n* + 1 *m* | 32.750 |
| 283 | Pernitrate of mercury | 1 *n* + 2 *m* | 60.750 |
| 284 | Subnitrate of platinum | 1 *n* + 4 *pl* | 53.250 |
| 285 | Nitrate of bismuth | 1 *n* + 1 *b* | 16.750 |
| 286 | Nitrate of uranium | 1 *n* + 1 *u* | 21.750 |

The analysis of the nitrates is attended with considerable difficulty, because we have no substance which forms an insoluble compound with nitric acid. We cannot, therefore, separate the acid by precipitation, as we do in the case of the sulphates, neither does it fly off when another acid is applied, as happens in the carbonates, so as to enable us to determine, by the loss of weight, how much acid the salt contains. Nevertheless, as a considerable number of the nitrates are destitute of water of crystallization, and composed only of the acid and base united together, we have the means of ascertaining the composition of such salts very accurately, by determining the proportion of base which they contain.

According to the analysis of Dr Thomson, nitre is composed of 100 acid + 83.823 base. According to Dr Wollaston, it is composed of 100 acid + 86.764 base. The statement in the table supposes it a compound of 100 acid + 88.8 potash. The difference between this result and experiment may be owing to our having made an atom of nitric acid a very little too great.

According to Dr Thomson, nitrate of soda is composed of 100 acid + 57.8 soda. According to Wenzel, it is composed of 100 acid + 60 base. Our tabular statement supposes 100 acid + 57.92, which almost coincides with the result of Dr Thomson.

Berzelius found nitrate of ammonia composed of 100 acid + 31.266 ammonia. Our tabular state-

ment supposes the salt to be composed of 100 acid + 30.853 ammonia, which very nearly coincides with the experiment of Berzelius.

According to Wenzel, nitrate of magnesia is composed of 100 acid + 38.88 base. According to Dr Thomson, of 100 acid + 34.729 base. Our tabular statement supposes it a compound of 100 acid + 37.881 base, which comes very near the experiment of Wenzel.

According to Kirwan, nitrate of lime is composed of 100 acid + 55.70 lime. According to Dr Thomson, of 100 acid + 53.091 lime. The tabular statement supposes it composed of 100 acid + 53.2 lime; a number which comes sufficiently near experiment.

According to Berzelius, nitrate of barytes is composed of 100 acid + 140.73 barytes. The tabular statement supposes 100 acid + 143.02 base, which does not differ more than 1 *per cent.* from experiment.

Vauquelin informs us that nitrate of strontian is composed of 100 acid + 98.341 base. Now, our statement supposes it a compound of 100 acid + 101.42 base, which is within less than 1 *per cent.* of the experimental result.

We suppose nitrate of ammonia and magnesia to be a compound of 3 integrant particles of nitrate of magnesia, and 1 integrant particle of nitrate of ammonia; because that comes nearest the analysis of Fourcroy. But indeed his analyses are very seldom to be depended on.

The nitrate of copper has not been analyzed. Its composition is inferred from the sulphate of copper, which has been examined with accuracy. Berzelius found the subnitrate composed of 100 acid + 349.2 base. Proust obtained from the same salt 100 acid + 418.7 base. The mean of these two experiments gives 100 acid + 383.95 base. Now, the constitution of the salt which we have supposed in the table requires its composition to be 100 acid + 386.67 base, which comes within half a *per cent.* of the preceding mean, and cannot, therefore, be far from the truth.

The nitrates of iron are given from theory and from analogy, as it would be scarcely possible, in the present state of the science of chemistry, to analyze them with accuracy.

Neither has the nitrate of zinc been analyzed; yet we do not think there can be any hesitation in admitting the statement given in the table to be correct.

According to Berzelius, octahedral nitrate of lead is composed of 100 acid + 205.1 oxide. This analysis, which we consider as exact, corresponds well with our statement in the table. The three subnitrates are described and analyzed by Berzelius (*Annals of Philosophy*, II. 278). The first contains 2 *ce* as much oxide as the octahedral nitrate, the second thrice as much, and the third six times as much. The second of these salts exhibits one of Berzelius's exceptions to the Atomic Theory. Its symbol would be, $1\ (a\ o^5) + 1\frac{1}{2}\ (l\ o^2)$, or 1 integrant particle of nitric acid united with $1\frac{1}{2}$ integrant particles of oxide of lead. This appears an absurdity at first sight, because half an integrant particle can have no existence. But when stated, as we have done in the table, the absurdity vanishes: the symbol then becomes $2\ (a\ o\ 5) + 3\ (l\ o\ 2)$, or two integrant particles of nitric acid, united to three integrant particles of oxide of lead. There is nothing in such an union incompatible with the Atomic Theory; though it is inconsistent with one of Berzelius's general laws, that, in all unorganic compounds, one of the elements enters always in the state of a single atom. In this compound there is no single atom. It consists of 11 atoms of oxygen, + 3 atoms of lead, + 2 atoms of azote.

Nitrate of nickel, according to Proust, is composed of 100 acid + 45.45 base. If so, its composition must be as represented in the table. Proust found the subnitrate composed of 100 acid + 735.3 oxide. This leads to the constitution of the salt in the table; if any confidence can be put in the accuracy of the analysis.

The analysis of Berzelius makes nitrate of silver a compound of 100 acid + 216.45 base. Proust gives us 100 acid + 233.33 base. The statement in the table supposes 100 acid + 216.286, which almost coincides with the result obtained by Berzelius.

Nitrate of mercury has not been analyzed. But Messrs Braamchamp and Siguiera Oliva found the pernitrate composed of 100 acid + 733.33 base. This constitutes a very near approximation to the tabular statement, especially when we consider the difficulty of the analysis.

Chenevix found the subnitrate of platinum composed of 100 acid + 809.09. This comes within $1\frac{1}{2}$ *per cent.* of our statement in the table; a sufficiently near coincidence, if the difficulty of analysis be attended to.

According to Berzelius, nitrate of bismuth is composed of 100 acid + 142.69 base. Our statement supposes it composed of 100 acid + 145.42; a sufficiently near coincidence for our purpose.

Nitrate of uranium, according to Bucholz, is composed of 100 acid + 232 base. This approaches pretty nearly to the statement in the table, which supposes the salt to be composed of 100 acid + 220.4 base.

Thus, we have gone over the composition of the nitrates, without finding any thing inconsistent with the Atomic Theory. On the contrary, they agree with that theory so exactly, wherever accurate methods of analysis can be had recourse to, that we may apply the theory, without hesitation, to determine the composition of those nitrates which cannot, in the present state of the science, be analyzed correctly. But, when we apply Berzelius's law, that the oxygen in the acid is a multiple of the oxygen in the base, by a whole number to the nitrates, we find that it fails in several cases, though it holds in the greatest number. As nitric acid contains 5 atoms of oxygen, it is obvious that it cannot combine with a single particle of a deutoxide, without transgressing the rule. But Berzelius has fallen upon a way of reconciling the nitrates to his law. According to him, azote is a compound of 1 atom of oxygen, and 1 atom of *nitricum*, so that nitric acid, according to him, is a compound of 6 atoms oxygen, and 1 atom nitricum. This opinion is certainly plausible, though it cannot

be adopted till something better than mere theory is brought forward in support of it. Let us now examine the phosphates, a genus of salts still much more imperfectly analyzed than any of the three preceding genera.

Genus IV.—*Phosphates.*

| | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|
| 287 Phosphate of potash | 1 *ph* + 1 *p* | 9.625 |
| 288 Biphosphate of potash | 2 *ph* + 1 *p* | 13.250 |
| 289 Subphosphate of potash | 1 *ph* + 2 *p* | 15.625 |
| 290 Phosphate of soda | 2 *ph* + 1 *s* | 15.125 |
| 291 Biphosphate of soda | 4 *ph* + 1 *s* | 22.375 |
| 292 Phosphate of ammonia | 5 *ph* + 4 *a* | 26.625 |
| 293 Biphosphate of ammonia | 5 *ph* + 2 *a* | 22.875 |
| 294 Quadrosteophosphate of lime | 5 *ph* + 1 *l* | 21.750 |
| 295 Binosteophosphate of lime | 5 *ph* + 2 *l* | 25.375 |
| 296 Bigephosphate of lime | 5 *ph* + 3 *l* | 29.000 |
| 297 Osteophosphate of lime * | 5 *ph* + 4 *l* | 32.625 |
| 298 Phosphate of lime | 5 *ph* + 5 *l* | 36.350 |
| 299 Gephosphate of lime † | 5 *ph* + 6 *l* | 39.975 |
| 300 Phosphate of barytes | 1 *ph* + 1 *b* | 13.375 |
| 301 Phosphate of strontian | 1 *ph* + 1 *str* | 10.125 |
| 302 Phosphate of magnesia | 1 *ph* + 2 *m* | 8.625 |
| 303 Protophosphate of copper | 1 *ph* + 1 *c* | 12.625 |
| 304 Perphosphate of copper | 1 *ph* + 2 *c* | 23.625 |
| 305 Protophosphate of iron | 2 *ph* + 1 *i* | 16.393 |
| 306 Perphosphate of iron | 2 *ph* + 1 *i* | 17.393 |
| 307 Phosphate of lead | 2 *ph* + 1 *l* | 35.250 |
| 308 Phosphate of zinc | 1 *ph* + 1 *z* | 8.720 |
| 309 Biphosphate of zinc | 2 *ph* + 1 *z* | 12.345 |
| 310 Phosphate of nickel | 2 *ph* + 1 *n* | 16.553 |

Phosphate of potash, supposing it composed of 1 integrant particle of acid, and 1 integrant particle of base, ought to consist of 100 acid + 166.762 potash. Now, according to the analysis of Saussure jun. it is composed of 100 acid + 185.714 base. According to Berthollet, it is composed of 100 acid + 199.242 base. The author of this article lately subjected all the three phosphates of potash to a careful analysis. The results agree exactly with the tabular number.

We are not acquainted with any analysis of phosphate of soda, except one made lately by Dr Thomson. He found it composed of 100 acid + 109.59 soda. Now, according to the statement in the table, it is composed of 100 acid + 109.533. In this salt, the difference between the theoretical and experimental result may be considered as nothing.

The phosphates of ammonia and of magnesia are given from analyses of these salts made by the author of this article, but not yet published.

Phosphate of magnesia and ammonia, according to the analysis of Fourcroy, is composed of equal parts of phosphate of magnesia and phosphate of ammonia. But this result not agreeing with the constituents of these salts, as determined by experiment, this triple salt has been left out of the table.

There can be no doubt that phosphate of lime is composed of an integrant particle of phosphoric acid, united with an integrant particle of lime. This is the case with the sulphate, carbonate, and nitrate of lime, and unless the phosphate of lime were so formed, Richter's law could not hold good. According to this constitution, the salt must consist of 100 acid + 100 base. We have a considerable number of analyses of phosphate of lime; but all deviating so much from each other, that little confidence can be put in any of them. According to Klaproth, it is composed of 100 acid + 254.281 lime. But the salt which he formed by saturating phosphoric acid with marble, certainly was not the common phosphate of lime, but a subsalt, which has not yet been accurately examined. According to Ekeberg (when his calculations are rectified), phosphate of lime is composed of 100 acid + 82.186 base. This approaches much nearer the true composition, though it is not correct. The salt which Ekeberg found exists, and constitutes earth of bones. It is the osteophosphate of the table. According to Fourcroy and Vauquelin, phosphate of lime is composed of 100 acid + 143.9 lime. Here there is still a greater error on the opposite side than that fallen into by Ekeberg. But their analysis approaches to that of apatite, the gephosphate of the table. The other phosphates of lime in the table were discovered by the author of this article, and are detailed by him in a paper on phosphoric acid, read to the Royal Society, but not yet published.

Phosphate of barytes, according to the experiments of Berzelius, is composed of 100 acid + 259.715 barytes. Our statement in the table, founded on evidence, which seems quite satisfactory, supposes it a compound of 100 acid + 270.477 base. The difference here between experiment and theory does not exceed 3 *per cent.*

If phosphate of strontian be composed of 1 integrant particle of phosphoric acid, and 1 integrant particle of strontian, as there can be no doubt is the case, then its composition must be 100 acid + 191.773 base. We have an analysis of this salt by Vauquelin, according to whom it is composed of 100 acid + 142.48 base. But the data upon which he founded his conclusions, were necessarily so inaccurate, in consequence of the erroneous notions which he entertained respecting the composition of phosphate of lime, that a nearer approach to accuracy could not, in his case, be expected. The numbers in the table are the result of experiments by the author of this article.

It seems to be a law in saline combinations, that a deutoxide always combines with two integrant particles of acid. Thus, black oxide of copper unites with two integrant particles of sulphuric acid, and likewise with two integrant particles of nitric acid.

* So called, because it is a constituent of bones.

† This is the apatite of mineralogists.

Hence we may conclude, that it will combine likewise with two integrant particles of phosphoric acid. According to this statement, it must be composed of 100 acid + 138.854 black oxide of copper. Now, according to the analysis of Chenevix, it is composed of 100 acid + 141.428 black oxide of copper. This agrees with the tabular statement very nearly.

We have the same reason for considering phosphate of iron as a compound of two integrant particles of acid, and one of deutoxide of iron. According to this statement, it ought to be composed of 100 acid + 126.667 black oxide of iron. We have no analysis of this sort. Lougier, indeed, has analyzed a substance which occurs in small prisms in Brazil, and in the Isle of France. He found it composed of 100 acid + 214.285 black oxide. This approaches to a compound of 1 integrant particle of acid, and 1 integrant particle of oxide. Dr Thomson found two phosphates composed as in the table.

The perphosphate of iron is a white insoluble powder, obtained by precipitating persulphate of iron by phosphate of ammonia. It has not been analyzed. Nor do we know whether the theoretical result, as stated in the table, can be admitted to much confidence. This salt is converted into a subsalt, by the action of an alkali.

Phosphate of lead has been analyzed with great care by three different chemists. According to Berzelius, it is composed of 100 acid + 380.565 base; according to Dr Wollaston, of 100 acid + 370.72 base; and according to Dr Thomson, of 100 acid + 398.49 base. The mean of these experiments gives us 100 acid + 38, nearly 3.258 base. This agrees with the composition of the salt, as stated in the table. It was from it, in part, that we deduced the weight and composition of phosphoric acid.

The phosphates of zinc, and phosphate of nickel, have been analyzed by Dr Thomson. The composition of these salts in the table is stated from this analysis.

There is no analysis of the phosphate of mercury. We do not even know if it exists. But the perphosphate of mercury has been analyzed by Messrs Braamcamp and Siguiera. According to them, it is composed of 100 acid + 250.887 peroxide of mercury. Now, if it be a compound of 3 integrant particles of acid and 1 integrant particle of base, its constituents ought to be 100 acid + 250.159 base. This may be considered as identical with the experiment, since the difference is far within the limits of unavoidable error, from the imperfection of our methods.

Thus it appears, not only that no exception to the atomic theory exists among the salts; but that it puts it in our power to determine the composition of all the genera of salts, provided we know the analysis of one species, with more accuracy than would result from ordinary experiment. We have not the least doubt, that, when an accurate analysis of the phosphates is published, it will be found in almost every instance to agree with our table. We shall give another example of a genus of salts, the constituents of which we have determined almost entirely from theory,—we mean the borates; for very few of them have been hitherto subjected to analysis.

GENUS V.—*Borates.*

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 311 | Borate of potash | 1 *b* + 1 *p* | 8.733 |
| 312 | Sub-borate of potash | 1 *b* + 2 *p* | 14.733 |
| 313 | Borate of soda | 2 *b* + 1 *s* | 13.341 |
| 314 | Sub-borate of soda | 1 *b* + 2 *s* | 18.483 |
| 315 | Borate of ammonia | 1 *b* + 1 *a* | 4.858 |
| 316 | Sub-borate of ammonia | 1 *b* + 2 *a* | 6.983 |
| 317 | Borate of magnesia | 1 *b* + 1 *m* | 5.233 |
| 318 | Borate of lime | 1 *b* + 1 *l* | 6.358 |
| 319 | Borate of barytes | 1 *b* + 1 *bar* | 12.483 |
| 320 | Borate of strontian | 1 *b* + 1 *str* | 9.233 |
| 321 | Borate of alumina | 1 *b* + 1 *a* | 4.858 |
| 322 | Borate of yttria | 1 *b* + 1 *y* | 11.133 |
| 323 | Borate of glucina | 1 *b* + 1 *g* | 12.566 |
| 324 | Borate of zirconia | 1 *b* + 1 *z* | 8.358 |
| 325 | Borate of copper | 2 *b* + 1 *c* | 15.466 |
| 326 | Borate of iron | 2 *b* + 1 *i* | 14.581 |
| 327 | Borate of nickel | 2 *b* + 1 *n* | 14.771 |
| 328 | Borate of cobalt | 2 *b* + 1 *c* | 14.792 |
| 329 | Borate of lead | 2 *b* + 1 *l* | 33.466 |
| 330 | Borate of zinc | 1 *b* + 1 *z* | 7.828 |
| 331 | Borate of mercury | 1 *b* + 1 *m* | 28.733 |
| 332 | Borate of silver | 1 *b* + 1 *s* | 17.483 |
| 333 | Borate of bismuth | 1 *b* + 1 *b* | 12.733 |
| 334 | Borate of manganese | 2 *b* + 1 *m* | 10.566 |
| 335 | Borate of uranium | 1 *b* + 1 *u* | 15.733 |
| 336 | Borate of platinum | 1 *b* + 1 *p* | 15.894 |

We shall take one other genus of salts, as a farther elucidation of the atomic theory; and we shall select one of the vegetable acids, which have been analyzed by Berzelius, that we may be able to judge how far the weight of an integrant particle of the acid derived from his analysis, will agree with the constitution of the salts.

GENUS VI.—*Oxalates.*

| | | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|---|
| 337 | Oxalate of potash | 1 *ox* + 1 *p* | 10.634 |
| 338 | Binoxalate of potash | 2 *ox* + 1 *p* | 15.268 |
| 339 | Quadroxalate of potash | 4 *ox* + 1 *p* | 24.536 |
| 340 | Oxalate of soda | 2 *ox* + 1 *s* | 17.150 |
| 341 | Oxalate of ammonia | 1 *ox* + 1 *a* | 6.783 |
| 342 | Oxalate of magnesia | 1 *ox* + 1 *m* | 7.211 |
| 343 | Oxalate of lime | 1 *ox* + 1 *l* | 8.254 |
| 344 | Binoxolate of lime | 2 *ox* + 1 *l* | 12.888 |
| 345 | Oxalate of barytes | 1 *ox* + 1 *b* | 14.365 |
| 346 | Oxalate of strontian | 1 *ox* + 1 *st* | 11.534 |
| 347 | Oxalate of alumina | 1 *ox* + 1 *a* | 6.770 |
| 348 | Oxalate of yttria | 1 *ox* + 1 *y* | 13.034 |
| 349 | Oxalate of glucina | 1 *ox* + 1 *gl* | 14.467 |
| 350 | Oxalate of zirconia | 1 *ox* + 1 *z* | 10.290 |
| 351 | Oxalate of copper | 2 *ox* + 1 *c* | 19.268 |

| | Number of Atoms. | Weight of an Integrant Particle. |
|---|---|---|
| 352 Oxalate of potash and copper | 2 ox + 1 p + 1 c | 29.902 |
| 353 Oxalate of soda and copper | 3 ox + 1 s + 1 c | 32.410 |
| 354 Oxalate of ammonia and copper | 2 ox + 1 a + 1 c | 26.051 |
| 355 Oxalate of iron | 2 ox + 1 i | 18.383 |
| 356 Peroxalate of iron | 3 ox + 1 i | 23.017 |
| 357 Oxalate of nickel | 2 ox + 1 n | 18.573 |
| 358 Oxalate of cobalt | 2 ox + 1 c | 18.594 |
| 359 Oxalate of lead | 2 ox + 1 l | 37.242 |
| 360 Oxalate of zinc | 1 ox + 1 z | 9.661 |
| 361 Oxalate of mercury | 1 ox + 1 m | 30.634 |
| 362 Oxalate of silver | 1 ox + 1 s | 19.348 |
| 363 Oxalate of bismuth | 1 ox + 1 b | 14.628 |
| 364 Oxalate of manganese | 2 ox + 1 m | 17.401 |
| 365 Oxalate of uranium | 1 ox + 1 u | 19.634 |
| 366 Oxalate of cerium | 2 ox + 1 c | 23.115 |
| 367 Oxalate of platinum | 1 ox + 1 p | 17.795 |

According to the analysis of Berzelius, exhibited in a preceding part of this article, oxalic acid is a compound of 21 atoms, namely, 12 atoms of oxygen, 8 atoms of carbon, and 1 atom of hydrogen. But there can be little hesitation in doubling the quantity of hydrogen found in this acid by Berzelius; because this will greatly increase the simplicity of the composition of the acid, and the difference is considerably within the unavoidable errors in such experiments. In that case, the acid would be constituted of 11 atoms; namely, 6 of oxygen, 4 of carbon, and 1 of hydrogen; and its weight would be 9.070. But the weight of an atom of oxalic acid, even when thus corrected, will not agree with the known constitution of the oxalates. Berzelius analyzed oxalate of lead with great care, and found it composed of 100 acid + 307.5 oxide of lead. Now, it appears from all the genera of salts which we have examined, that the yellow oxide of lead unites always with 2 integrant particles of acid. The weight of an integrant particle of yellow oxide of lead is 28.

Now, $307.5 : \frac{100}{2} :: 57 : 4.528 =$ the weight of an integrant particle of oxalic acid. Now, this is very nearly one half of the weight resulting from analysis. To obtain this weight, it would be necessary to quadruple the quantity of hydrogen found in oxalic acid by Berzelius, and to consider it as composed of 3 atoms oxygen, 2 atoms carbon, and 1 atom hydrogen. Now, it deserves to be noticed, that this is the constitution of oxalic acid adopted by Mr Dalton (*Annals of Philosophy*, III. 179.), obtained, we presume, from an examination of the composition of the oxalates, and from the analysis of oxalic acid, previously made by Dr Thomson and by Gay-Lussac and Thenard. Whatever confidence the analytical experiments of Berzelius may be entitled to, we have no alternative in the present case but to adopt the conclusion suggested by the oxalates. The analysis of these bodies is much easier, and therefore more likely to prove correct, than that of oxalic acid itself. We may adopt 4.625 as the weight of an atom of oxalic acid; and consider it as a compound of 6 atoms, 3 of oxygen, 2 of carbon, and 1 of hydrogen. Its composition would then be

| | |
|---|---|
| Oxygen - - - | 64.739 |
| Carbon - - - | 32.413 |
| Hydrogen - - - | 2.848 |
| | 100.000 |

We do not pretend to reconcile this result with that obtained by Berzelius; but the constitution of the oxalates obliges us to adopt it as nearest the truth.

We have three analyses of the oxalate of potash, one by Dr Thomson (*Phil. Trans.* 1807), one by Vogel (*Schweigger's Journal*, II. 470), and one by M. Berard (*Annals de Chimie*, 73. 270). The statement in the table supposes the salt a compound of 100 acid + 129.477 potash. Now, Dr Thomson's analysis gives us 100 acid + 122.86 base, Vogel's 100 acid + 132.558 base, and Berard's 100 acid + 102.757 base. The first two analyses, especially the second, are very near the truth. Berard's is a good deal more incorrect. Dr Wollaston has shown, that binoxalate of potash contains exactly twice as much acid, and quadroxalate of potash four times as much acid as neutral oxalate of potash.

If oxalate of soda be composed of two integrant particles of acid, and 1 of soda, it must be composed of 100 acid + 85.045 soda. Now, the analysis of Vogel gives us 100 acid + 82.563 base, which agrees very nearly with theory. The analysis of Thomson and Berard are both considerably more incorrect.

Supposing oxalate of ammonia to be constituted as represented in the table, it must be a compound of 100 acid + 46.374 ammonia. Now, the analysis of Berzelius gives us 100 acid + 45.264 base, and that of Berard 100 acid + 44.369 base. Both of these agree well with the tabular statement.

Superoxalates of soda and of ammonia exist, but we did not give them a place in the table, as they have been but superficially examined. The first is probably a compound of 3 integrant particles of acid, and 1 integrant particle of soda; the second no doubt contains 2 integrant particles of acid and 1 of ammonia. Oxalate of magnesia, supposing it constituted as in the table, is a compound of 100 acid + 55.610 magnesia. Now, Bergman's analysis gives us 100 acid + 53.846 base. This agrees sufficiently with the theory. The analysis of Thomson and Berard are both very faulty. It is not difficult to see how they were misled.

Oxalate of lime has been analyzed with great care by different chemists, Bergman, Thomson, Berard, Vogel, Gay-Lussac, and Thenard, &c. But the results differ considerably from each other. The reason is, that various oxalates of lime exist, and that experimenters are always sure to get a mixture of them, when they form oxalate of lime by precipitation. The neutral salt must be composed of 100 acid + 78.117 lime. Now, Vogel's analysis gives us 100 acid + 76 lime, which is sufficiently near to show us, that he calculated the composition of the neutral salt. Dr Thomson gives 100 acid + 60 lime,

this must have been a mixture of neutral oxalate and binoxalate of lime. Berard found 100 acid + 61.2 lime, and Thenard, and Gay-Lussac, nearly the same proportions. All these must have been mixtures.

The analyses of the oxalate of barytes hitherto made, do not correspond with its composition as represented in the table; owing, probably, to the same causes that have occasioned inaccuracy in the analysis of oxalate of lime. This salt ought to be composed of 100 acid + 209.991 barytes. Dr Thomson's analysis gives us 100 acid + 142.86 base, and Berard's 100 acid + 164.3 base. Both of these are very far from accurate.

Oxalate of strontian, according to the statement in the table, ought to be composed of 100 acid + 148.894 strontian. Now, according to Dr Thomson's analysis, it is composed of 100 acid + 151.51 base. This agrees sufficiently. Berard's analysis is much less accurate. He obtained 100 acid + 119.5 base. The oxalates of alumina, yttria, glucina, and zirconia, have not been analyzed. But there can be no hesitation in considering their composition as stated in the table to be correct.

Oxalate of copper, according to the constitution of it given in the table, is composed of 100 acid + 107.898 black oxide of copper. Now, Vogel found it composed of 100 oxide + 100 acid, including a little water. This agrees sufficiently with the theoretic statement. The three triple oxalates are composed respectively as follows:

1. One integrant particle oxalate of potash, + 1 integrant particle oxalate of copper.
2. 1 oxalate of soda + 1 oxalate of copper.
3. 1 oxalate of ammonia + 1 oxalate of copper.

This agrees with Vogel's analysis. He found oxalate of potash and copper composed of

| | |
|---|---|
| Acid - | 45 |
| Potash - | 30 |
| Oxide of copper | 25 |
| | 100 |

Oxalate of soda and copper of

| | |
|---|---|
| Acid - | 46.48 |
| Soda - | 19.02 |
| Oxide of copper | 23.50 |
| Water - - | 11.00 |
| | 100.00 |

And oxalate of ammonia and copper of

| | |
|---|---|
| Acid - | 47.5 |
| Ammonia - | 10.5 |
| Oxide of copper | 25.0 |
| Water - | 17.0 |
| | 100.0 |

The remaining oxalates, if we except the oxalate of lead, have not yet been subjected to an accurate analysis. The composition, as stated in the table, is deduced from a comparison with the other genera of salts, and there can be no doubt that, in general, it is correct.

It would be easy for us to exhibit the composition of the remaining genera of salts; but we have already extended this article to as great a length as is consistent with our limits. The remaining genera, indeed, have been so imperfectly examined, that they would throw no additional light on the atomic theory; though that theory would enable us to calculate their compositions in most cases with sufficient precision. We have omitted, likewise, the *chlorides* and *iodes*, two numerous classes of bodies analogous to the oxides to which the atomic theory applies, with as much precision as it does to those substances which we have examined in this article. But these two classes of bodies being but recently discovered, are not probably so familiar to the reader, as to warrant our introducing them without any previous explanation. (J.)

# ATTRACTION.

THE word ATTRACTION (see *Encyclopædia*), is used to denote what we observe, when one body approaches another, or tends to approach it, without any apparent impulse, or other cause, to which the motion can be ascribed.

General Observations.

We have instances of attraction when iron approaches the magnet,—when certain bodies are placed near an excited electric,—when a stone falls to the earth. We say likewise that the earth attracts the moon; by this mode of expression meaning no more than that the moon is continually deflected towards the earth, from the rectilineal course which it would otherwise pursue. It is likewise in this sense that we must be understood, when we say that the sun attracts all the planets.

In the instances already mentioned, attraction extends to a distance. In other cases, it is confined within limits so extremely narrow, as to become imperceptible at an interval which cannot be appreciated by the senses. Of this kind is the attraction which takes place between the particles of the same fluid, as is apparent from the round figure of small drops. To this class likewise belongs the attraction between fluid and solid bodies; whence originate the very interesting appearances observed in capillary tubes, and other kindred phenomena. An attraction between the small elementary particles of all solid bodies, is manifest from the force with which they cohere, or resist an endeavour to separate them. In many cases, the intensity of this force is prodigiously great in contact, or at the nearest distances; while it ceases to act, upon making the smallest separation between the parts. Lastly, Chemistry developes innumerable instances of attraction between the molecules of the bodies about which it is conversant; insomuch, that it is to this principle, under the name of affinity,

that we must ultimately ascribe the various decompositions and new combinations which occur in that science.

All these phenomena, although very different from one another in other respects, yet have this in common, that we observe, in certain bodies, a tendency to approach one another, and to resist a separation, with some degree of force. The facts are certain, and are attended with no ambiguity; and it is to express these facts that the term *attraction* is used in physics.

We likewise observe, in some bodies, a tendency to fly off from one another when they are brought near. This is called *repulsion*.

The word *force* has, in general, some degree of obscurity. It is used to denote the cause of motion; but we have no direct knowledge of it, and we judge of its intensity by the effect which we suppose it to produce. In all our reasoning concerning forces, it is the changes of motion which we measure and compare together, and which are really the subjects of our thoughts. Attraction and repulsion are forces, or principles of motion, known to us only by the phenomena we observe; but the circumstance of their implying action at a distance, is an additional source of obscurity, in which other kinds of force do not participate.

It certainly is inconceivable, that motion should be produced at a distance, when no connection can be traced between the body moved and that which is supposed to produce the motion. We are strongly impressed with the prejudice, that a body cannot act but where it is; and we find difficulty in admitting that the mere presence of two bodies, without the intervention of any mechanical means, can be a satisfactory cause of motion. On this account, Attraction has been classed by some with the occult qualities of the schools; and the favourers of this doctrine have been reproached with reviving exploded notions in philosophy. Impulse is a principle of motion more familiar to us, and to which we are not disposed to make equal objection. Whenever the communication of motion can be traced to this source, we are satisfied that the effect is justly explained. Hence, many philosophers have been of opinion, that impulse is the only cause of motion that can be admitted in physical science; and many attempts have been made to reduce to this principle, all cases in which distant bodies act on one another. With regard to these attempts, it will be sufficient to remark here, that they are all built upon hypothesis: no evidence is adduced to prove that such things exist, as the elastic ether, or gravific matter, which they set out with supposing. And, as far as such systems have no other object but to obviate the difficulty of action at a distance, this argument alone is sufficient to confute them, without adverting to the difficulties that attend each of them separately—their inconsistency with the received laws of motion—and the innumerable contradictions and improbabilities to which they are liable on every side.

A little reflection is sufficient to show, that, in reality, we have no clearer notion of impulse as the cause of motion, than we have of attraction. We can as little give a satisfactory reason why motion should pass out of one body into another, on their contact, as we can, why one body should begin to move, or have its motion increased, when it is placed near another body. It is equally impossible in both cases to prove that there is a necessary connection between the related facts; in this respect, both the phenomena are alike inexplicable.

When motion is produced by impulse, it is probably the circumstance of contact apparently taking place, which leads us to think that the effect is so clearly explained. It is in this manner only, or by actual contact, that we ourselves can move external objects. We have no power to produce motion in distant bodies, except by the intervention of other bodies on which we act immediately. Impulse is, therefore, a cause of motion familiar to us, and strikes us as the plainest, and most satisfactory, ultimate principle at which we can arrive. On the other hand, when one body attracts another at a distance, there is nothing familiar to us with which we can compare it; our curiosity is excited, and we are led to seek out some hidden connection between them.

But, it may be doubted whether there is actual contact in any case of the communication of motion. When a body is impelled by the air, it will hardly be affirmed that the particles of that elastic fluid are in contact with one another, since there is no space, however small, within which a given bulk of it may not be compressed, by applying an external force sufficiently great. The particles of air, therefore, act on one another at a distance; and the same thing must be true of all other elastic fluids. And, by the way, what is here said is sufficient to prove, that no scheme, founded on the hypothesis of an elastic ether, will enable us to account for attraction; because such a contrivance can do nothing more than substitute one species of action at a distance in the room of another. There is good reason to think that absolute contact never takes place in the component parts of the hardest and most compact solid bodies. This seems to be an unavoidable consequence of the fact, well established by experience, that all bodies contract in their bulk by cold, and expand by heat. It is, therefore, not only not impossible, but it is even in some degree probable, that the communication of motion may, in every instance, be a case of action at a distance.

If, then, we are apt to think that impulse is a clearer physical principle than attraction, there is, in reality, no good ground for the distinction; it has its origin in prejudice, and in our mistaking the proper object of natural philosophy. All our researches in nature are confined to the phenomena we observe, and to the laws by which they are regulated. A physical cause is no other than a general fact discovered by a careful observation, and an attentive comparison, of many particular and subordinate facts. We have no evidence, independent of experience, that any consequence, deduced from a physical cause, will actually take place. There is, in this case, no necessary connection from which we can, with absolute certainty, infer the expected event. If, then, we regard impulse and attraction as princi-

Attraction.

ples founded in fact, and regulated by laws, confirmed by observation and experiment, they are both equally entitled to be classed as physical causes, and they ought both to be admitted as of equal authority in explaining the phenomena of the universe.

If we turn our attention to the different kinds of attraction enumerated above, and inquire what progress has been made in the investigation of their laws of action, we shall find that, generally speaking, this branch of physics is little advanced. We are very imperfectly acquainted with magnetical and electrical attraction. We know still less of those attractive powers which take place at small distances, and which are confined within such narrow limits, that their mode of action escapes the observation of our senses. Attraction is, indeed, much used by philosophers to account for many important natural phenomena; but their explanations are often vague, and destitute of that precision which ought always to be aimed at in physical science. There is only one class of phenomena in which the laws of attraction have been fully developed. We allude to gravitation, that principle which occasions the fall of heavy bodies at the surface of the earth, and which retains the planets and comets in their orbits. Referring the other species of attraction, which are little susceptible of general discussion, to their several heads, we shall now confine our attention to gravitation.

Discovery of the Law of Gravitation.

Traces of the principle of gravitation are to be found in writers of great antiquity. But their speculations on this subject do not go beyond a vague notion of a tendency which the planets have to one another, or to a common centre. It would contribute little either to entertainment or instruction, to collect all the passages of ancient authors that speak of this principle. The revival of the true system of the world by Copernicus, introduced the most admirable simplicity in the explanation of the planetary motions, and likewise led to more just conjectures concerning the laws by which they are upheld. Copernicus himself attributed the round figure of the planets to a tendency which their parts possess of uniting with one another; thus extending to all the planets which we observe at the surface of the earth. He stopt short, indeed, at this point; conceiving attraction to be confined to the matter of each planet, without making it extend from one planet to another, so as to actuate all the bodies of the system. This step was made by the bold and systematic genius of Kepler. Adopting the opinion of Dr Gilbert of Colchester, that the earth is a great magnet, Kepler formed to himself a notion of attraction, in some respects remarkably just. He says that the earth and moon attract one another; and, were it not for some powers which retain them in their orbits, they would move towards one another, and would meet in their common centre of gravity. He attributes the tide to the moon's attraction (*virtus tractoria quæ in luna est*), which heaps up the waters of the ocean immediately under her. But in many respects, his notions of attraction were fanciful and extravagant; a more perfect knowledge of the laws of motion than had been attained to in his time, and a new geometry, were both wanting, in order to guide him in this research without danger of wandering. Yet he was able to penetrate so far into the causes of the planetary motions, as to foresee that they would not long continue latent; he tells us, he was persuaded that "the full discovery of those mysteries was reserved for the next age, when God would reveal them." So full an exposition of a physical system of the world, as is contained in the writings of Kepler, could not fail to draw the attention of succeeding philosophers. Many remarks concerning the principle of gravitation are to be found in the writings of Fermat, Roberval, Borelli, and other authors. But no one, before Newton, entertained so clear and systematic a view of the doctrine of universal gravitation as Dr Robert Hook. In his work on the motion of the earth, published in 1674, twelve years before the appearance of Newton's *Principia*, he lays down these three positions as the foundations of his system, viz.

"1*st*, That all the heavenly bodies have not only a gravitation of their parts to their own proper centre, but likewise that they mutually attract each other within their spheres of action.

"2*dly*, That all bodies having a simple motion, will continue to move in a straight line, unless continually deflected from it by some extraneous force, causing them to describe a circle, or an ellipse, or some other curve.

"3*dly*, This attraction is so much the greater, as the bodies are nearer."

The principle of universal gravitation is here very precisely enunciated. Dr Hook seems to have clearly perceived, that the planetary motions are the result of an attraction towards the sun, and of a rectilineal motion produced by a projectile force. Not having discovered the law according to which the force diminishes, as the distance from the sun increases, he contrived experiments to elucidate his theory. Having suspended a ball by means of a long thread, he placed another ball upon a table immediately under the point of suspension, and he caused the suspended ball to revolve round the stationary one. When the moveable ball was pushed laterally with a force properly adjusted to its deviation from the perpendicular, it described an exact circle round the ball on the table: in other cases, it described an ellipse, or an oval resembling an ellipse, having the other ball in the centre. Dr Hook observed, that although this experiment, in some measure, illustrated the planetary motions, yet it did not represent them accurately; because the ellipses which the planets describe, have the sun placed in one focus, and not in the centre. Thus, at the appearance of Newton, many things were known, or rather surmised, that prepared the way for the discovery of the principle which regulates the celestial motions. This does not detract, in any degree, from the glory of Newton, who, discarding the conjectures of his predecessors, proposed to himself to investigate, with mathematical strictness, the law of the attractive force, and to ascertain, with precision, its sufficiency to retain the planets in their orbits. He invented a new kind of geometry, which was necessary to enable him to accomplish his purpose. With this help, and by admitting no-

thing without the sanction of the established principles of Dynamics, he deduced from the motions of the celestial bodies, the law of universal gravitation, the most important and the most general truth hitherto discovered by the industry and sagacity of man, viz. "That all the particles of matter attract one another, directly as their masses, and inversely as the squares of their distances." The particular occasion which gave rise to the speculations of Newton, on the subject of gravity, is noticed in the life of that great man in the *Encyclopædia*; and, in the article Astronomy (Part IV. Chapter II.) there is an account of the several steps of the analytical process of reasoning, by which the above general law is inferred from the motions of the celestial bodies.

Having arrived at a principle which belongs to every part of matter, another inquiry comes into view. Setting out from this principle, it is now necessary to proceed in an inverted order, and deduce from it, by synthetical reasoning, the phenomena which we observe in the universe. The first step in this process, is to find out the attractive force of the planets, which arises from the united attractions of their component parts. Two things only are involved in this investigation, viz. the known law of attraction between the particles of matter, and the figure of the attracting bodies. This is a subject of great importance, and it is connected with some principal points of the system of the world, with the theory of the figure of the planets, that of the tides, and many other phenomena. It is but imperfectly discussed in Newton's immortal work; and there is no part of his philosophy which has been improved more slowly by the labours of his followers. We now propose to treat of it at some length, endeavouring to lay before our readers as complete a view of this part of science as the nature of our work will permit.

Definitions and Properties of Elliptical Spheroids.

We begin with laying down some definitions, and demonstrating some properties of elliptical spheroids.

*Def.* 1. A solid generated by the revolving of an ellipse about either axis is called a spheroid of revolution. If the ellipse revolve about the less axis, the spheroid is oblate; if about the greater axis, it is oblong.

Let $k$ and $k'$ denote the two axes of the spheroid, $k$ being that of revolution; and let $x$ and $y$ be two coordinates of a point in the surface of the spheroid, having their origin in the centre, $x$ being parallel to the axis of revolution, and $y$ perpendicular to it; then the equation of the spheroid, whether oblate or oblong, will be $\frac{x^2}{k^2} + \frac{y^2}{k'} = 1$.

*Def.* 2. An elliptical spheroid, in general, or an ellipsoid, is a solid bounded by a finite surface of the second order. Let ACB and ADE (Plate XXX. fig. 1. This figure represents one eighth of an ellipsoid contained in one of the solid angles formed by the three principal sections) be two ellipses that have the same axis AO, the same centre O, and their planes perpendicular to one another: from any point K in the common axis, let there be drawn ordinates in both ellipses, as KC and KD; then, having described an ellipse of which KC and KD are the semiaxes, the periphery DMC of that ellipse will be in the surface of the ellipsoid. This solid figure has a centre; three axes crossing one another at right angles in the centre; and three principal sections made by planes passing through every two of its axes.

Let $k$, $k'$, $k''$, denote the three semiaxes; viz. $k = \text{OB}$, $k' = \text{OE}$, $k'' = \text{OA}$: and let $x, y, z$ denote three rectangular coordinates of a point M in the surface, the coordinates being parallel to the axes, and having their origin in the centre; viz. $\text{MN} = x$, $\text{NK} = y$, and $\text{OK} = z$; then the equation of the surface will be $\frac{x^2}{k^2} + \frac{y^2}{k'^2} + \frac{z^2}{k''^2} = 1$; as it is easy to prove from the foregoing construction.

The ellipsoid becomes a sphere, when all the three axes are equal: it becomes a spheroid of revolution, when two of them are equal.

1. *If any plane cut an elliptical spheroid, the section will be an ellipse. In the spheroid of revolution, a section made by a plane perpendicular to the axis of revolution is a circle.*—All this follows so easily from the nature of the solids, that we need not stop to give a formal demonstration.

2. *If a straight line cut two concentric ellipses, that are similar and similarly situated, the parts of it between the outer and inner peripheries are equal to one another.*

Let AHBK and MDNC (Plate XXX. fig. 2.) be two similar and similarly situated ellipses that have the same centre O; and let the straight line AB cut them both; then AC and BD are equal. Bisect CD in L, and through L and the common centre draw the straight line HMNK to cut both ellipses. Because the ellipses are similar and similarly situated, and that CD is an ordinate of the diameter MN, it is plain that AB will be an ordinate of the diameter HK; wherefore, AB and CD being both bisected in L, AC is equal to BD.

3. *If there be two ellipses, one within the other, such that, any straight line being drawn to cut them, the parts of it between their peripheries are equal to one another; these ellipses are concentric, similar, and similarly situated.*

Let D (fig. 2.) be any point in the inner ellipse, and through D draw EF, terminating in the outer ellipse: then, if we make FG = DE, G must be a point in the inner ellipse. Hence all the points of the inner curve are determined, when the outer ellipse and the point D are given: wherefore there cannot be two different curves, both passing through D, that will answer the conditions. But an ellipse described through D, concentric with the outer ellipse, and similar to it, and similarly situated, will answer the conditions (2). Wherefore the two ellipses are concentric, and similar, and similarly situated.

4. *If a straight line be drawn to cut two elliptical spheroids, that have the same centre, and are similar and similarly situated, the part of it between the outer and inner surfaces will be equal to one another.*

Conceive a plane, which contains the straight line, to pass through the common centre of the solids;

the sections made by the plane will be concentric ellipses (1.); and these will be similar and similarly situated, because the solids are so: wherefore the parts of the straight line between the surfaces are equal (2.).

5. *If two elliptical spheroids that have the same centre, and are similar and similarly situated, be cut by a plane, the two sections will be concentric ellipses that are similar and similarly situated.*

For the sections are ellipses (1.); and, any straight line being drawn to cut them, the parts of it between the peripheries will be equal (4.): wherefore the ellipses are concentric, similar, and similarly situated (3.)

6. *Let ADE and CFG (fig. 3.) be two concentric ellipses that are similar and similarly situated; let AO and CO, in the same straight line, be two of their axes, and let DE, drawn through C, be perpendicular to AO; then if CF and CG be two chords of the interior ellipse that make equal angles with the axis CO, and if the chords DM and DN of the exterior ellipse be drawn respectively parallel to CF and CG; the sum of CF and CG will be equal to the sum or difference of DM and DN, according as they both fall on the same side, or on different sides of DE.*

For draw EP parallel to CF, and it will likewise be parallel to DM. Because CF and CG are equally inclined to CO and to DE, it is plain that DN and EP, which are parallel to CF and CG, are likewise equally inclined to DE: consequently $DN = EP$. Draw a straight line through the common centre to bisect DM in L, and that straight line will likewise bisect EP, parallel to DM, in H: and because the ellipses are similar and similarly situated, the same straight line will likewise bisect the chord CF of the interior ellipse, in K. Because $DC = CE$, therefore $DL + EH = 2CK = CF$. Wherefore $DM + DN = 2DL + 2EH = 2CF = CF + CG$.

The demonstration of the other case, when DM and DN fall on different sides of DE, is entirely similar.

*Some general Properties, resulting from the Law of Attraction, that obtains in Nature.*

7. *Let AB and EF (fig. 4.) be two indefinitely slender pyramids, that are similar to one another, and both composed of the same homogeneous matter, which attracts in the inverse proportion of the square of the distance: the attractions of the pyramids upon particles placed at the vertices A and E, are proportional to the length of the pyramids.*

Conceive each of the pyramids to be divided into an indefinitely great number of thin slices of equal thickness, by planes parallel to its base; then, if CD and GH be any two of these slices, their attractions upon particles placed at A and E, will be proportional to $\frac{CD}{AC^2}$, and $\frac{GH}{EG^2}$. Now, these are equal: for, the solids CD and GH, having the same thickness, they are proportional to the sections CM and GN, that is, to $AC^2$ and $EG^2$, because the pyramids are similar. Wherefore, the attraction of any one of the slices in the pyramid AB, upon a particle placed at A, is equal to the attraction of any one of the slices in EF upon a particle placed at E. Consequently, the whole attraction of the pyramid AB, is to the whole attraction of the pyramid EF, as the number of slices in AB to the number of slices in EF, that is, as the length AB to the length EF.

*Cor.* 1. The attractions of any portions of the pyramid, are as the lengths of the portions. For the attractions are proportional to the number of slices in the portions, that is, as the lengths.

*Cor.* 2. If the pyramids have different densities, their attractions are proportional to the lengths multiplied by the densities. For, in this case, the attraction of each slice will be proportional to its density: wherefore, the attractions will be as the densities multiplied by the number of slices; or, as the densities multiplied by the lengths.

8. *If there be two similar solids composed of the same homogeneous matter, which attracts in the inverse proportion of the square of the distance; any two particles of matter, similarly situated with regard to the solids, will be attracted by them with forces that are proportional to any of the homologous lines of the solids.*

Because the solids are similar, they may be resolved into an indefinitely great number of slender pyramids, and frustums of pyramids, that are similar to one another, and similarly placed in the solids; each pyramid having its vertex at one of the attracted particles. The direct attractions of any corresponding pair of pyramids will have constantly the same ratio to one another: for they will be as the lengths of the pyramids or frustums (7.); that is, because the solids are similar, as any two homologous lines of the solids. Wherefore, the whole attractive forces, compounded of all the direct attractions which act in directions that make the same angles with one another, will likewise have to one another the proportion of any two of the homologous lines of the solids.

*Cor.* If the two solids have different densities, their attractions will be proportional to the densities multiplied by any homologous lines of the solids (7. *Cor.* 2.).

9. *If there be two concentric elliptical spheroids that are similar and similarly situated, a particle placed anywhere within the inner surface will be in equilibrium, or will be urged equally in all opposite directions by the shell of homogeneous matter contained between the two surfaces, supposing the law of attraction to be that of the inverse proportion of the square of the distance.*

Let P (Plate XXX. fig. 5.) be a particle placed within such a shell, and let a slender double pyramid, having P for the common vertex, be extended to meet the surfaces of the solid on both sides of P. The portions of the pyramid, AGHB and CEFD between the surfaces on opposite sides of P, will have equal lengths (4.): wherefore, these portions will attract a particle placed at P with equal forces (7. *Cor.* 1.). The same thing may be proved of all the pyramids which have their vertices at P, and fill the spheroids. Wherefore, P is attracted equally in all opposite directions by the homogeneous matter contained between the surfaces of the spheroids.

10. *To find the attractive force of an indefinitely slender prism, acting in a direction parallel to the prism, upon a particle of matter placed anywhere.*

Attraction.

Let BC (Plate XXX. fig. 6.) be a prism of homogeneous matter, upon the indefinitely slender base CH, and let a particle of matter be placed at A; draw AB and AC to the extremities of the prism, and AE to any point in it; and draw AD perpendicular to BC. Let S = base CH, and put $AD = a$, $DE = x$; the element of the prism is $= S \times dx$; the element of the attraction in the direction AE, is $= \frac{S \times dx}{AE^2}$; and the element of the attraction in the direction parallel to the prism, is $= \frac{S \times dx}{AE^2} \times \frac{DE}{AE} = \frac{S \times x dx}{(a^2+x^2)^{\frac{3}{2}}}$.

Now, $\int \frac{S \times x dx}{(a^2+x^2)^{\frac{3}{2}}} = \text{Const.} - \frac{S}{\sqrt{a^2+x^2}} = \text{Const.} - \frac{S}{AE}$; and the constant quantity is determined by making the fluent begin at the end of the prism nearer to A: wherefore, the whole attractive force of the prism, in the direction parallel to the prism, is $= S \times \left\{\frac{1}{AB} - \frac{1}{AC}\right\}$.

*Cor.* In like manner may the attractive force of the prism be found, when the attraction of the particles is proportional to any function of the distance.

Let $AB = f$, $AC = f'$; suppose that $\varphi(f)$ is the function of the distance that expresses the law of attraction; and put $\int df. \varphi(f) = \Psi(f)$: then the attraction parallel to the prism, is =

$$S \times \pm \left\{\Psi(f) - \Psi(f')\right\},$$

observing that the attraction is always positive.

### Attraction of Spheres.

Attraction of Spheres.

11. *Spheres of the same homogeneous matter, attract particles placed on their surfaces, with forces proportional to their radii.*

Spheres being similar solid figures, this proposition is no more than a particular case of what was before proved (8.).

*Cor.* If the spheres have different densities, the attractions at their surfaces are proportional to their radii multiplied by their densities (8. Cor.).

12. *The force with which a particle, placed anywhere within a sphere of homogeneous matter, is urged towards the centre, is proportional to its distance from the centre.*

Conceive a concentric sphere to be described, which contains the attracted particle in its surface; the matter between the two surfaces will exert no force on the particle (9.), which will therefore be urged to the centre, only by the attraction of the inner sphere, in the surface of which it is placed: but this force is proportional to the radius of the sphere, or to the distance of the particle from the centre (11.).

13. *Let PNQ and ABC (fig. 7.) be two spheres of the same homogeneous matter, which attracts in the inverse proportion of the square of the distance: let the centres of the spheres be at M and D, and take MR equal to the radius of the sphere ABC, and ED equal to the radius of the sphere PNQ: the attractions of the spheres upon particles placed at R and E are to one another as the squares of the radii of the spheres.*

4

In the spheres draw two great circles perpendicular to the diameters PQ and AC, that pass through the points R and E; and let PpQ and AbC be two great circles, making equal indefinitely small angles NMp and BDb with the great circles PNQ and ABC. Let HK and FG, parallel to PQ and AC, be any two chords of the circles PpQ and AbC, that subtend similar arcs, or arcs containing the same number of degrees; and through HK and FG, let planes perpendicular to the circles PpQ and AbC, be drawn to cut the portions of the spheres contained in the angles NMp and BDb: join RH, RK, MH, MK, DF, DG, EF, EG. Because the arcs subtended by HK and FG, are like parts of their circumferences, it is plain, that the angle RMH = EDF, and RMK = EDG. And because ED = MH = MK, and RM = DF = DG (*hyp.*), therefore RH = EF, and RK = EG.

Conceive the chords HK and FG, together with the planes passing through them, to change their place a little, so as to describe two slender prisms, or elements of the portions of the spheres contained in the angles NMp and BDX. It is plain that MR and DO, the distances of the chords HG and FG from the centres of their circles, are constantly proportional to MN and DB, the radii of the spheres; wherefore RT and OS, the perpendicular sections of the small prisms, are similar figures, and have to one another the same ratio that $MX^2$ has to $DO^2$, or $MN^2$ to $DB^2$. Now, the attraction of the prism HK urging a particle at R to the centre M, is = $XT \times \left\{\frac{1}{RH} - \frac{1}{RK}\right\}$ (10.); and the attraction of the prism FG urging a particle at E to the centre D, is $= OS \times \left\{\frac{1}{EF} - \frac{1}{EG}\right\}$. But, in consequence of what was proved, $\frac{1}{RH} - \frac{1}{RK} = \frac{1}{EF} - \frac{1}{EG}$; wherefore the attractions of the prisms are to one another as XT to OS, or as $MN^2$ to $DB^2$.—The same thing may be proved of all the elements of the two portions of the spheres contained in the angles NMp and BDb; wherefore those portions attract particles at R and E with forces proportional to the squares of the radii of the spheres. But because the small angles NMp and BDb are equal, each of the spheres may be divided into an equal number of such portions; wherefore the attractions of the whole spheres upon particles placed at R and E, are proportional to the squares of the radii of the spheres.

*Cor.* This proposition is true, when the particles of matter attract one another with forces proportional to any proposed function of the distance.

Let $RH = EF = f$, and $RK = EG = f'$; then, adopting the same notation as before (8. *Cor.*), the attractions of the prisms urging particles placed at R and E to the centres M and D, are respectively $XTx \times \pm \left\{\Psi(f) - \Psi(f')\right\}$, and $OSx \times \pm \left\{\Psi(f) - \Psi(f')\right\}$: consequently, those attractions have the same pro-

Attraction. portion that RT has to SO, or $MN^2$ to $DB^2$. Wherefore the attractions of the whole spheres are in the same proportion.

14. *A particle placed anywhere without a sphere of homogeneous matter which attracts in the inverse proportion of the square of the distance, will be urged to the centre of the sphere, with a force that is inversely proportional to the square of the particle's distance from the centre.*

Let ABC (Plate XXX. fig. 8.) be the sphere, O its centre, and P a particle without the sphere: conceive a concentric sphere PMN, of the same homogeneous matter with the sphere ABC, to be described with the radius PO. Then, by the last proposition, the attraction of the sphere ABC upon the particle P, is to the attraction of the sphere PMN upon a particle placed at A, as $AO^2$ to $PO^2$. But the attraction of the sphere PMN upon a particle placed at A, is equal to the attraction of the sphere ABC upon the same particle; for the attraction of the matter between the two spherical surfaces exerts no force upon a particle at A (9.). Wherefore, in the proportion set down above, the two middle terms are constantly the same wherever the point P is placed without the sphere ABC. Consequently, the first term of the proportion must follow the inverse ratio of the last term; that is, the attraction of the sphere ABC upon the external particle at P is inversely proportional to $PO^2$.

15. *The same law of attraction being supposed, a homogeneous sphere will attract a particle placed without it, with the same force as if all the matter of the sphere were collected in the centre.*

Let $f$ denote the distance of the particle from the centre; then it follows, from the last proposition, that the attraction of the sphere upon the particle will have, for its measure, $\frac{A}{f^2}$; A denoting a constant quantity that will be determined by any particular case; that is, by the actual attractive force corresponding to any determinate distance from the centre. Let $r$ denote the radius of the sphere, and M its mass; then no part of the matter of the sphere being nearer the attracted particle than $(f-r)$, and none of it more remote than $(f+r)$, the attraction of the sphere on the particle will be greater than $\frac{M}{(f+r)^2}$, and less than $\frac{M}{(f-r)^2}$. Therefore $\frac{A}{f^2}$ is always contained between those limits, which requires that $A = M$. For, if A were greater than M, such values of $f$ might be found as would make $\frac{A}{f^2}$ equal to, or greater than $\frac{M}{(f-r)^2}$; and, if A were less than M, such values of $f$ might be found as would make $\frac{A}{f^2}$ equal to, or less than $\frac{M}{(f+r)^2}$. Therefore $A = M$; and the attraction of the sphere is equal to $\frac{M}{f^2}$, or the same as if all the matter were collected in the centre.

If the radius of the sphere $= r$, the density of the matter contained in it $= d$; then the mass, or $M = \frac{4\pi r^3 d}{3}$ ($\pi$ being the circumference of the circle whose diameter is unit), and the attraction of the sphere at the distance $f$ from the centre $= \frac{4\pi r^3 d}{3f^2}$. This is still true at the surface of the sphere when $f = r$, so that the attraction at the surface $= \frac{4\pi r d}{3}$; which expression, with the help of what is proved in (12.), enables us to compare the intensities of the attractions of homogeneous spheres, at all distances from the centre, without or within the surfaces.

*Cor.* 1. A shell of homogeneous matter contained between two concentric spherical surfaces, will attract a particle placed without it, with the same force as if all the matter of the shell were collected in its centre.

For the attractive force of such a shell is equal to the difference of the attractions of two concentric spheres of the same homogeneous matter with the shell.

*Cor.* 2. A sphere composed of concentric shells, that vary in their densities according to any law, will attract a particle placed without it, with the same force as if all the matter were collected in the centre.

For this having been proved of one shell (*Cor.* 1.), it must be true of any number of shells.

If $\varphi(r)$ denote the density at the distance $r$ from the centre, the quantity of matter in the sphere will be $= 4\pi . \int \varphi(r) . r^2 dr$; and the attraction on a particle without the sphere at the distance $f$ from the centre $= \frac{4\pi . \int \varphi(r) . r^2 dr}{f^2}$.

16. *Two spheres, each composed of concentric shells of variable density, attract one another with the same force as if all the matter of each were collected in its centre.*

For the attraction of a sphere A upon every particle of another sphere B will remain the same, if we suppose all the matter of A to be collected in its centre (15.). But the attraction of any particles of matter placed in A's centre, upon the sphere B, is equal and opposite to the attraction of B, upon the same matter so placed: and, again, the attraction of B upon all the particles placed in the centre of A, will remain unchanged, if we suppose the matter of B to be collected in its centre. Wherefore A attracts B with the same force as if the matter of each were collected in its centre.

17. *Supposing that the particles of matter attract with a force proportional to the distance, a body of any shape will attract a particle of matter placed anywhere with the same force, and in the same direction, as if all the matter of the body were collected in its centre of gravity.*

Suppose that the attracted particle is placed at P (fig. 9.), and the centre of gravity of the attracting body at G; join PG, and let any plane pass through that line. Let L be a small part, or element of the body, and

from L draw LK perpendicular to the plane passing through PG, and KF perpendicular to PG; join PL and PK. Put $dm$ to denote the quantity of matter, or the mass of the element L; then its attractive force, urging the particle in the direction PL, is $= PL \times dm$, which, by the resolution of forces, is equivalent to the two forces, $PK \times dm$ and $KL \times dm$; and, again, the single force $PK \times dm$ is equivalent to the two forces $FK \times dm$, and $PF \times dm = PG \times dm + GF \times dm$. Wherefore, the attraction of the element L, upon the particle at P, is equivalent to these four separate forces, viz. $PG \times dm$, $GF \times dm$, $FK \times dm$, $KL \times dm$, which urge the particle P respectively in the directions, PG, GF, FK, KL. But, from the nature of the centre of gravity, the sum of all the forces, $KL \times dm$, that urge the particle P to one side of the plane passing through PG, is just equal to the sum of the forces that urge it to the other side of the same plane; and the sum of all the forces, $FK \times dm$, that urge P to one side of the line PG, is just equal to the sum of the forces that urge it to the other side of the same line; and the sum of all the forces, $GF \times dm$, that urge P towards the point G, is just equal to the sum of the forces that urge it from the same point. Wherefore all the preceding forces mutually destroy one another, excepting the forces, $PG \times dm$, the sum of which, when extended to all the elements of the attracting body, is $= PG \times$ mass of the body. Wherefore the whole attraction upon P is the same as if all the matter of the body were collected in its centre of gravity.

*Cor.* Supposing that the particles of matter attract with a force proportional to the distance, a homogeneous sphere will attract a particle placed anywhere in the same manner as if all the matter of the sphere were collected in the centre.

For the centre of gravity of a homogeneous sphere, is the same as the centre of its figure. This corollary is likewise true of a sphere composed of concentric shells of variable density; and it is easy to apply the demonstration of (16.) to prove that, in this law of attraction, two spheres, each composed of concentric shells of variable density, will attract one another with the same force as if the matter of each were collected in its centre.

18. *To investigate what are the laws of attraction, in regard to the distance, according to which a shell of homogeneous matter, contained between two concentric spherical surfaces, will attract a particle placed without it, in the same manner as if all the matter of the shell were collected in the centre.*

It has been proved that this property actually belongs to homogeneous shells in the law of attraction which obtains in nature, and likewise when the particles of matter attract with a force proportional to the distance; but it is interesting to know whether it is confined to these two cases alone, or extends to other laws of attraction. This can only be discovered by a direct analysis.

Let $r = PC$ (fig. 10.), the distance of the attracted point from the centre of the shell; $u = CA$ the radius of the inner surface of the shell; $f = PM$, the distance of P from any point in the surface. Having drawn the diameter AD through P, let AMD and AND be two great circles, making, with one another, an indefinitely small angle $MAN = dq$; and let two small circles BMG, $bmg$, indefinitely near one another, of which A and D are the poles, meet the former circles in M, N, $m$, $n$; and draw MS, NS to the centre of the circle BMG. Put $\theta$ for the measure of the arc AM; then $MS = u \sin. \theta$; $MN = dq \,.\, u \sin. \theta$; $Mm = ud\theta$; and the quadrilateral space $MNnm = u^2.dq.d\theta \sin.\theta$. We may suppose the thickness of the shell indefinitely small; since, if the property belong to an elementary shell indefinitely thin, it will be true of one of a determinate thickness, which can be resolved into such elements. Suppose the thickness of the shell to be $= du$; then, the quantity of matter in the part standing upon the quadrilateral space $MNnm = u^2du.dq.d\theta \sin. \theta$. Let $\varphi(f)$ represent the direct attraction of a particle at M in the direction PM; then its attraction directed to the centre $C = \varphi(f) \times \frac{PS}{PM} = \frac{r - u\cos.\theta}{f} \times \varphi(f)$;

and the attraction of the element of the shell in the same direction $= u^2du \,.\, dq \,.\, d\theta \sin.\theta \times \frac{r - u\cos.\theta}{f} . \varphi(f)$.

This expression is proportional to $dq$, when $\theta$ and $f$ remain constant; and, therefore (denoting by $\pi$ the circumference of the circle whose diameter is unit), the attraction of the whole zone contained between the small circles BMG, $bmg$, will be $= 2\pi . u^2du \,.\, d\theta \sin.\theta . \frac{r - u \cos.\theta}{f} . \varphi(f)$: and the attractive force of the whole shell will be

$$2\pi . u^2du \int d\theta \sin.\theta \,.\, \frac{r - u\cos.\theta}{f} . \varphi(f);$$

the fluent to be extended from $\theta = 0$ to $\theta = \pi$.

Again, the quantity of matter in the shell is $= 4\pi \,.\, u^2du$; and the attraction of this matter placed in the centre, at the distance $r$ from P, is $= 4\pi . u^2du . \varphi(r)$.

If now we equate the attraction of the shell, to the attraction of its matter placed in the centre, and leave out the factors common to both, we shall get

$$2\varphi(r) = \int d\theta \sin.\theta \,.\, \frac{r - u\cos.\theta}{f} . \varphi(f)$$

the limits of the integral being the same as before.

But $f^2 = r^2 - 2ru \cos. \theta + u^2$; then $d\theta \sin. \theta = \frac{fdf}{ru}$; also $r - u \cos. \theta = \frac{f^2 + r^2 - u^2}{2r}$: wherefore, by substitution, we get

$$4 \,.\, r^2\varphi(r) \,.\, u = \int (f^2 + r^2 - u^2) \,.\, df \,.\, \varphi(f);$$

or, which is equivalent, $4.r^2\varphi(r) \,.\, u =$

$(f^2 + r^2 - u^2) \,.\, \int df \,.\, \varphi(f) - 2 \int fdf \int df \,.\, \varphi(f)$,

the limits of this integral being from $f = r - u$ to $f = r + u$, which correspond to $\theta = 0$ and $\theta = \pi$.

Now let $\int df . \varphi(f) = \Psi(f)$; and $\int fdf \int df . \varphi(f) = \int fdf . \Psi(f) = \Psi'(f)$: then, by taking the fluents between the proper limits, we get

Attraction.

$$4.r^2\varphi(r).u = 2r.\left\{(r+u)\Psi(r+u)-(r-u)\Psi(r-u)\right\}$$
$$-2\left\{\Psi'(r+u)-\Psi'(r-u)\right\}.$$

If we develope the binomial functions in the last expression, all the even powers of $u$ will disappear, and the odd powers only will remain; these last terms being all contained in this general formula,

$$\text{viz. } \frac{4}{1.2.3\ldots 2n+1}.$$
$$\left\{r.\frac{d^{2n+1}\, r\Psi(r)}{dr^{2n+1}}-\frac{d^{2n+1}\,\Psi'(r)}{dr^{2n+1}}\right\}.u^{2n+1};$$

and, observing that $\frac{d.\Psi'(r)}{dr}=r\Psi(r)$, the same expression will become $\frac{4}{1.2.3\ldots.2n+1}$.

$$\left\{r.\frac{d^{2n+1}\, r\Psi(r)}{dr^{2n+1}}-\frac{d^{2n}\, r\Psi(r)}{dr^{2n}}\right\}.u^{2n+1};$$

which, again, is more simply expressed thus, viz.

$$\frac{4r^2}{1.2.3\ldots.2n+1}.\frac{d.\left\{\frac{1}{r}.\frac{d^{2n}r\Psi(r)}{dr^{2n}}\right\}}{dr}.u^{2n+1}.$$

Wherefore, by substituting the developement instead of the functions, and then, by dividing by $4\,r^2\,u$, we get

$$\varphi(r)=\frac{d.\Psi(r)}{dr}+\frac{1}{1.2.3}.\frac{d.\left\{\frac{1}{r}.\frac{d^2 r\Psi(r)}{dr^2}\right\}}{dr}.u^2$$
$$+\frac{1}{1.2.3.4.5}.\frac{d.\left\{\frac{1}{r}.\frac{d^4 r\Psi(r)}{dr^4}\right\}}{dr}.u^4$$
$$+\ \&c.$$

From the nature of the function $\Psi(r)$, we get $\varphi(r) = \frac{d.\Psi(r)}{dr}$; wherefore each of the remaining terms must be separately equal to nothing: Hence

$$d.\left\{\frac{1}{r}.\frac{d^2\, r\,\Psi(r)}{d\,r^2}\right\}=0;$$

from which we find $r\,\Psi(r)=\frac{1}{2}\,A\,r^3+A'r-A''$, $A, A', A''$ being arbitrary constant quantities; and this value of $r\,\Psi(r)$, it is plain, will likewise render all the succeeding terms of the developement evanescent. Wherefore

$$\varphi(r)=\frac{d.\Psi(r)}{dr}=A\,r+\frac{A''}{r^2}.$$

Thus the most general expression of the law of attraction, that possesses the property in question, is a combination of the two laws above mentioned, with each of which it coincides, according as we make the one or other of the constant quantities equal to nothing. We have therefore a direct proof, that the law of nature is the only one which will make the attraction decrease as the distance increases, and in which a spherical shell, or a sphere, will attract in the same manner as if all the matter were collected in the centre.

Laplace has arrived at the same conclusion by a different process. (*Mech. Celeste*, Liv. 2d. Chap. 2. No. 12. Rem. Part.)

### ATTRACTION OF SPHEROIDS OF REVOLUTION.

Attraction of Spheroids of Revolution.

19. *Let APBQ (Plate XXXI. fig. 11.) and CMDN be two concentric ellipses, similar to one another, and similarly situated, of which AB and CD are either the greater, or less, axes; and let PCQ be perpendicular to AB. Conceive the ellipses to revolve about PQ, so as to describe an indefinitely small angle; then, supposing the law of attraction to be inversely proportional to the square of the distance, the thin solid of homogeneous matter described by the ellipse APBQ, will attract a particle placed at P, in a direction perpendicular to any plane passing through PQ, with the same force that the thin solid of the same matter described by the ellipse CMDN, will attract a particle placed at C perpendicularly to the same plane.*

From C draw CM, CN, making equal angles with CD, and PR, PT respectively parallel to CM, CN; and let C$m$, C$n$, P$r$, P$t$, be drawn in the same manner, and indefinitely near the former lines. While the ellipses revolve about PQ, the small sectors will describe pyramids that have their vertices at C and P. It is manifest that the pyramids so described are similar: for their angles at C and P in the planes of the ellipses are equal; and their other angles described by revolving about PQ are likewise equal, because the sectors are equally inclined to that axis. Wherefore, the direct attractions of all the small pyramids upon the particles P and C, are proportional to the lengths PR, PT, CM, CN (7); and consequently the forces that urge the particles P and C in a direction at right angles to any plane passing through PQ, are proportional to the perpendiculars let fall upon that plane from R, T, M, N. But, because PR, PT, CM, CN are equally inclined to PQ, they will make equal angles with any plane passing through PQ: wherefore the perpendiculars drawn to the plane from R, T, M, N, will be respectively proportional to CM, CN, PR, PT. But CM + CN = PR + PT (6.): wherefore, the sum of the perpendiculars drawn to the plane from M and N, will be equal to the sum of the perpendiculars drawn to it from R and T. Consequently the force of the pyramids PR and PT, which urges the particle P at right angles to the plane, is equal to the force of the pyramids CM and CN, which urges the particle C in a parallel direction. The same thing is true of all the small pyramids that make up the thin solids described by the ellipses APBQ and CMDN; and it is therefore true of the whole solids.

It is to be observed, that when the pyramids PR and PT fall on opposite sides of PQ, it is the difference of their attractions which is equal to the sum of the attractions of CM and CN: and it is the difference of the perpendiculars let fall from T and R on opposite sides of the plane, which is equal to the sum of the perpendiculars let fall from M and N.

20. *Let APBQ be a spheroid of revolution, PQ the axis of revolution, and ACB a plane through the centre perpendicular to PQ (Plate XXXI. fig. 12.). If D be a particle in the surface of the spheroid, and DL perpendicular to the plane ACB; then the attraction of the spheroid on a particle placed at the pole P, will be to the force with which a particle placed at C, is attracted in the direction DL, as PC is to DL.*

Through D draw a plane parallel to the plane ACB, and let the plane so drawn cut the axis PQ in F: draw the straight line DFE to terminate in the spheroid, and describe another spheroid through F, having the same centre with the spheroid APBQ, and similar to it, and similarly situated. Conceive an indefinitely great number of planes, making indefinitely small angles with one another, to be drawn through DE, so as to divide the two spheroids into an indefinitely great number of thin solids, or slices: then the sections which every one of the planes make with the spheroids will be similar ellipses, having the same centre (5.); and it is manifest that a straight line drawn through F at right angles to DE, in any one of the planes, will pass through the centre of the two ellipses contained in it, and will coincide with an axis of each. Wherefore, the force with which every one of the slices, or elements, of the spheroid APBQ attracts a particle placed at D in the direction DL, is equal to the force with which the corresponding slice, or element, of the spheroid GFHK, attracts a particle placed at F in the direction FC (19.). Wherefore, the whole attraction of the spheroid APBQ upon a particle at D, in the direction DL, is equal to the whole attraction of the spheroid GFHK, upon a particle at F. But the attractions of the spheroids APBQ and GFHK, upon particles placed at P and F, are to one another as PC to FC (8.). Wherefore, the attraction of the spheroid APBQ upon a particle at P, is to the force with which the same spheroid attracts a particle at D, in the direction DL, as PC is to FC or DL.

21. *Let APBQ be a spheroid of revolution, and PQ the axis of revolution, as before. If D be a particle in the surface, ADPB (fig. 13.) a section through D, and the axis PQ, and DL perpendicular to PQ; the attraction of the spheroid upon a particle at A, will be to the force with which a particle at D is attracted, in the direction DL, as AC is to DL.*

Through D draw a plane perpendicular to AB, which cuts the section ADB in the straight line DFE; and let a spheroid FGHK be described through F, having the same centre with the spheroid APBQ, and similar to it, and similarly situated. Then, conceiving the two spheroids to be divided into an indefinitely great number of thin slices by planes passing through DE, the force with which every slice, or element, of the spheroid APBQ attracts a particle at D in the direction DL, will be equal to the force with which the corresponding slice, or element, of the spheroid FGHK attracts a particle at F (19.). But the attractions of the spheroids APBQ and FGHK upon particles placed at A and F, are to one another as AC to CF (8.). Wherefore, the attraction of the spheroid APBQ upon a particle at A, is to the force with which the same spheroid attracts a particle at D, in the direction DL, as AC to FL or DL.

The two last propositions will enable us to find both the direction and the intensity of the attraction of a homogeneous spheroid of revolution upon a particle placed anywhere on the surface, when we have ascertained the attractive forces at the poles, and at the circumference of the circular section made by a plane through the centre perpendicular to the axis. For the whole attraction at any point, is the compound force arising from the attractions perpendicular to the axis, and parallel to it. The next object of our research is, therefore, to determine the two forces above-mentioned, viz. the attraction at the poles, and at the circular section, equally distant from both poles.

22. *Let ABD be an indefinitely slender pyramid, of which the base BD is perpendicular to the edge AD (fig. 14.): let B = base BD, and f = length AD; then $\frac{B}{f}$ = the attraction of the whole matter of the pyramid upon a particle placed at the vertex A.*

Let AM $= x$; then the section MN parallel to the base BD $= \frac{B.x^2}{f^2}$; and, MP = element of the prism $= \frac{B.x^2 dx}{f^2}$; and the attraction of the element upon a particle placed at A $= \frac{MP}{AM^2} = \frac{B.dx}{f^2}$: the fluent of which is $= \frac{Bx}{f^2}$ = attraction of the pyramid AM upon a particle at A. And, when $x = f$, this becomes $= \frac{B}{f}$ = attraction of the pyramid AD upon a particle placed at A.

23. *To investigate the attraction of a homogeneous spheroid of revolution, upon a particle placed at the pole.*

Let P (fig. 15.) be the pole, PCQ the axis of revolution, and APBQ a section of the spheroid by a plane passing through PQ, and any point M, in the surface; draw PM, P$m$ indefinitely near PM, and M$m$ perpendicular to P$m$. Conceive the plane PMQ to revolve about PQ, so as to describe the indefinitely small angle BCO; then the small triangle MP$m$ will describe a slender pyramid, having its vertex at P, and of which the base is a rectangle, contained by M$m$ and RT; for the point M moving parallel to R, it will describe a line equal and parallel to that described by R, namely, to RT.

Let PM $= f$; and the angle KPM, which PM makes with a perpendicular to the axis, $= \theta$; and the indefinitely small angle BCO $= d\varphi$. Then M$m = f d\theta$; RT $=$ CR $\times d\varphi = f \cos.\theta . d\varphi$; and B, the base of the slender pyramid described by the triangle MP$m$, $= d\varphi . d\theta \cos.\theta . f^2$: wherefore, the direct attraction of the pyramid on a particle at P $= \frac{B}{f}$ (22) $=$

Attraction. $d\varphi . d\theta \cos.\theta . f$; and the elementary attraction of the spheroid in the direction PC = direct attraction of the pyramid $\times \frac{PS}{PM} = d\varphi . d\theta \cos.\theta \sin.\theta . f$.

Again, let MR $= x$, CR $= y$, PC $= k$, AC $= k'$; then $y = f \cos.\theta$; $x = k - f \sin.\theta$; if we substitute these values in the equation of the solid (1.), we get

$$\frac{(k - f\sin.\theta)^2}{k^2} + \frac{f^2 \cos.^2\theta}{k'^2} = 1;\text{ whence}$$

$$f = \frac{2k'^2 k}{k^2} \cdot \frac{\sin.\theta}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta}.$$

By substituting the value of $f$ just found in the preceding expression of the elementary attraction of spheroid, it will become

$$\frac{2k'^2 k.}{k^2} d\varphi \cdot \frac{d\theta \cos.\theta . \sin.^2\theta}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta};$$

which must be integrated from $\varphi = o$ to $\varphi = 2\pi$; and from $\theta = o$ to $\theta = \frac{\pi}{2}$; $\pi$ denoting always the half-circumference when radius is unit.

In an oblate spheroid $k$ is less than $k'$; put $k'^2 - k^2 = k^2 . e^2$, and $z = \sin.\theta$; then the element of the attractive force will become, by substitution,

$$\frac{2\,k'^2 k.}{k^2} d\varphi \cdot \frac{z^2 dz}{1 + e^2 z^2} = \frac{2\,k'^2 k . d\varphi}{k^2 e^3} \cdot \left\{ e dz - \frac{edz}{1 + e^2 z^2} \right\};$$

and by integrating from $z = o$ to $z = 1$, we get,

$$\frac{2k'^2 k . d\varphi}{k^2 e^3} \cdot \left\{ e - \text{arc. tan. } e \right\};$$

for the force with which the matter between the planes PBQ and POQ urges the particle P to the centre. Wherefore the whole attractive force of the spheroid upon a particle at P is =

$$\frac{4\pi . k'^2 k}{k^2 e^3} \cdot \left\{ e - \text{arc. tan. } e \right\};$$

And, because $\frac{4\pi . k'^2 k}{3}$ = mass of the spheroid = M, we get the measure of the attraction of the oblate spheroid upon a particle placed at the pole, equal to

$$k . \frac{3\,M}{k^3 e^3} \cdot \left\{ e - \text{arc. tan. } e \right\}.$$

In an oblong spheroid, $k$ is greater than $k'$; put $k^2 - k'^2 = k^2 e^2$; then the element of the attractive force will become, by substitution,

$$\frac{2k'^2 k.}{k^2} d\varphi \cdot \frac{z^2 dz}{1 - e^2 z^2} = \frac{2\,k'^2 k . d\varphi}{k^2 e^3} \left\{ \frac{edz}{1 - e^2 z^2} - edz \right\}:$$

whence, by proceeding as before, we get the measure of the attractive force of the oblong spheroid on a particle placed at the pole, equal to

$$k . \frac{3\,M}{k^3 e^3} \cdot \left\{ \frac{1}{2}\text{hyp.log.}\frac{1+e}{1-e} - e \right\}.$$

*Cor.* In an oblate spheroid differing little from a sphere, $e^2$ will be a very small fraction, of which we may reject the higher powers. When this is done, the preceding expression of the polar attraction, viz.

$$\frac{4\pi . kk'^2}{k^2 e^3} \cdot (e - \text{arc. tan. } e),$$

will be $= 4\pi k . \ (1 + e^2)(\frac{1}{3} - \frac{1}{5}e^2) = \frac{4\pi k}{3} \cdot \left(1 + \frac{2}{5}e^2\right)$.

And, if $k' = k + \tau = k\sqrt{1 + e^2}$, be the radius of the equator, then $2\frac{\tau}{k} = e^2$: so that the attraction at the pole will be

$$\frac{4\pi k}{3} \cdot \left(1 + \frac{4}{5} \cdot \frac{\tau}{k}\right).$$

24. *To investigate the attraction of a homogeneous spheroid of revolution, on a particle placed in the circumference of the circular section, made by a plane through the centre, at right angles, to the axis of revolution.*

Let P (Plate XXXI. fig. 16.) be the pole, PC the axis of revolution. A, a point in the circular section AOB, made by a plane through the centre perpendicular to PC. Let M be any point in the surface of the spheroid; AMO a section through A and M by a plane perpendicular to AOB; A$m$ a line in that plane indefinitely near AM, and M$m$ perpendicular to A$m$; MR perpendicular to AO, and RS to AB. Conceive the plane AMO to revolve about A, so as to describe an indefinitely small angle OAQ; then the triangle AM$m$ will describe a slender pyramid, having its vertex at A, and of which the base is equal to a rectangle contained by M$m$ and RT; for the point M moving parallel to the point R, it will describe a line equal to that described by R, namely to RT.

Let AM $= f$; the angle MAR $= \theta$; and the angle OAQ $= d\varphi$: then M$m$ $= fd\theta$; and TR = AR $\times\, d\varphi = f\cos.\theta . d\varphi$: Wherefore, B = base of the pyramid described by MA$m$ $= d\varphi . d\theta \cos.\theta . f^2$: and the direct attraction of the pyramid in the direction AM $= \frac{B}{f}$(22.) $= d\varphi . d\theta \cos.\theta . f$. Wherefore, the elementary attraction of the spheroid, in the direction AC = direct attraction of the pyramid $\times \frac{AR}{AM} \times \frac{AS}{AR} = d\varphi \cos.\varphi . d\theta \cos.^2\theta . f$.

Again, let MR $= x$, RS $= y$, CS $= z$, CP $= k$ and AC $= k'$; then (1.)

$$\frac{x^2}{k^2} + \frac{y^2 + z^2}{k'^2} = 1.$$

But $x = f\sin.\theta$; $y = \text{AR} . \sin.\varphi = f\cos.\theta\sin.\varphi$; and $z = k' - f\cos.\theta\cos.\varphi$: wherefore, by substitution, we get

$$\frac{f^2\sin.^2\theta}{k^2} + \frac{f^2\cos.^2\theta\sin.^2\varphi}{k'^2} + \frac{(k' - f\cos.\theta\cos.\varphi)^2}{k'^2} = 1.$$

From this equation we get

$$f = 2k' . \frac{\cos.\theta\cos.\varphi}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta}.$$

Let this value of $f$ be substituted in the expression of the elementary attraction of the spheroid before found, and it will become

$$2k' . d\varphi \cos.^2 \varphi . \frac{d\theta \cos.^3\theta}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta} :$$

which expression, when integrated from $\varphi = o$ to $\varphi = \pi$, and from $\theta = o$ to $\theta = \frac{1}{2}\pi$, will give the attraction of half the spheroid: and the double of it, viz.

$$4k' . d\varphi \cos.^2 \varphi . \frac{d\theta \cos.^3\theta}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta},$$

being integrated between the same limits, will give the whole attraction of the spheroid.

In the oblate spheroid, $k$ is less than $k'$: Let $k'^2 - k^2 = k^2e^2$, and $z = \sin. \theta$: and, by substitution, the element of the attractive force will become

$$4k' . d \cos.^2\varphi . \frac{dz(1-z^2)}{1+e^2z^2} =$$

$$4k' . d\varphi \cos.^2 \varphi . \frac{1+e^2}{e^3} . \left\{\frac{edz}{1+e^2z^2} - \frac{edz}{1+e^2}\right\}.$$

And, by integrating from $z = o$ to $z = 1$, we get

$$4k' . d\varphi \cos. \varphi . \frac{1+e^2}{e^3} . \left\{\text{arc. tan.}\, e - \frac{e}{1+e^2}\right\},$$

for the force with which the matter between the sections that contain the angle OAQ, attracts the particle A to the centre. But $\int d\varphi \cos.^2 \varphi = \int\frac{d\varphi}{2} . (1+\cos.^2\varphi) = \frac{\varphi}{2} + \frac{1}{4}\sin. 2\varphi$; the value of which, between the limits $\varphi = o$, and $\varphi = \pi$, is $= \frac{\pi}{2}$: wherefore, the attraction of the spheroid on a particle at A, is equal to

$$2\pi . k' \frac{1+e^2}{e^3} . \left\{\text{arc. tan.}\, e - \frac{e}{1+e^2}\right\}.$$

Because $\frac{4\pi . k'^2 k}{3} = \frac{4\pi . k^3 . (1+e^2)}{3} = M$; we get $2\pi . (1+e^2) = \frac{3\,M}{2k^3}$: wherefore, the measure of the attractive force of the oblate spheroid on a particle placed anywhere in the circumference of the circular section made by a plane through the centre at right angles to the axis, is equal to

$$k' . \frac{3\,M}{2k^3 . e^3} . \left\{\text{arc. tan.}\, e - \frac{e}{1+e^2}\right\}.$$

In the oblong spheroid, $k$ is greater than $k'$; put $k^2 - k'^2 = k^2 . e^2$: then the element of the attractive force will become, by substitution,

$$4k'\ d\varphi \cos.^2\varphi . \frac{dz\,(1-z^2)}{1-e^2z^2} = 4k' . d\varphi \cos.^2\varphi . \frac{1-e2}{e^3} .$$

$$\left\{\frac{edz}{1-e^2} - \frac{edz}{1-e^2z^2}\right\}:$$

whence, by proceeding as before, we get the measure of the attractive force of the oblong spheroid upon a particle placed anywhere in the circumference of the circular section, made by a plane through the centre at right angles to the axis, equal to

$$k' . \frac{3M}{2k^3 . e^3} . \left\{\frac{e}{1-e^2} - \frac{1}{2}\,\text{hyp. log.}\, \frac{1+e}{1-e}\right\}.$$

*Cor.* In an oblate spheroid, differing little from a sphere, the higher powers of $e^2$ may be neglected. The expression of the attractive force at the equator, viz. $2\pi . k' . \frac{1+e^2}{e^3} . \left\{\text{arc. tan.}\, e - \frac{e}{1+e^2}\right\}$ will then become

$$2\pi . k' . (1+e^2)\left(\frac{2}{3} - \frac{4}{5}e^2\right) = \frac{4\pi k'}{3} . (1 - \frac{1}{5}e^2).$$

And if $k'$, the radius of the equator, $= k + \tau$; then $\frac{2\tau}{k} = e^2$ (23. *Cor.*); and the attraction at the equator will be equal to

$$\frac{4\pi k}{3} . \left(1 + \frac{\tau}{k}\right) . \left(1 - \frac{2}{5} . \frac{\tau}{k}\right) = \frac{4\pi k}{3} . \left(1 + \frac{3}{5} . \frac{\tau}{k}\right).$$

25. *An oblate spheroid of revolution being given, it is required to find the measures of the attractive forces that urge a particle placed anywhere in the surface, in a direction perpendicular to the axis, and in a direction parallel to it.*

Let $k$ and $k'$ be the semiaxes of the ellipse by the revolution of which the spheroid is described, $k$ being the axis about which it revolves: and let $b$ be the perpendicular distance of the particle from the axis, and $a$ its distance from the plane, drawn through the centre at right angles to the axis: Then, from which was proved in (20.) and (21.), the attractions sought will be found by multiplying the attractions at the pole, and at the circular section equally distant from both poles, by $\frac{a}{k}$ and $\frac{b}{k'}$.

Thus we get the attraction in the direction of $a$, equal to

$$a \times \frac{3M}{k . e^3}\ \left\{e - \text{arc. tan.}\, e\right\};$$

and the attraction in the direction of $b$, equal to

$$b \times \frac{3M}{2k^3 . e^3} . \left\{\text{arc. tan.}\, e - \frac{e}{1+e^2}\right\}.$$

The same formulæ likewise serve for finding the attractions upon a particle placed anywhere within the spheroid. For the attraction upon a particle within the spheroid is equal to the attraction of a similar concentric spheroid, which contains the particle in its surface (9.); and it is evident, that the coefficients, which multiply $a$ and $b$ in the above expressions, depend only upon the proportion of $k$ and $k'$; and they are therefore the same for all similar spheroids.

If we denote by A and B the coefficients of $a$ and $b$ in the expressions of the attractive force found above, the whole attraction of the spheroid, which is compounded of the forces $a$ . A and $b$ . B, will be $= \sqrt{a^2 A^2 + b^2 B^2}$. And if $\Psi$ denote the angle which the direction of this force makes with $a$, or with the axis of the spheroid; then $\tan. \Psi = \frac{b.B}{a.A}$.

*Cor.* In the very same manner we may determine the attractions of an oblong spheroid of revolution, upon a point in the surface, or within the solid.

26. *If $k$, $k'$, $k''$, the semiaxes of a homogeneous ellipsoid, be related to those of another ellipsoid of the same matter, $h$, $h'$, $h''$, so that $k'^2-k^2=h'^2-h^2$ and $k''^2-k^2=h''^2-h^2$, the attractions perpendicular to the planes of the principal sections, which the first ellipsoid (Plate XXXI. fig. 17.) exerts upon a point determined by the coordinates $h \sin. m$, $h' \cos. m \sin. n$, $h'' \cos. m \cos. n$. respectively parallel to $k$, $k'$, $k''$, will be to the attractions which the second ellipsoid exerts upon a point determined by the coordinates $k \sin. m$. $k' \cos. m \sin. n$, $k'' \cos. m \cos. n$, respectively parallel to $h$, $h'$, $h''$, in the direct proportion of the areas of the principal sections to which the attractions are perpendicular.*

This proposition is an extension to all elliptical spheroids of what was proved of the sphere in (13.). It is here enunciated of the ellipsoid, because the demonstration is not more difficult for that solid than for spheroids of revolution.

Let ABDM be an ellipsoid, the semiaxes of which are $BC=k$, $EC=k'$, and $AC=k''$; and *acdm* another ellipsoid, of which the semiaxes are, $bc=h$, $ec=h'$, and $ac=h''$; those quantities being so related, that $k'^2-k^2=h'^2-h^2$, and $k''^2-k^2=h''^2-h^2$. Also, let G be a point about the ellipsoid ABDM, so determined that GH, parallel to BC, $=h \sin. m$; HK, parallel to CE, $=h' \cos. m \sin. n$; and $CK=h'' \cos. m \cos. n$; and let $g$ be a point about the ellipsoid *abdm*, so determined that $gh$, parallel to $bc$, $=k \sin. m$; $hk$, parallel to $ce$, $=k' \cos. m \sin n$; and $ck=k'' \cos. m \cos. n$. Then the force with which the ellipsoid ABDM attracts a particle placed at G in the direction GH, will be to the force with which the ellipsoid *abdm* attracts a particle placed at $g$ in the direction $gh$, as the area of the section AEDM to the area of the section *aedm*, or as $k' k''$ to $h' h''$.

Let $RP=k \sin. \theta$; $PO=k' \cos. \theta \sin. \varphi$; and $CO=k'' \cos. \theta \cos. \varphi$; which suppositions are allowable, because they satisfy the equation of the ellipsoid (1.), whatever be the angles $\theta$ and $\varphi$. Draw CPM through the centre, and CN indefinitely near it; then $CP=\cos. \theta \sqrt{k'^2 \sin.^2 \varphi + k''^2 \cos.^2 \varphi}$; and when $\cos. \theta = 1$, $CM=\sqrt{k'^2 \sin.^2 \varphi + k''^2 \cos.^2 \varphi}$: wherefore $\frac{CP}{CM}=\cos. \theta$. Let the angle $DCM=\Psi$; then $\tan. \Psi = \frac{PO}{CO} = \frac{k'}{k''} \tan. \varphi$; and, by taking the fluxions, $\frac{d\Psi}{\cos.^2 \Psi} = \frac{k'}{k''} \cdot \frac{d\varphi}{\cos.^2 \varphi}$; but $\frac{1}{\cos.^2 \Psi} = 1 + \tan.^2 \Psi = \frac{k'^2 \sin.^2 \varphi + k''^2 \cos.^2 \varphi}{k''^2 \cos.^2 \varphi} = \frac{CM^2}{k''^2 \cos.^2 \varphi}$; wherefore $d\Psi \cdot CM^2 =$ twice the sector $MCN = k' k'' . d\varphi$.

And, in like manner, in the other ellipsoid, if $rp = h \sin. \theta$; $po=h' \cos. \theta \sin. \varphi$; and $co=h'' \cos. \theta \cos. \varphi$: then $\frac{cp}{cm}=\cos. \theta$, and twice the sector $mcn = h' h'' d\varphi$.

It is plain, from what has been shown, that, when $\theta$ varies, and $\varphi$ remains constant in the expressions of the coordinates, the points P and $p$ will move along CM and $cm$, so that, in every position, $\frac{PC}{MC} = \frac{pc}{mc}$.

Let Q and $q$ be indefinitely near P and $p$; and through P and Q draw lines parallel to MN; and through $p$ and $q$ draw lines parallel to $mn$. Let S denote the quadrilateral contained between the parallels drawn through P and Q; and S′ that contained between the lines drawn through $p$ and $q$: Then $\frac{S}{MCN} = \frac{QC^2 - PC^2}{MC^2}$; and $\frac{S'}{MCN} = \frac{qc^2 - pc^2}{mc^2}$; wherefore, since $\frac{PC}{MC} = \frac{pc}{mc}$, and $\frac{QC}{MC} = \frac{qc}{mc}$, it is manifest that $\frac{S}{S'} = \frac{MCN}{mcn} = \frac{k' k''}{h' h''}$.

Upon the quadrilaterals S and S′ let upright prisms RS and $rs$ be erected, and be prolonged to meet the surfaces of the spheroids; join GR, GS, $gr$, $gs$. Then,

$$GR^2 = (h \sin. m - k \sin. \theta)^2 + (h' \cos. m. \sin. n - k' \cos. \theta \sin. \varphi)^2. + (h'' \cos. m \cos. n - k'' \cos. \theta \cos. \varphi)^2;$$

$$g r^2 = (k \sin. m - h \sin. \theta)^2 + (k' \cos. m \sin. n - h' \cos. \theta \sin. \varphi)^2. + (k'' \cos. m \cos. n - h'' \cos. \theta \cos. \varphi)^2:$$

And, by expanding these expressions, we get

$$GR^2 = \Big\{ (h^2 + (h'^2 - h^2) \cos.^2 m \sin.^2 n + (h''^2 - h^2) \cos.^2 m \cos.^2 n) + (k^2 + (k'^2 - k^2) \cos.^2 \theta \sin.^2 \varphi + (k''^2 - k^2) \cos.^2 \theta \cos.^2 \varphi) - 2 (hk \sin. m \sin. \theta + h' k' \cos. m \cos. \theta \sin. n \sin. \varphi + h'' k'' \cos. m \cos. \theta \cos. n \cos. \varphi) \Big\};$$

$$gr^2 = \Big\{ (k^2 + (k'^2 - k^2) \cos.^2 m \sin.^2 n + (k''^2 - k^2) \cos.^2 m \cos.^2 n) + (h^2 + (h'^2 - h^2) \cos.^2 \theta \sin.^2 \varphi + (h''^2 - h^2) \cos.^2 \theta \cos.^2 \varphi) - 2 (hk \sin. m \sin. \theta + h' k' \cos. m \cos. \theta \sin. n \sin. \varphi + h'' k'' \cos. m \cos. \theta \cos. n \cos. \varphi) \Big\}.$$

These expressions are equal, because $k'^2 - k^2 = h'^2 - h^2$, and $k''^2 - k^2 = h''^2 - h^2$: wherefore $RG = rg = f$. And, in like manner, it is shown, that $GS = gs = f'$.

Now, the attraction of the prism RS urging a particle at G in the direction GH, is equal to $S \times \left\{ \frac{1}{f} - \frac{1}{f'} \right\}$ (10); and the attraction of the prism $rs$ urging a particle at $g$ in the direction $gh$, is $= S' \times \left\{ \frac{1}{f} - \frac{1}{f'} \right\}$: wherefore these attractions

are to one another as S to S′, or as $k'k''$ to $h'h''$. The same thing may be proved of all the elementary prisms that make up the two portions of the spheroids contained between the planes BCM, BCN, and *bcm*, *bcn* : wherefore, those portions attract particles at G and *g*, with forces proportional to $k'k''$ and $h'h''$. But the two spheroids may be divided into an equal number of such portions: wherefore the spheroids attract particles placed at G and *g*, in the directions GH and *gh*, with forces proportional to $k'k''$ and $h'h''$, or to the sections AMDE and *amde*.

*Cor.* 1. This proposition is true when the law of attraction is expressed by any function of the distance. The demonstration is the same as in the corollary of (13).

*Cor.* 2. If the two ellipsoids be so placed, that their centres, and the planes of their principal sections, shall coincide, the surface of the one will be entirely within the other. Also the point which one ellipsoid attracts, will be in the surface of the other, as is plain from the expressions of the coordinate. And hence, the attraction of one ellipsoid upon a point without the surface, is made to depend upon the attraction of another ellipsoid upon a point within the surface.

*Cor.* 3. When the ellipsoids become spheroids of revolution, the two principal sections through the axis of revolution become equal, and will be represented by any two sections whatever passing through the axis at right angles to one another. But, in this case, the attractions of the spheroids on the points may be reduced to two, one acting perpendicular to the axis, and one parallel to it: And it is plain, that these attractions will be to one another as the areas of the sections, perpendicular to their directions.

27. *To find the attraction of an oblate spheroid upon a particle placed without the surface.*

Let $k'$ be the radius of the equator, and $k$ the axis of revolution: and let $a$ be the perpendicular distance of the point without the spheroid from the plane of the equator, and $b$ its distance from the axis. In the first place, it is necessary to determine the semiaxis of another oblate spheroid that shall contain the given point in its surface, and such, that it shall have the same centre, and its equator in the same plane, as the given spheroid; and likewise, the difference of the squares of its semiaxes equal to the difference of the squares of the semiaxes of the given spheroid. Let $h'$ denote the radius of the equator, and $h$ the semiaxis of the required spheroid: then, because the attracted point is to be in the surface of the solid, we have $\frac{a^2}{h^2}+\frac{b^2}{h'^2}=1$ : and, because $h'^2-h^2=k'^2-k^2=\varepsilon^2$; we get

$$\frac{a^2}{h^2}+\frac{b^2}{h^2+\varepsilon^2}=1:$$

Whence,

$$2h^2=a^2+b^2-\varepsilon^2+\sqrt{(a^2+b^2-\varepsilon^2)^2+4a^2\varepsilon^2}:$$

and when $h$ is determined, then $h'=\sqrt{h^2+\varepsilon^2}$.

In consequence of the equation $\frac{a^2}{h^2}+\frac{b^2}{h'^2}=1$, we may suppose, $a=h\ \text{sin.}\ m$, and $b=h'\ \text{cos.}\ m$; let $a'=k\ \text{sin.}\ m$, and $b'=k'\ \text{cos.}\ m$; or $a'=\frac{k}{h}a$, and $b'=\frac{k'}{h'}\times b$: then the point determined by the coordinates $a'$ and $b'$ will be in the surface of the given spheroid, and, consequently, it will be within the surface of the other spheroid. Let M′ denote the mass of the spheroid of which the axis is $h$; and let $e'^2=\frac{h'^2-h^2}{h^2}=\frac{k'^2-k^2}{h^2}$: then (25.) the attractions of this spheroid upon the point within its surface, determined by the coordinates $a$ and $b$, are these, viz.

That perpendicular to the equator, equal to

$$a'\times\frac{3M'}{h^3e'^3}\cdot\left\{e'-\text{arc. tan.}\ e'\right\};$$

and that perpendicular to the axis, equal to

$$b'\times\frac{3M'}{2h^3e'^3}\cdot\left\{\text{arc. tan.}\ e'-\frac{e'}{1+e'^2}\right\}.$$

But (26. Cor. 3.) the attractions of the given spheroid, whose semiaxis are $k$ and $k'$ upon the point without its surface determined by the coordinates $a$ and $b$, will be found by multiplying the preceding expressions respectively by $\frac{k'^2}{k^2}$ and $\frac{kk'}{hh'}$. Let M be the mass of the given spheroid; then $\frac{M}{M'}=\frac{k'^2k}{h'^2h}$; consequently $\frac{k'^2}{h'^2}=\frac{M}{M'}\cdot\frac{h}{k}=\frac{M}{M'}\cdot\frac{a}{a'}$; and $\frac{kk'}{hh'}=\frac{M}{M'}\cdot\frac{h'}{k'}=\frac{M}{M'}\cdot\frac{b}{b'}$: Wherefore, the attractions of the given oblate spheroid upon a point, without the surface determined by the coordinates $a$ and $b$, are as follows, viz.

The attraction perpendicular to the equator, equal to

$$a\times\frac{3M}{h^3e'^3}\left\{e'-\text{arc. tan.}\ e'\right\};$$

and that perpendicular to the axis, equal to

$$b\times\frac{3M}{2h^3e'^3}\left\{\text{arc. tan.}\ e'-\frac{e'}{1+e'^2}\right\}.$$

*Cor.* In the very same manner we may determine the attractions of an oblong spheroid of revolution upon a point without the surface.

### ATTRACTIONS OF ELLIPSOIDS.

28. *Let AMBN be one of the principal sections of an ellipsoid, C the centre, AB and MN the axes, D a point in the periphery of the section, and DO perpendicular to MN (Plate XXXI. fig. 18.); the attraction of the ellipsoid upon a particle placed at the pole A, is to the force with which a particle placed at D is attracted in the direction DO, as AC to DO.* Attractions of Ellipsoids.

Attraction.

Draw DFG perpendicular to AB, and through F describe an ellipsoid similar to the given ellipsoid, and similarly situated, and having the same centre. Conceive an indefinitely great number of planes making indefinitely small angles with one another, to be drawn through DG, so as to divide the two ellipsoids into an indefinitely great number of thin solids or slices: Then, the sections of the ellipsoids made by every one of the planes will be similar and concentric ellipses, each of them having an axis perpendicular to DG (5.). Wherefore the attractions of the elements of the ellipsoid FHKL upon a particle at F, are respectively equal to the attractions of the elements of the ellipsoid AMBN, upon a particle at D in the direction DO (19.). Wherefore, the whole attraction of the ellipsoid FHKL upon a particle at F, is equal to the attraction of the ellipsoid AMBN upon a particle at D, in the direction DO. But the attractions of the ellipsoids AMBN, and FHKL upon particles at A and F, are to one another as AC to CF (8.). Wherefore, the attraction of the ellipsoid AMBN upon a particle at the pole A, is to the force with which it attracts a particle at D in the direction DO, as AC to DO.

29. *The attractions of ellipsoids upon particles placed in the surface, urging them in directions perpendicular to any of the principal sections, are proportional to the distances of the particles from that section.*

Let AMBN be one of the principal sections of an ellipsoid, C the centre, AB and MN the axes of the section, and P a point in the surface of the solid; the attraction of the ellipsoid upon a particle at the pole A (Plate XXXI. fig. 19.), is to the force with which a particle at P is attracted in a direction parallel to AB, as the semiaxis AC is to the distance of P from the principal section perpendicular to AC.

Draw PDQ perpendicular to the section AMBN, and let it meet the surface again in Q; through D describe an ellipsoid similar to AMBN, similarly situated, and having the same centre; and through P draw a section SPRQ perpendicular to AB. As before, divide the solids into an indefinitely great number of thin slices by planes drawn through PQ: the sections made by every one of those planes will be similar, and concentric ellipses having an axis of each perpendicular to PQ (5.). Wherefore, the attractions of the elements of the ellipsoid AMBN, upon a particle at P, in a direction perpendicular to the plane PRQS, are respectively equal to the attractions of the elements of the ellipsoid FHKL, upon a particle at D, in a direction perpendicular to the same plane (19.). Wherefore, the attraction of the ellipsoid AMBN, upon a particle at P, in a direction parallel to the axis AB, is equal to the attraction of the ellipsoid FHKL, upon a particle at D in the same direction. But the ellipsoids AMBN and FHKL being similar, their attractions upon particles at A and F, are to one another as AC to CF (8.); and the attraction of the ellipsoid FHKL, upon a particle at the pole F, is to its attraction upon a particle at D, in a direction parallel to AC, as FC to CN (28.). Wherefore (*ex æquali*), the attraction of the ellipsoid AMBN, upon a particle, at the pole A, is to the force with which it attracts a particle at P, in the direction AC, as AC to CN.

This proposition will enable us to find the attractions of an ellipsoid on all points on the surface, or within the solid, when the attractions at the poles are determined.

30. *To investigate the differential expressions of the attractions at the poles of an ellipsoid.*

Let APD be an ellipsoid; C the centre; AC, CE, and PC, the semiaxes; and PMB a section made by a plane through PC and any point, M in the surface: draw PM (fig. 20.) P$m$ indefinitely near PM, and M$m$ perpendicular to P$m$: also MR perpendicular to the plane ADB, MS perpendicular to PC, and RH perpendicular to AD. Conceive the plane PCB to revolve about PC, so as to describe an indefinitely small angle BCO; and let PM $= f$; the angle KPM, which PM makes with a perpendicular to the axis, $= \theta$; and the angle DCB $= \varphi$: then by proceeding as in (23), it will be found that the attraction of the small pyramid described by the triangle MP$m$, urging a particle at P to the centre of the ellipsoid, is $= d\varphi \,.d\theta \cos.\theta \sin.\theta.f$.

Again, let MR $= x$, HR $= y$, CH $= z$; also let PC $= k$, AC $= k'$, CE $= k''$; then $x = k - f \sin.\theta$; $y = f \cos.\theta \sin.\varphi$; $z = f \cos.\theta \cos.\varphi$: and if we substitute these values in the equation of the ellipsoid (1.), we shall get

$$\frac{(k-f\sin.\theta)^2}{k^2}+\frac{f^2\cos.^2\theta\sin.^2\varphi}{k'^2}+\frac{f^2\cos.^2\theta\cos.^2\varphi}{k''^2}=1: \text{ whence}$$

$$f=\frac{k}{k^2}\cdot\frac{2\sin.\theta}{\frac{\sin.^2\theta}{k^2}+\frac{\cos.^2\theta\sin.^2\varphi}{k'^2}+\frac{\cos.^2\theta\cos.^2\varphi}{k''^2}}$$

This is the value of $f$ at the pole of $k$; and, by a like procedure, its values at the poles of $k'$ and $k''$ may be found, viz.

$$f=\frac{k'}{k'^2}\cdot\frac{2\sin.\theta}{\frac{\sin.^2\theta}{k'^2}+\frac{\cos.^2\theta\sin.^2\varphi}{k^2}+\frac{\cos.^2\theta\cos.^2\varphi}{k''^2}};$$

$$f=\frac{k''}{k''^2}\cdot\frac{2\sin.\theta}{\frac{\sin.^2\theta}{k''^2}+\frac{\cos.^2\theta\sin.^2\varphi}{k^2}+\frac{\cos.^2\theta\cos.^2\varphi}{k'^2}}.$$

Suppose that $k$ is the least of the semiaxes; and let $k'^2=\frac{k^2}{m}$, and $k''^2=\frac{k^2}{n}$: then the values of $f$ at the poles of $k, k', k''$, will be, respectively,

$$f=\frac{2\,k\sin.\theta}{\sin.^2\theta+m\cos.^2\theta\sin.^2\varphi+n\cos.^2\theta\cos.^2\varphi}$$

$$f=\frac{2\,k'\sin.\theta\times m}{m\sin.^2\theta+\cos.^2\theta\sin.^2\varphi+n\cos.^2\theta\cos.^2\varphi}$$

$$f=\frac{2\,k''\sin.\theta\times n}{n\sin.^2\theta+\cos.^2\theta\sin.^2\varphi+m\cos.^2\theta\cos.^2\varphi}$$

Now, let A, A′, A″, denote the attractions of the spheroid upon particles placed at the poles of $k, k', k''$; then, by substituting the values of $f$ just found in the foregoing differential expression, we get

$$A=k\times\iint\frac{2\,d\varphi\;d\theta.\cos.\theta\sin.^2\theta}{\sin.^2\theta+m\cos.^2\theta\sin.^2\varphi+n\cos.^2\theta\cos.^2\varphi}$$

$$A' = k' \times \iint \frac{m \times 2 d\varphi . d\theta \cos \theta \sin.^2\theta}{m \sin.^2\theta + \cos.^2\theta \sin.^2\varphi + n \cos.^2\theta \cos.^2\varphi}$$

$$A'' = k'' \times \iint \frac{n \times 2 d\varphi . d\theta \cos. \theta \sin.^2\theta}{n \sin.^2\theta + \cos.^2\theta \sin.^2\varphi + m \cos.^2\theta \cos.^2\varphi}$$

the limits of the integrals being from $\theta = o$ and $\varphi = o$ to $\theta = \frac{\pi}{2}$ and $\varphi = 2\pi$.

31. *To reduce the expressions of the polar attractions to the most simple integrals.*

Let us consider the general expression

$$\iint \frac{d\varphi . d\theta \cos. \theta \sin.^2\theta}{\alpha \sin.^2\theta + \beta \cos.^2\theta \sin.^2\varphi + \gamma \cos.^2\theta \cos.^2\varphi}$$

which includes all the formulas found in (30.) Let $p = \alpha \sin.^2\theta + \beta. \cos.^2\theta$; and $q = \alpha \sin.^2\theta + \gamma \cos.^2\theta$; then the above expression will become

$$\iint \frac{d\varphi. d\theta \cos. \theta \sin.^2\theta}{p \sin.^2\varphi + q \cos.^2\varphi}.$$

Suppose $\sqrt{\frac{q}{p}}. \frac{\sin.\varphi}{\cos.\varphi} = \frac{\sin. u}{\cos. u}$: then the preceding expression will become, by substitution,

$$\iint \frac{du . d\theta \cos. \theta \sin.^2\theta}{\sqrt{p.q}};$$

the limits of $u$ being from 0 to $2\pi$; wherefore, by integrating with regard to $u$, and restoring the values of $p$ and $q$, the integral becomes

$$2\pi. \int \frac{d\theta . \cos. \theta \sin.^2\theta}{\sqrt{(\alpha \sin.^2\theta + \beta \cos.^2\theta).(\alpha \sin.^2\theta + \gamma \cos.^2\theta)}}$$

and, by putting $x = \sin. \theta$, the integral, which is to be taken from $\theta = 0$ to $\theta = \frac{\pi}{2}$, or from $x = 0$ to $x = 1$, will become

$$2\pi. \int \frac{x.^2 dx}{\sqrt{\left\{\beta + (\alpha - \beta) x^2\right\} . \left\{\gamma + (\alpha - \gamma) x^2\right\}}}.$$

If now we take $\alpha$, $\beta$, $\gamma$, so as to make the assumed expression coincide with the quantities A, A′ A″, respectively, we shall get

$$A = 4\pi k . \int \frac{x^2 dx}{\sqrt{\left\{m + (1-m)x^2\right\} . \left\{n + (1-n)x^2\right\}}}$$

$$A' = 4\pi k' . \int \frac{m . x^2 dx}{\sqrt{\left\{1 + (m-1)x^2\right\} . \left\{n + (m-n)x^2\right\}}}$$

$$A'' = 4\pi k'' . \int \frac{n . x^2 dx}{\sqrt{\left\{1 + (n-1)x^2\right\} . \left\{m + (n-m)x^2\right\}}}$$

These expressions have the inconvenience of containing different factors in the denominators; but they may be reduced to others having the same factors, by putting $x = \frac{\tau}{\sqrt{m + (1-m)\tau^2}}$ in the second and $x = \frac{\tau}{\sqrt{n + (1-n)\tau^2}}$ in the third; we thus get

$$A = 4\pi k . \int \frac{x^2 dx}{\sqrt{\left\{m + (1-m) x^2\right\} . \left\{n + (1-n) x^2\right\}}}$$

$$A' = 4\pi k' . \int \frac{m . \tau^2 d\tau}{\left\{m + (1-m)\tau^2\right\}^{\frac{3}{2}} . \left\{n + (1-n)\tau^2\right\}^{\frac{1}{2}}}$$

$$A'' = 4\pi k'' . \int \frac{n . \tau^2 d\tau}{\left\{n + (1-n)\tau^2\right\}^{\frac{3}{2}} . \left\{m + (1-m)\tau^2\right\}^{\frac{1}{2}}}$$

Now let

$\frac{1-m}{m} = \frac{k'^2 - k^2}{k^2} = \lambda^2$; and $\frac{1-n}{n} = \frac{k''^2 - k^2}{k^2} = \lambda'^2$:

Also let the mass of the ellipsoid $= M = \frac{4\pi k k' k''}{3} = \frac{4\pi k^3}{3\sqrt{mn}}$; then $\frac{3M}{k^3} = \frac{4\pi}{\sqrt{mn}}$: wherefore, by substitution, we get

$$A = k . \frac{3M}{k^3} . \int \frac{x^2 dx}{\sqrt{(1 + \lambda^2 x^2) . (1 + \lambda'^2 x^2)}}$$

$$A' = k' . \frac{3M}{k^3} . \int \frac{x^2 dx}{\left\{1 + \lambda^2 x^2\right\}^{\frac{3}{2}} . \left\{1 + \lambda'^2 x^2\right\}^{\frac{1}{2}}}$$

$$A'' = k'' \frac{3M}{k^3} . \int \frac{x^2 dx}{\left\{1 + \lambda^2 x^2\right\}^{\frac{1}{2}} . \left\{1 + \lambda'^2 x^2\right\}^{\frac{3}{2}}}$$

the integrations extending from $x = 0$ to $x = 1$.

These integrals cannot be expressed in finite terms. When $\lambda$ and $\lambda'$, or the eccentricities of the ellipsoid are small, the values of the integrals may easily be found to a sufficient degree of exactness, by series.—They may likewise be all expressed by means of this fluent, viz.

$F = \int \frac{dx}{\sqrt{(1 + \lambda^2 x^2) . (1 + \lambda'^2 x^2)}}$ (from $x = o$ to $x = 1$) and its partial fluxions. Thus we have, in general, $\int \frac{x^2 dx}{\sqrt{(1 + \lambda^2 x^2) . (1 + \lambda'^2 x^2)}} =$

$$\frac{x^3}{\sqrt{(1 + \lambda^2 x^2) . (1 + \lambda'^2 x^2)}} + \frac{1}{\lambda} . \left(\frac{dF}{d\lambda}\right) + \frac{1}{\lambda'} . \left(\frac{dF}{d\lambda'}\right)$$

Wherefore, making $x = 1$, we get

$$A = k. \frac{3M}{k^3} . \left\{\frac{1}{\sqrt{(1 + \lambda^2) . (1 + \lambda'^2)}} + \frac{1}{\lambda}\left(\frac{dF}{d\lambda}\right) + \frac{1}{\lambda'} . \left(\frac{dF}{d\lambda'}\right)\right\}$$

$$A' = k' . \frac{3M}{k^3} . \frac{1}{\lambda} . \left(\frac{dF}{d\lambda}\right).$$

$$A'' = k'' . \frac{3M}{k^3} . \frac{1}{\lambda'} . \left(\frac{dF}{d\lambda'}\right).$$

32. *To find the forces with which a homogeneous ellipsoid attracts a particle placed in the surface, or within the solid, in directions perpendicular to the principal sections.*

Let $k$, $k'$, $k''$, denote the semiaxes of an ellipsoid,

Attraction. and $a$, $b$, $c$ (respectively parallel to $k$, $k'$, $k''$), the perpendicular distances of a particle placed in the surface, or within the solid, from the principal sections: then, from what is proved in (29.), the attractions we are seeking will be found by multiplying the polar attractions by $\frac{a}{k}, \frac{b}{k'}, \frac{c}{k''}$. Wherefore the forces that urge the particle in the directions of $a$, $b$, and $c$, are respectively, $a \times \frac{3\,M}{k^3}$.

$$\left\{\frac{1}{\sqrt{(1+\lambda^2).(1+\lambda'^2)}}+\frac{1}{\lambda}.\left(\frac{dF}{d\lambda}\right)+\left(\frac{dF}{d\lambda'}\right)\right\};$$

$$b \times \frac{3\,M}{k^3}.\frac{1}{\lambda}.\left(\frac{dF}{d\lambda}\right);$$

$$c \times \frac{3\,M}{k^3}.\frac{1}{\lambda'}.\left(\frac{dF}{d\lambda'}\right):$$

Which formulas serve both for points in the surface, and within the solid, for the reason already explained in (25.).

33. *To find the attractions of an ellipsoid upon a particle placed without the surface.*

Let $k$, $k'$, $k''$ be the semiaxis of the ellipsoid, and $a$, $b$, $c$ (respectively parallel to $k$, $k'$, $k''$), the coordinates of a particle without the surface Let $h$, $h'$, $h''$, so related to $k$, $k'$, $k''$, that $h'^2 - h^2 = k'^2 - k^2$ and $h''^2 - h^2 = k''^2 - k^2$, denote the semiaxis of another ellipsoid, which contains the attracted point in its surface, and has its principal sections in the same planes as the given ellipsoid: then, because the attracted point is in the surface, we have (1.)

$$\frac{a^2}{h^2}+\frac{b^2}{h'^2}+\frac{c^2}{h''^2}=1:$$

And, because $h'^2 - h^2 = k'^2 - k^2 = \varepsilon^2$, and $h''^2 - h^2 = k''^2 - k^2 = \varepsilon'^2$, we get

$$\frac{a^2}{h^2}+\frac{b^2}{h^2+\varepsilon^2}+\frac{c^2}{h^2+\varepsilon'^2}=1.$$

This equation now contains only one unknown quantity; and it is plain, that one value of $h$, and only one, can be found from it. For, when $h = 0$, the function on the left hand side is infinitely great: And while $h$ increases from 0 *ad infinitum*, the same function decreases continually from being infinitely great, to be infinitely little. When $h$ is found, then $h' = \sqrt{h^2+\varepsilon^2}$, and $h'' = \sqrt{h^2+\varepsilon'^2}$. Because $a$, $b$, $c$, are the coordinates of a point in the surface of the ellipsoid, we may suppose $a = h$ sin. $m$, $b = h'$ cos. $m$ sin. $n$, $c = h''$ cos. $m$ cos. $n$: let $a' = k$ sin. $m$, $b' = k'$ cos. $m$ sin. $n$, $c' = k''$ cos. $m$ cos. $n$; or $a' = \frac{k}{h} \times a$, $b' = \frac{k'}{h'} \times b$, $c' = \frac{k''}{h''} \times c$; then $a'$, $b'$, $c'$, will be the coordinates of a point in the surface of the given ellipsoid, and consequently, it will be within the other solid. Let $M'$ denote the mass of the ellipsoid of which $h$, $h'$, $h''$ are the semiaxes; also let $\lambda^2 = \frac{h'^2-h^2}{h^2} = \frac{k'^2-k^2}{k^2}$; and $\lambda'^2 = \frac{h''^2-h^2}{h^2} = \frac{k''^2-k^2}{k^2}$; Attraction.

then, F denoting the same fluent as before, the attractions of this ellipsoid upon the point within it, determined by the coordinates $a'$, $b'$, $c'$, in the directions of those coordinates, are (32.) respectively equal to

$$a' \times \frac{3\,M'}{h^3}\left\{\frac{1}{\sqrt{(1+\lambda^2)(1+\lambda'^2)}}+\frac{1}{\lambda}.\left(\frac{dF}{d\lambda}\right)+\frac{1}{\lambda}.\left(\frac{dF}{d\lambda'}\right)\right\},$$

$$b' \times \frac{3\,M'}{h^3} \times \frac{1}{\lambda}.\left(\frac{dF}{d\lambda}\right),$$

$$c' + \frac{3\,M'}{h^3} \times \frac{1}{\lambda'}.\left(\frac{dF}{d\lambda'}\right).$$

Now, the attractions of the given ellipsoid upon the point without the surface, determined by the coordinates $a$, $b$, $c$, will be found (26.) by multiplying the preceding expressions respectively by $\frac{k'\,k''}{h'\,h''}$, $\frac{k\,k''}{h\,h''}$, $\frac{k\,k'}{h\,h'}$. Let M be the mass of the given ellipsoid; then $\frac{M}{M'} = \frac{k\,k'\,k''}{h\,h'\,h''}$; consequently $\frac{k'\,k''}{h'\,h''} = \frac{M}{M'}.\frac{h}{k} = \frac{M}{M'}.\frac{a}{a'}$; and $\frac{k\,k''}{h\,h''} = \frac{M}{M'} \times \frac{b}{b'}$; and $\frac{k\,k'}{h\,h'} = \frac{M}{M'} \times \frac{c}{c'}$: wherefore, the attractions of the given ellipsoid upon the point without the surface, determined by $a$, $b$, $c$, in the directions of those coordinates, are respectively equal to $a \times \frac{3\,M}{h^3} \times$

$$\left\{\frac{1}{\sqrt{(1+\lambda^2)(1+\lambda'^2)}}+\frac{1}{\lambda}\left(\frac{dF}{d\lambda}\right)+\frac{1}{\lambda'}.\left(\frac{dF}{d\lambda'}\right)\right\},$$

$$b \times \frac{3\,M}{h^3} \times \frac{1}{\lambda}.\left(\frac{dF}{d\lambda}\right)$$

$$c \times \frac{3\,M}{h^3} \times \frac{1}{\lambda'}\left(\frac{dF}{d\lambda'}\right).$$

---

The preceding propositions contain a complete theory of homogeneous elliptical spheroids. They enable us to compute the attractive force with which a solid of this kind urges a particle placed anywhere in the surface, or within the solid, or without it. It remains, indeed, to find the exact value of the function F in its general form, to which we can do no more than approximate by series; but this is an analytical difficulty, which it is impossible to overcome; because the nature of this function is such, that it cannot be expressed in finite terms by the received notation of analysis.

In the preceding investigations, we have followed the method of Maclaurin for points situated in the surface of a spheroid, or within the solid. This method has always been justly admired; but neither its inventor, nor, as far as we know, any other Geometer, has applied it, excepting to spheroids of revolution; and it is here, for the first time, extended to ellipsoids. In regard to points without the surface, we have employed the method first given by Mr Ivory, in the *Philosophical Transactions* for 1809. The combination of these two methods has enabled us to derive the attractions of an ellipsoid on a point placed anywhere, from the attractions at the poles. Thus, this extremely complicated problem has, by geometrical reasoning of no great difficulty, been reduced to the investigation of the polar attractions, which are the only cases that require a direct computation.

34. *Of the attractions of spheroids composed of elliptical shells that vary in their densities and figures according to any law.*

When a spheroid is composed of concentric elliptical shells of variable density and figure, we may consider every shell as the difference of two homogeneous spheroids of the same density with the shells, and having their surfaces coinciding with the surfaces of the shell. The attractions of the spheroids being computed by the preceding methods, their difference will be equal to the attractions of the shell; and the integral obtained by summing the attractions of all the shells, will give the attractions of the heterogeneous spheroid. This case, therefore, gives rise to no new difficulties, except what are purely mathematical, and depend upon the law, according to which, the densities and figures of the shells are supposed to vary. ATTRACTION OF MOUNTAINS. See Mountains, Attraction of, in the *Encyclopædia*, and in this Supplement.

ATWOOD (George), an Author celebrated for the accuracy of his mathematical and mechanical investigations, and considered as particularly happy in the clearness of his explanations, and the elegance of his experimental illustrations, was born in the early part of the year 1746. He was educated at Westminster school, where he was admitted in 1759. Six years afterwards he was elected *off* to Trinity College, Cambridge. He took his degree of Bachelor of Arts in 1769, with the rank of third *wrangler*, Dr Parkinson, of Christ's College, being senior of the year. This distinction was amply sufficient to give him a claim to further advancement in his own College, on the list of which he stood foremost of his contemporaries; and, in due time, he obtained a fellowship, and was afterwards one of the tutors of the College. He became Master of Arts in 1772; and, in 1776, was elected a Fellow of the Royal Society of London.

The higher branches of the Mathematics had, at this period, been making some important advances at Cambridge, under the auspices of Dr Waring, and many of the younger members of the University became diligent labourers in this extensive field. Mr Atwood chose, for his peculiar department, the illustration of mechanical and experimental philosophy, by elementary investigations and ocular demonstrations of their fundamental truths. He delivered, for several successive years, a course of lectures in the Observatory of Trinity College, which were very generally attended, and greatly admired. In the year 1784, some circumstances occurred which made it desirable for him to discontinue his residence at Cambridge; and soon afterwards Mr Pitt, who had become acquainted with his merits by attending his lectures, bestowed on him a patent office, which required but little of his attendance, in order to have a claim on the employment of his mathematical abilities in a variety of financial calculations, to which he continued to devote a considerable portion of his time and attention throughout the remainder of his life.*

The following, we believe, is a correct list of Mr Atwood's publications:

1. *A Description of Experiments to illustrate a Course of Lectures.* 8vo. About 1775, or 1776.

2. This work was reprinted with additions, under the title of *An Analysis of a Course of Lectures on the Principles of Natural Philosophy.* 8vo. Cambr. 1784.

3. *A General Theory for the Mensuration of the Angle subtended by two objects, of which one is observed by Rays after two Reflections from plane Surfaces, and the other by Rays coming directly to the Spectator's Eye.* Phil. Trans. 1781, p. 395.

4. *A Treatise on the Rectilinear Motion and Rotation of Bodies, with a Description of Original Experiments relative to the Subject.* 8vo. Cambr. 1784.

5. *Investigations founded on the Theory of Motion, for determining the Times of Vibration of Watch Balances.* Phil. Trans. 1794, p. 119.

6. *The Construction and Analysis of Geometrical Propositions, determining the positions assumed by homogeneal bodies, which float freely, and at rest, on a fluid's surface; also Determining the Stability of Ships, and of other Floating Bodies.* Phil. Trans. 1796, p. 46.

7. *A Disquisition on the Stability of Ships.* Phil. Trans. 1798, p. 201.

8. *A Review of the Statutes and Ordinances of Assize, which have been established in England from the 4th year of King John, 1202, to the 37th of his present Majesty.* 4to. Lond. 1801.

9. *A Dissertation on the Construction and Properties of Arches.* 4to, Lond. 1801.

10. *A Supplement to a Tract entitled a Treatise on the Construction and Properties of Arches, published*

Atwood.

*in the year* 1801 ; *and containing Propositions for Determining the weights of the several sections which constitute an arch, inferred from the angles. Also containing a Demonstration of the angles of the several sections, when they are inferred from the weights thereof. To which is added, a Description of original experiments to verify and illustrate the principles in this treatise. With occasional remarks on the construction of an iron bridge of one arch, proposed to be erected over the river Thames at London. Part II. By the author of the first part.* 4to, Lond. 1804. Dated 24th Nov. 1803.

11. A *Treatise on Optics* is mentioned by Nichols as having been partly printed by Bowyer in 1776, but never completed.

It may be very truly asserted, that several of these works of Mr Atwood have materially contributed to the progress of science, by multiplying the modes of illustration, which experimental exhibitions afford for the assistance of the instructor; at the same time, they can scarcely be said to have extended very considerably the bounds of human knowledge, or to demonstrate that their author was possessed of any extraordinary talent or energy of mind in overcoming great difficulties, or in inventing new methods of reasoning. The *Analysis of a Course of Lectures* has been little read: and it bears evident marks of having been composed before Mr Atwood had acquired a habit of accurate reasoning on Physical subjects. In the first page, for example, the forces of cohesion and gravitation are completely confounded; and in the third we find the idea of perfect spheres touching each other in a greater or less number of points, notwithstanding the appearance of precision which the author attempts to maintain in his language.

The object of the paper on *Reflection* is, to illustrate and improve the construction of Hadley's quadrant; and Mr Atwood proposes, for some particular purposes in practical Astronomy, two new arrangements of the speculums, by which the rays are caused to move in different planes, and which he considers as affording greater accuracy for the measurement of small angles than the common form of the instrument, although not of general utility, nor very easily adjusted for observation.

The treatise on *Rectilinear motion and rotation* exhibits a good compendium of the elementary doctrines of mathematical Mechanics; but it shows a great deficiency in the knowledge of the higher refinements which had been introduced into that science by Daniel Bernoulli, and Euler, and Lagrange. The properties of simply accelerated and retarded motion are first discussed, and the phenomena of penetration experimentally examined; the laws of varying forces are then investigated, and the properties of the pendulum demonstrated; the vibrations of an elastic chord are calculated, "considering the whole mass to be concentrated in the middle point," as an approximation; and then, instead of imitating and simplifying the elegant but complicated demonstrations of the continental mathematicians, the author most erroneously repeats, in the words of Dr Smith, the exploded doctrine, that "the string, during any instant of its vibration, will coincide with the harmonic curve." The subject of a resistance, varying as the square of the velocity, is next examined; and some useful experiments on the descent of bodies in water are stated in confirmation of the theory. On this occasion, the author observes, with regard to the formation of the different strata of the earth, that bodies disposed to break into large masses, though specifically lighter, may easily have descended more rapidly through a fluid, than denser but more brittle bodies, so that the natural order of densities may thus have become inverted. He next examines the theory of rotation, and relates some very interesting experiments on rectilinear and rotatory motions; and he shows that Emerson and Desaguliers were totally mistaken in asserting "that the momentum produced is always equal to the momentum which produces it." The last section of the work, which is devoted to the subject of free rotation, is the most elaborate of the whole; but it exhibits no material extension of the earlier investigations of the Bernoullis and Professor Vince; nor does it contain the important proposition of Segner, relating to the existence of three axes of permanent rotation, at right angles to each other, in every body, however irregular.

Notwithstanding these partial objections, the work may still, in many respects, be considered as classical. The paper on *Watch-balances* is principally intended to show the advantages which may be obtained, in Mr Mudge's construction, from the effect of subsidiary springs in rendering the vibrations isochronous, their actions being limited to certain portions of the arc of motion. If the author has here again omitted to follow the Continental Mathematicians in some of their refinements of calculation, it must be confessed that his view of the subject has, in this instance, not only the advantage of simplicity, but also that of a nearer approach to the true practical state of the question, than is to be found in the more complicated determinations which had been the result of the labours of some of his predecessors.

But, whatever may be the merits of these investigations, they appear to be far exceeded in importance by the papers on *Ships*, the first of which obtained for its author the honour of a Copleian Medal. Its principal object is to show how much the stability of a ship will commonly vary, when her situation, with respect to the horizon, is materially altered; and how far the assumptions of theoretical writers, respecting many others of the forces concerned in Naval Architecture, will generally differ from the true state of these forces when they actually occur in Seamanship. In the second part of the investigation, some errors of Bouguer and of Clairbois are pointed out, and the theoretical principles of stability are exemplified by a detailed calculation, adapted to the form and dimensions of a particular vessel, built for the service of the East India Company.

The latter years of our author's life do not appear to have been productive of any material advantage to Science. His application to his accustomed pursuits was unremitting; but his health was gradually declining. He had no amusement, except such as was afforded by the continued exercise of his mind, with

a change of the object only; the laborious game of chess occupying, under the name of a recreation, the hours which he could spare from more productive exertions. He became paralytic some time before his death; and though he partially recovered his health, he did not live to complete his 62d year.

His researches concerning the history of the *Assize of Bread* must have required the employment of considerable diligence, and some judgment, in the discovery and selection of materials; although certainly the subject was not chosen for the purpose of affording a display of talent. His opinion respecting the operation of the assize, as favourable to the community, may by some be thought to be justified by the want of success which has hitherto attended the experiment on its suspension; but the advocates of that measure would certainly not admit the trial of a year to be sufficient for appreciating its utility.

The title-pages of the works on *Arches* explain the occasion on which they were brought forwards, and at the same time exhibit a specimen of the want of order and precision which seems to have begun to prevail in the author's faculties: and the works themselves betray a neglect of the fundamental principles of Mechanics, which is inconceivable in a person who had once reasoned with considerable accuracy on mathematical subjects. An anonymous Critic, who is supposed to have been the late Professor Robison (*British Critic*, Vol. XXI. Jan. 1804), very decidedly, and, at the same time, very respectfully asserted Mr Atwood's error in maintaining, that there was no manner of necessity for the condition, that the general curve of equilibrium of an arch should pass through some part of every one of the joints by which it is divided: and in fact we may very easily be convinced of the truth of this principle, if we reflect that the curve of equilibrium is the true representative of the direction of all the forces acting upon each of the blocks; and that if the whole pressure be anywhere directed to a point situated beyond the limit of the joint, there can be nothing whatever to prevent the rotation of the block on the end of the joint as a centre, until some new position of the block shall have altered the direction of the forces, or until the whole fabric be destroyed. The Critic has also very truly remarked, that the effects of friction have never been sufficiently considered in such arrangements: but a later Author has removed a considerable part of this difficulty in an anonymous publication, by showing, that no other condition is required for determining these effects, than that every joint should be perpendicular to the direction of the curve of equilibrium, either accurately, or within the limit of a certain angle, which is constant for every substance of the same kind, and which he has termed the angle of repose.

In the appointment which enabled Mr Atwood to devote a considerable part of his life to scientific researches, he appears to have had no successor. It was held, and perhaps wisely, that such sinecures have regularly become, in process of time, mere instruments of party interest, instead of being bestowed as encouragements to merit; and it seems to be the invariable maxim of the British Government, that talents deserve no protection, unless they are immediately employed in the service of the Church or of the State; that ornamental accomplishments repay their possessor by the splendour which they confer on his personal existence, but that, in a commercial country, the actual utility of mental as well as of corporal powers, must be measured by their effects; and that these effects must be of a negociable kind, in order to have a claim to reward. Other Nations, and other Sovereigns, have often thought and acted differently; and they have, perhaps, obtained a forced growth of Science or of Literature, which has contributed, in some degree, to the embellishment of their age; but where the native forest tree acquires so often a form at once beautiful and magnificent, though exposed to all the storms of the seasons, there is little reason to lament the want of the shelter of the Plantation, or of the artificial warmth of the Conservatory. (FO.)

# ADDENDUM.

ANNUITIES. As an addition to the article ANNUITIES, we beg to insert here an expeditious method of calculating the values of annuities on single or joint lives, from any tables or bills of mortality, with sufficient accuracy for all practical purposes.

We must begin by determining the mean complement of life, according to the average number of deaths during a certain period, which must vary according to the nature of the proposed calculation; being shorter as the rate of interest is higher; and as the number of lives concerned is greater; but not requiring to be very accurately defined. If the rate of interest be $r$, we must find the time in which the number of deaths is expressed by the fraction $\frac{3}{r+3}$ of the whole number of survivors at the given age, for a single life: for two lives, the fraction must be $\frac{3}{r+5}$, and for three, $\frac{3}{r+7}$; and, in each of these cases, the time determined from the age of the oldest life must be employed for finding the complements of both the others.

Having thus calculated the complements for each of the ages, we may, in most instances, save ourselves the trouble of further computation, by employing tables of the value of annuities on one and two lives, according to Demoivre's hypothesis. For this purpose, we have only to subtract the complement from 86, and we obtain an equivalent life on this hypothesis. If we take, for example, the age of 20, the number of survivors in the Northampton tables is 5132; and, for a single life, at 3 and at 6 per cent. we must find the time at which they are reduced $\frac{3}{6}$ and $\frac{3}{9}$ respectively; that is, to about 2566 and 3421: now at 54 and 43, the numbers are 2530 and 3404; and $\frac{5132 \times 34}{5132-2530} = 67{\cdot}07$, and $\frac{5132 \times 23}{5132-3404} = 68{\cdot}3$; whence the equivalent ages in Demoivre's tables are 18·93 and 17·7, giving 18·62 and 12·43, for the value of the annuity; while Dr Price's table, deduced from the actual decrements at all ages, gives 18·64 and 12·40.

The utility of this mode of calculation will be still further illustrated by a comparison of the very different values of lives, as indicated by different tables. Taking, for example, the age of 30, and the interest at 5 per cent. we may find the value of the annuity, by this approximation, in different situations, for which correct tables have been published by Dr Price, and may thence infer how much nearer it approaches to the truth than the generality of the results approach to each other:

| | | | |
|---|---|---|---|
| London, 1730 | Compl. 41·52 | Value 11·22 | Dr P. 11·6 |
| Northampton | 57·05 | 13·09 | 13·07 |
| Sweden, males | 67·93 | 14·04 | 13·89 |
| Deparcieux | 71·11 | 14·28 | 14·72 |
| Sweden, females | 75·60 | 14·58 | 14·27 |

According to the bills of mortality of London for 1815, out of 9472 survivors at 30, 5573 lived to 50, and this is near enough to $\frac{3}{8}$ for our purpose: hence the complement is 48·58, and the value of an annuity at 5 *per cent.* 12·16 years' purchase. Where the age is much greater, the approximation is somewhat less accurate, though not often materially erroneous; thus, at 70, the values, according to the Northampton tables, at 3 and 6 per cent. are 6·23 and 5·35, instead of 6.73 and 5.72 respectively.

In the values of joint lives, there is more difference, according to the different tables employed, than in those of single lives: thus, at 30, the value of an annuity, at 4 per cent. on a single life, differs at Northampton, and in Sweden, in the proportion of 14·78 to 16·00, or of 12 to 13; but, for two joint lives at 30, in that of 11·31 to 12·96, or of 7 to 8; and for three lives, the disproportion would be still greater.

In the absence of Demoivre's tables, or for cases to which they do not extend, it becomes necessary to calculate the value of the annuity for each particular instance. Calling then the complement, as already determined, $a$, the number of survivors after $x$ years will be represented by $a-x$, and the present value of any sum to be paid to each of them by $av^x - xv^x$, $v$ being the present value of a unit payable at the end of a year: and if we suppose such payments to be made continually, their whole present value may be found by multiplying this expression by the fluxion of $x$, and finding the fluent, which will be $-pv^x(a-x-p)$, $p$ being $= -\frac{1}{\text{HL}v}$, or the reciprocal of the hyperbolical logarithm of the amount of a unit after a year. When $x$ vanishes, this fluent becomes $-p(a-p)$, and when $x=a$, $p^2v^a$; the difference, divided by $a$, gives the present value of the annuity, $p - \frac{p^2}{a} + \frac{p^2v^a}{a}$; from which, when the annuity is supposed to become due and to be paid periodically, we must subtract in all cases half a payment; that is, $\frac{1}{2}$ for yearly payments, and $\frac{1}{4}$ for quarterly; and if, at the same time, we choose to assume that money is capable of being improved by laying out the interest more frequently than once

a year at the given rate, we must alter the value of $v$ accordingly.

For two joint lives, the complement of the elder, determined from the fraction $\frac{3}{r+5}$, being $a$, and that of the younger, deduced from the deaths in an equal number of years, $b$, we have for the binary combinations of the survivors, after $x$ years, $(a-x)(b-x)$, and the fluent will be $-pv^x\ (ab-(a+b)(x+p)+x^2+2px+2p^2)$, which, corrected and divided by $ab$, gives the value of the annuity $p-\frac{p^2}{ab}(a+b-2p)-\frac{p^2v^a}{ab}(a-b+2p)$; and this, with the deduction of half a payment, agrees with the tables calculated on Demoivre's hypothesis, taking the same complements of life.

But for three lives we have no such tables, and this method of calculation becomes therefore of still greater importance. Employing here the fraction $\frac{3}{r+7}$ for the oldest life, we must determine the complement $a$ for this life, and those of the two younger, $b$ and $c$, from an equal period. The combinations will then be $(a-x)(b-x)(c-x)=abc-(ab+ac+bc)x+(a+b+c)x^2-x^3$, which we may call $d-ex+fx^2-x^3$; hence the fluent is found $-pv^x\Big(d-e(x+p)+f(x^2+2px+2p^2)-(x^3+3px^2+6p^2x+6p^3)\Big)$ this, when $x$ vanishes, becomes $-p\ (d-ep+f\,p^2-6p^3)$, and calling this $-pg$, the corrected fluent will give the value of the annuity $\frac{pg}{d}-\frac{pv^a}{d}\ (g-ea+fa^2+2fpa-a^3-3pa^2-6p^2a)$. Thus, if the ages are 10, 20, and 30, and the rate of interest 4 *per cent.* we find, in the Northampton tables, the survivors at 30 4385, $\frac{8}{11}$ of which are 3199; and at 46, the survivors are 3170; whence $a=57{\cdot}7$, and $b$ and $c$ found also from periods of 16 years after the respective ages, are 68·5 and 91·7. Calculating with these numbers, we find the value of the annuity 10·954—·5 =10·454. Dr Price's short table gives it 10·438; and Simpson's approximation from the tables of two joint lives 10·563, which is less accurate in this instance, even supposing such tables to have been previously calculated.

It would, indeed, be easy to form, by this mode of computation, a table of the corrections required at different ages for Simpson's approximation, since these corrections must be very nearly the same, whether Demoivre's hypothesis, or the actual decrements of lives be employed, both for the two joint lives, and for the correct determination of the three. But the value thus found would still be less accurate, with respect to any other place, or perhaps even any other time, than the immediate result of the mode of calculation here explained.

It may, perhaps, save some trouble to subjoin a table of the values of $p$ and their logarithms.

| | | |
|---|---|---|
| 3 *per cent.* | $p=$ 33·831 | log. $p=$ 1·5293132 |
| 4 | 25·497 | 1·4064846 |
| 5 | 20·497 | 1·3116680 |
| 6 | 17·162 | 1·2345630 |
